Table 19 lists world salt production statistics for 97 countries based on reported and estimated information. World production increased about 1% in 1991 compared with that of the previous year. Since 1971, world salt production has increased more than 27%, whereas world population has risen 44%, from 3.63 billion to 5.3 billion individuals. (See table 19.)

Industry Structure.—The United States remains the world's leading salt-producing nation, representing about one-fifth of total world production. The structure of the U.S. industry has changed throughout the years. In 1970, there were 50 companies operating 95 plants in the United States. Market competition, energy and labor costs, less expensive imports, and an excess of production capacity reduced the size of the industry to 31 companies and 73 plants by 1991.

Most countries possess some form of salt production capability with production levels set to meet their own domestic demand requirements with additional quantities available for export. Many developing nations tend to develop their agricultural resources first to feed their population. Development of easily extractable mineral resources follows with salt being one of the first commodities to be mined. Some countries, such as the United States, import a substantial amount of salt to meet total demand requirements because of economic factors. (See table 20.)

Capacity.—Each type of salt produced in the world has unique mining, processing, and marketing characteristics that determine the criteria for deriving rated capacities. The data shown in tables 12 and 20 are rated capacities for mines and refineries and salt requirements for salt-based chlorine facilities as of December 31, 1991. Rated capacity is

defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure. Capacity data were derived from industry sources, published reports, and estimates based on production trends.

Rock.—Because the majority of rock salt was used for deicing, the operating rate of rock salt facilities fluctuated with the demand for deicing salt, again dependent on the severity of winter weather conditions. During periods of strong demand, production levels often achieve, or exceed in certain situations, the rated capacities. Full mine capacity generally is a function of the hoisting capabilities of the mines. Assuming that the workweek is 5 days (250 workdays per year), two working shifts and one maintenance shift per day, and at least one short-term planned turnaround for the mine and mill per year, table 20 lists the production capacities for domestic rock salt operations.

Solar.—Solar salt, also known as marine and sea salt, is obtained from the solar evaporation of seawater, of landlocked bodies of saline water, and of discharged brines. Because evaporation rates must exceed the precipitation rates, the climatic conditions and geographic locations of solar evaporation facilities are critical to the successful production and harvesting of solar salt. Therefore, rated capacities generally are based on the historical evaporation patterns within a region and vary depending on the location and the surface areas of the evaporation ponds. Only unpredictable seasonal precipitation and market conditions usually affect the production, and market conditions usually affect the production rates of the facilities.

Vacuum Pan.—The mechanical evaporation of salt by the vacuum pan process is dependent on the number and size of the vacuum crystallizers operating in series. Rated capacities are usually easier to establish because of the proven design performance of the equipment.

Brine.—Brine capacities are difficult to derive because they are based on the variabilities of the injection rate of the solvent and the solubility rates of the underground salt bodies. Both determine the quantity of brine produced. In addition, production levels are dependent on the demand for the products that the brine is being used to manufacture. Therefore, individual company brine capacities are not included in table 20. Table 12 lists the quantity, type, and source of the salt required to manufacture chlorine. The amount of brine purchased or used captive is close with the quantity of brine used for chlor-alkali production as noted in table 9.

Canada.—CanadianOxy Chemicals suspended production of chlorine and caustic soda at its Squamish, British Columbia, facility because of the downturn in Canadian chlorine markets. The company had closed a smaller plant at Nanaimo, British Columbia, in 1990. All of CanadianOxy's chlor-alkali production capacity was consolidated at its North Vancouver, British Columbia, operation. Citing similar reasons, Dow Canada closed its Sarnia, Ontario, chlorine and caustic soda facility.

Germany.—Akzo NV announced that it will invest \$10 million to modernize its salt processing plant in Stade, Germany. The project was estimated to take 3 years to complete. The facility has a production capacity of 400,000 tons.

OUTLOOK

The outlook for salt in the 1990's is optimistic. The major producers have diversified into all types of salt across the Nation and have developed reliable import sources in Canada, the Caribbean,

Mexico, and South America. Consolidations and restructuring within the U.S. salt industry have strengthened it into a competitive North American enterprise in the Western Hemisphere. Domestic salt consumption is forecast to grow about 1.3% in 1995. (See table 21 and figure 2.)

¹The quantity of imports included in the total for each type of salt is the amount reported by the U.S. salt industry, not the quantity reported by the Bureau of the Census that appears in tables 16, 17, and 18.

²Data may not add to totals shown because of independent rounding. Because data includes salt imported, produced and/or sold from inventory from regional distribution centers, salt sold or used by type may differ from totals shown in tables 3, 6, 7, and 8, which are derived from plant reports at salt production locations. Data may differ from totals shown in table 10 because of changes in inventory and/or incomplete data reporting.

³Less than 1/2 unit.

⁴Includes exports.

Total⁴	4,651	4,113	17,153	25,917	4,487	4,059	15,586	24,132

W Withheld to avoid disclosing company proprietary data; included with "Other."

¹Each salt type includes domestic and imported quantities. Brine is excluded because brine usually is not shipped out of State.

²Less than 1/2 unit.

³Includes shipments to overseas areas administered by the United States, Puerto Rico, exports, some shipments to unspecified destinations, and shipments to States indicated by symbol W.

⁴Because data include salt imported, purchased and/or sold from inventory from regional distribution centers, evaporated and rock salt distributed by State may differ from totals shown in tables 3, 6, 7, and 8, which are derived from plant reports at salt production locations. Data may differ from totals shown in table 9 because of changes in inventory and/or incomplete data reporting.

PPG Industries, Inc.	Lake Charles, LA	1,150	2,012	Captive and purchased brine.
Do.	Natrium, WV	280	490	Captive brine.
Vulcan Materials Co.	Geismar, LA	246	431	Purchased brine.
Do.	Port Edwards, WI	73	128	Imported.
Do.	Wichita, KS	273	478	Captive brine.
Weyerhaeuser Co.	Longview, WA	130	228	Imported.
Total		12,217	21,381	

¹Includes only those chlorine plants that use salt directly as a feedstock. Does not include plants that produce byproduct chlorine from magnesium chloride and hydrochloric acid oxidation or plants using potassium chloride.

²Based on 365 days per year.

³Based on 1.75 tons of salt required to manufacture 1.0 ton of chlorine with the plant operating at 100% capacity. Salt may be from natural brines, rock, or solar sources, domestic or imported.

⁴Formerly Pennwalt Corp.

⁵An additional 730,000 tons available on standby basis; included in "Total."

NOTE.—The following plants closed in 1991: Alzo at LeMoyné, AL; Hanlin at Moundsville, WV; and RMI at Ashtabula, OH, (metallic sodium).

TABLE 13
SALT YEAREND PRICES

	1990	1991
Salt, evaporated, common:		
80-pound bags, carlots or truckloads:		
North, works, 80 pounds	\$4.02	\$4.02
Bulk, same basis, per ton	60.00-61.20	60.00-61.20
Salt, chemical-grade, same basis:		
North, works, 80 pounds	4.30	4.30
Salt, rock, medium, coarse:		
Same basis, 80 pounds	2.70	2.70
Bulk, same basis, per ton	18.00-25.00	18.00-25.00
Sodium chloride, U.S.P.:		
Granular bags, per pound	.29	.29

Sources: Chemical Marketing Reporter. Current Prices of Chemicals and Related Materials. V. 238, No. 27, Dec. 31, 1990, p. 31; and V. 240, No. 27, Dec. 30, 1991, p. 31.

TABLE 14
AVERAGE VALUES¹ OF SALT, BY PRODUCT FORM AND TYPE

(Dollars per short ton)

Product form	Vacuum pans and open pans	Solar	Rock	Brine
1990				
Bulk	45.30	¹ 16.05	14.99	⁴ 4.86

Total	¹197,010	²201,493	²209,914	²200,989	202,450

¹Estimated. ²Revised.

³Table includes data available through June 15, 1992.

⁴Salt is produced in many other countries, but quantities are relatively insignificant and reliable production data are not available. Some salt brine production data for manufacture of chlorine, caustic soda, and soda ash are not reported because of incomplete data reporting by many countries.

⁵Reported figure.

⁶Year ending June 30 of that stated.

⁷Less than 1/2 unit.

⁸Brine salt production as reported by the Burmese Government in thousand short tons, was as follows: 1987—64 (revised) 1988—66 (revised); 1989—66; 1990—55 (revised); and 1991—46 (reported).

⁹Year beginning Mar. 21 of that stated.

¹⁰Does not include production from Sardinia and Sicily, estimated at 200,000 metric tons annually.

¹¹Year ending July 15 of that stated.

¹²Great Britain only.

¹³Data captioned "Brine salt" for the United Kingdom are the quantities of salt obtained from the evaporation of brines; that captioned "Other salt" are the salt content of brines used for purposes other than production of salt.

TABLE 20—Continued
U.S. SALT ANNUAL PRODUCTION CAPACITIES IN 1991

(Thousand short tons)

Company	Plant	Type of salt			Total
		Rock	Solar	Vacuum pan	
Brine producers ⁷	Various locations	—	—	—	20,569
Grand total		<u>17,395</u>	<u>4,825</u>	<u>4,740</u>	<u>47,529</u>

¹Operated as Akzo Salt of Utah Inc., a wholly owned subsidiary of Akzo.

²Formerly operated by Leslie Salt Co. As of Sept. 1, 1991, Leslie's plants merged with Cargill to become Cargill Salt Western Area.

³Closed Dec. 1990. Sold from inventory during 1991.

⁴Formerly Carey Salt Co's., rock salt operation. The vacuum pan salt operation is owned by North American Salt Co. effective Dec. 1990.

⁵Formerly American Salt Co's., rock salt operation. The vacuum pan operation is owned by North American Salt Co. effective Dec. 1990.

⁶Company formed in 1990 by the acquisition of the Kansas vacuum pan salt operations of American Salt Co. and Carey Salt Co., and the rock salt and solar salt facilities of Domtar Industries Inc., in Louisiana and Utah, respectively.

⁷Includes brine for sale and for captive use. Brine production capacity is assumed to be equal to the quantity of annual brine production, as shown in tables 4 and 5. Brine producers include those chloralkali manufacturers that purchase brine or use captive brine, as listed in table 12.

Rock salt	13.89	13.43	13.78	15.15	14.51	14.34	14.46	16.38	¹ 16.80	17.45
Solar salt	17.89	21.47	19.67	23.10	23.76	25.40	26.59	27.88	³ 31.60	25.20
Vacuum pan and open pan salt	86.72	87.39	92.78	92.66	91.27	94.21	97.71	92.73	100.32	104.10

^aEstimated. ^bPreliminary. ^cRevised.

¹Represents that amount sold or used captively within the industry, from the quantity produced and any sold from inventory. Accurate data on beginning and yearend inventories of salt are unavailable and often are underreported because of additional storage underground at mines, warehouses, terminals, etc. However, about 2.5 million tons is estimated to be stored annually nationwide.

²The total quantities of salt in inventory are underreported and are excluded in determining the supply-demand balance relationship for salt. However, the difference between production and sold or used is assumed to be because of changes in inventory.

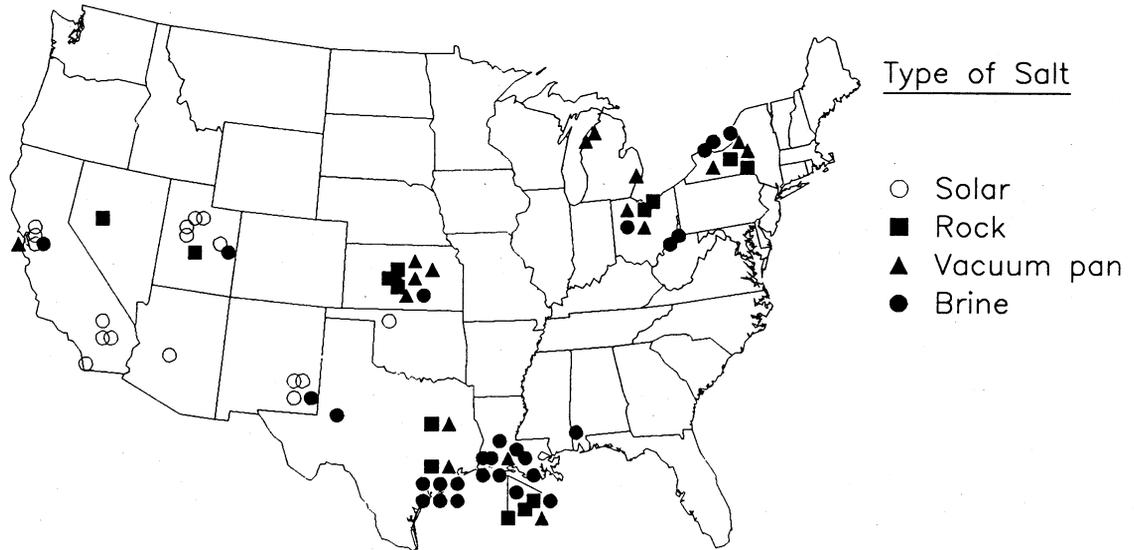

³Includes imports for consumption.

⁴Includes salt used in rubber; tanning; other industrial; institutional wholesalers and/or retailers; U.S. Government resale; other wholesalers; some exports for consumption in overseas territories administered by the United States; and other various minor uses.

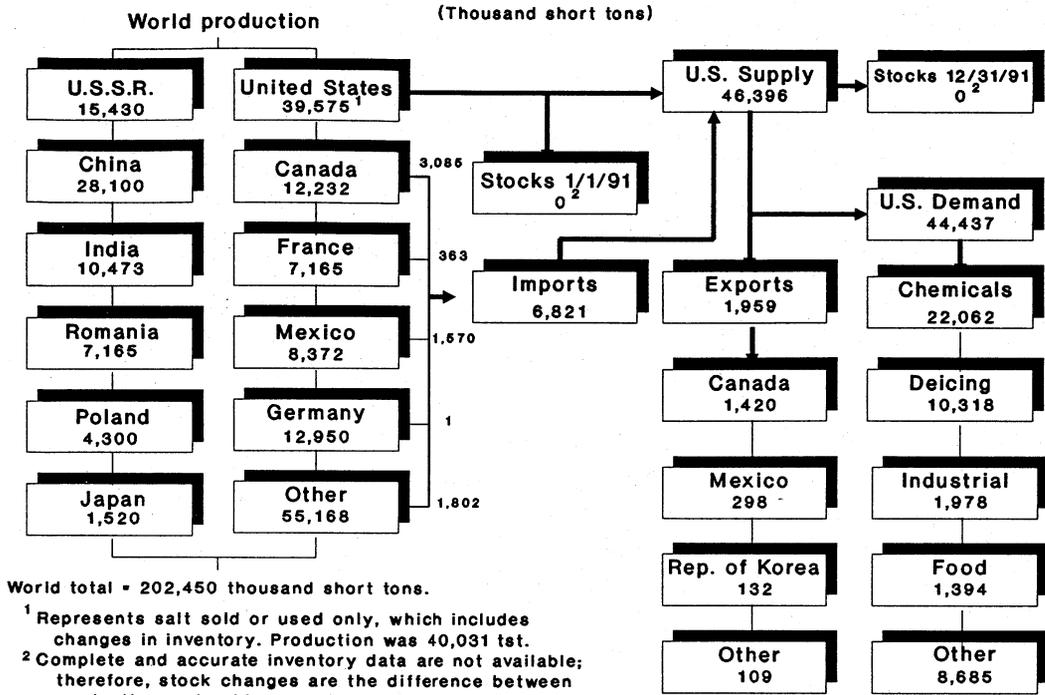

⁵Represents the difference between the quantity reported to the U.S. Bureau of Mines and total U.S. primary demand. The amount of discrepancy is attributed to variances in inventory and import statistics.

⁶Values are based on the average of all salt producers' valuations reported for bulk, f.o.b. plant, and includes all processing costs, depreciation of equipment, taxes, and profit.

CONSTRUCTION SAND AND GRAVEL

By Valentin V. Tepordei

Mr. Tepordei, a geological engineer with more than 20 years of industry experience, has been the construction sand and gravel commodity specialist with the U.S. Bureau of Mines since 1979. Domestic survey data were prepared by the construction sand and gravel survey staff of the Branch of Data Collection and Coordination.

Construction sand and gravel is one of the most accessible natural resources and a major basic raw material used mostly by the construction industries. Despite the relative low value of its basic products, the construction sand and gravel industry is a major contributor to and an indicator of the economic well-being of the Nation.

A total of 780 million short tons of construction sand and gravel was estimated to have been produced in the United States in 1991, a 14.3% decrease compared with the total production of 1990. This tonnage represents the lowest production level since 1986, indicating a significant decline in the demand for construction aggregates in the United States in 1991. (See table 1.)

Foreign trade of construction sand and gravel remained relatively minor. Exports of construction sand decreased 6.2% to 439,000 tons, while value increased 9.4% to \$13 million. Exports of construction gravel declined 17.8% to 700,000 tons compared with those of 1989, and value declined 21.6% to \$6 million, again compared with those of 1989, because no information on exports of gravel was available for 1990. Imports decreased 15.9% to 1.5 million tons, while the value decreased 27.4% to \$16.6 million. Domestic apparent consumption of construction sand and gravel was 781 million tons.

The removal of nonasbestiform Anthophyllite, Tremolite, and Actinolite (AT&A) from the scope of the present Occupational Safety and Health Administration (OSHA) standards for regulating occupational exposure to asbestos in general industries eliminates a major area of concern of the construction

aggregates industries. The implementation of the provisions of the amended Federal Water Pollution Control Act of 1977, the Clean Water Act, Section 404, dealing with "wetlands" and the establishment of a "no net loss of wetlands" policy continues to constitute one of the major areas of concern to the construction aggregates industry. The other area of concern is related to the final promulgation of the permissible exposure limit for crystalline silica measured as respirable silica.

DOMESTIC DATA COVERAGE

Domestic production data for construction sand and gravel are developed by the U.S. Bureau of Mines from voluntary surveys of U.S. producers. Full surveys of construction sand and gravel producers are conducted for even-numbered years only. For odd-numbered years, only annual estimates for each State are generated based on information provided by the quarterly sample survey of construction sand and gravel and crushed stone producers. This survey provides production estimates by quarters for each State and the nine geographic regions. The sample surveys canvass most of the large companies in each State, accounting for up to 80% of each State's total tonnage. The results of this survey are published each quarter in a separate publication, the quarterly Mineral Industry Surveys.

BACKGROUND

Sand and gravel is a granular, unconsolidated, and usually rounded agglomeration of particles of rocks and

minerals, resulting primarily from the natural disintegration and abrasion of rocks through weathering or erosion. Sand and gravel, as one of the most accessible natural resources, has been used since the earliest days of civilization, mostly as a construction material. At the beginning of the 20th century, the U.S. production of construction sand and gravel, the sand and gravel used mostly for construction purposes, was relatively small and its uses limited. Today, annual sand and gravel production tonnage ranks second in the nonfuel minerals industry after crushed stone and is the only mineral commodity produced in all 50 States. The United States is, in general, self-sufficient in sand and gravel, producing enough to meet all domestic needs and to be a small net exporter, mainly to consumption points along the United States-Canadian and United States-Mexican borders.

Most sand and gravel is used for construction purposes, mainly as aggregate in concrete; as road base material in the construction and repair of highways, railways, and runways; and as aggregate in asphaltic concrete for paving highways, streets, etc. Construction sand and gravel has one of the lowest average per ton values of all mineral commodities. The constant dollar price has changed relatively little over the past 20 years. Increased operating costs have been partially offset by automation and other means of increasing operating efficiency.

Although construction sand and gravel resources are widespread and in adequate supply nationally, local shortages exist. Land use conflicts and environmental

problems associated with rapid urban expansion are major factors contributing to these shortages. In addition, in some geographic areas with sufficient resources, some shortages occur because the proportions of various size fractions of sand or gravel may not meet size specifications of the construction industry. Demand pressures, land use regulations, and the cost of meeting environmental and reclamation requirements are factors that will cause a rising price trend. Larger operations with more efficient equipment, more automation, and better planning and design will be the trend of the industry in the future. This will permit increased use of less accessible and lower quality deposits and will keep prices at competitive levels.

Definitions, Grades, and Specifications

Sand is defined throughout the industry and by the American Society for Testing and Materials (ASTM) as naturally occurring unconsolidated or poorly consolidated rock particles that pass through a No. 4-mesh (4.75-millimeter) U.S. standard sieve and are retained on a No. 200-mesh (75-micrometers) U.S. standard sieve. Gravel consists of naturally occurring unconsolidated or poorly consolidated rock particles that pass through a sieve with 3-inch (76.2-millimeters) square openings and are retained on a No. 4-mesh U.S. standard sieve.

Sand and gravel is made up of varying amounts of different rock types and is, therefore, of varying chemical composition. Silica is the major constituent of most commercial sands, and lesser amounts of feldspar, mica, iron oxides, and heavy minerals are common. Most applications of sand and gravel have specifications for size, physical characteristics, and chemical composition. A compilation of 42 ASTM specifications and test methods, including the latest revisions and updates pertaining to aggregates, concrete, and admixtures, was reprinted by the National Aggregates Association (NAA).¹

Specifications for sand and gravel used in roadbuilding and concrete construction are often rigid regarding particle size gradation and shape and include physical as well as some chemical properties. However, these specifications can differ in detail from State to State or even from city to city within the State. Soil conditions, climate, and peculiarities in different deposits may necessitate adjustments of requirements of sand and gravel mixtures and chemical composition.

Specifications are written by commercial users; Government agencies, including Federal; State, county, and city construction and highway departments; and the ASTM. Problems arise for the producers of construction aggregates when their product is sold or used in several different cities, counties, or States, many of which may have different specifications. Some progress is being made toward the standardization of aggregate sizes for similar requirements. A need exists for a more active interchange of data and experience among aggregate consumers and producers.

Products for Trade and Industry

Concrete is made by mixing properly sized aggregate, portland cement, and water into a slurry. Chemical action between the cement and the water results in the crystallization of hydrous calcium aluminum silicates, which causes the mass to bind and harden. Round particles in the aggregate are desirable because they improve the workability of the concrete as it is poured. If broken material is used and angular or flattish fragments exceed about 15% of the total volume, workability can be maintained only by increasing the amount of sand and water, thus reducing strength, or by adding more cement, thus increasing the cost of the concrete.

Sized and broken sand and gravel is used to make asphaltic concrete aggregate and road bases. Broken surfaces adhere to the hot asphaltic mixture better than do rounded surfaces and provide interlocking surfaces that tend to strengthen the asphaltic concrete. Broken particles pack

better and tend to move less under load than do rounded particles and, therefore, make better road bases for highway and road construction. This is essential because bases and asphaltic concrete tend to flow when placed under great or long duration stresses.

Industry Structure

Because of the low unit value, construction sand and gravel is produced near the point of use; therefore, the industry is concentrated in or nearby large, rapidly expanding urban areas and, on a transitory basis, in areas where highways, dams, and other large-scale public and private works are under construction. In the United States, sand and gravel is produced in every State. The largest operations tend to be concentrated in the States with the largest population and largest production of sand and gravel.

Construction sand and gravel is produced in virtually all countries, but relatively few of them survey this industry and even fewer regularly publish official statistics on sand and gravel.

On the basis of tonnage, the construction sand and gravel industry is the second largest nonfuel mineral industry in the United States. In 1990, the last year when a full survey was conducted, there were 4,094 companies producing construction sand and gravel operating 5,665 pits. The individual operations range in size from those producing millions of tons annually to those reporting less than 25,000 tons per year. Most operations are small, turning out one product or a limited range of products, but most of the tonnage comes from large operations. For example, the 18 operations reporting more than 2.5 million tons each in 1990 represented only 0.3% of the total number of operations, but produced 8% of the total tonnage, while 101 operations reporting between 1 and 2.5 million tons each, representing only 1.8% of the total number of operations, produced 15.5% of the total tonnage. For the same year, most of the construction sand and gravel was produced by operations reporting

between 200,000 and 1 million tons each—1,094 operations, representing 19.2%, produced 49.2% of the total tonnage.

The leading companies producing construction sand and gravel, in descending order of tonnage, based on the 1990 survey, were Beazer U.S.A. Inc. of Pittsburgh, PA; CalMat Co. of Los Angeles, CA; CSR Ltd., of Sydney, Australia; Ashland Oil, Inc., of Ashland, KY; and Dravo Basic Materials Co. of St. Rose, LA. The top 5 companies operated 133 pits and produced 11% of the U.S. total. Two of these five companies are subsidiaries of foreign companies. Many producers are in the sand and gravel business exclusively, but others are diversified in various degrees in the production of other mineral raw materials; intermediate construction products such as ready-mixed concrete and concrete blocks; final manufactured products; or construction of buildings, roads, and other structures. At the same time, construction companies are entering more and more into the sand and gravel business to integrate their operations.

Geology-Resources

The processes of formation and deposition impart to sands and gravels the physical characteristics that largely determine the commercial value for a particular use and influence the manner of development. The principal types, based on origin, are stream, glacial, residual, marine, and lake. Windblown deposits are of minor importance. Much of the commercial production is from stream deposits, many of which are deficient in the fines required by present-day grading specifications for concrete aggregates. Stream deposits usually exhibit stratification and often large-size gradation. The beds vary in thickness and sometimes have interspersed lenses of clay or fine sand. The degree of roundness and the particle size varies with the hardness and distance transported. Glacial deposits have the least sorting of all transported deposits, while marine and lake deposits exhibit the best sorting with coarse and fine

particles, often well segregated. Residual deposits are found overlying the parent rock and are unstratified mixtures of pebbles, boulders, sand, and clay. They often contain much soft material that prohibits commercial production. Marine or offshore deposits could become more important as inland deposits become depleted or environmentally less desirable to extract. A comprehensive report showing geologic occurrences of potential sources of sand and gravel and crushed stone of the conterminous United States for use as natural aggregates was published by the U.S. Geological Survey.²

On the basis of geologic evidence, world reserves are sufficient to meet demands, although not necessarily at precisely the locations where needed. Reserves, which are measurable amounts of sand and gravel that can be produced profitably with current technology under existing economic and political conditions, are controlled mostly by land-use and/or environmental constraints. The total sand and gravel resources of the United States are very large. However, the geographic distribution and/or quality of the reserve base often does not match market patterns or requirements.

Technology

Major technological developments that have been instrumental in maintaining adequate production at relatively stable real costs include use of larger operating units, more efficient portable and semiportable plants, unitized plants for versatility of plant capacity, new prospecting methods utilizing aerial and geophysical surveying methods, and greatly increased rehabilitation and resale of mined areas. Use of mined-out pits as lake beds and as sanitary landfill areas has been successful at numerous localities. Automatic controls, along with monitoring by closed-circuit television coordinated with automated counting and recording and radio communications systems, have been installed in many of the larger and newer operations; these, along with the use of improved equipment, have permitted recovery of

salable fractions from deposits previously considered too low in quality for profitable exploitation. These practices will increase as pressures build to increase productivity and minimize environmental conflicts.

Exploration.—Sand and gravel deposits, like any mineral deposit, must be explored and evaluated before development. Preliminary examination can establish the extent and nature of the deposits. This is followed by a detailed exploration program aimed at obtaining reasonably accurate information on the quantity of material available, the degree of uniformity throughout the deposit, and especially, variations in particle size, both vertically and horizontally. Also, the nature and amount of waste materials and the economic feasibility of their removal must be studied.

Geophysical methods are of value in preliminary surveys. Detailed exploration may be achieved by a systematic arrangement of test pits, trenches, boreholes, or other procedures designed to obtain a cross section of the deposit in conjunction with sampling and testing. Advances in interpretation of aerial photographs and increased application of geophysical techniques have made evaluation of sand and gravel deposits more quantitative. For underwater exploration, mining devices such as dredges and draglines are used. Pilot runs are necessary to determine if required specifications can be met consistently and economically.

Much of the sand and gravel that is being mined in stream, flood plain, alluvial fan, riverbeds and terrain, and glacial deposits is good quality material with nearly equal amounts of gravel and sand and small amounts of unusable material. As these deposits become depleted in future years, less desirable and more expensive sources will have to be developed where mining, reserves, ratio of sand to gravel, quality of material, waste factors, and environmental factors such as waste disposal will present more problems.

Exploration and planning will become more important in assessing deposits,

particularly hillslope deposits of older sand and gravel. Grading to meet required slope and setback requirements at hillslope sites may necessitate leaving large tonnages of material unmined. Many millions of tons of material is available, but it may not be of proper quality or ratio of sand to gravel. More deposits of marginal quality will have to be developed to provide for future demand.

Mining.—Sand and gravel generally occur in the same deposit, but the relative proportions of each vary greatly within most deposits. Consequently, the control problem of producing aggregate to rigid specifications involves combinations of many types of equipment like screens, washers, classifiers, crushers, and grinding mills. The two basic sand and gravel mining methods are open pit excavation and dredging. Open pit excavation and processing has four major steps: (1) site clearing—removing trees and vegetation; stripping overburden and topsoil; and transporting, redepositing, or stockpiling it at or off the site; (2) mining—removing the sand and gravel from the deposit; (3) processing—screening, washing, crushing, blending, and stockpiling the mined material to conform to standards and specifications; and (4) reclamation of the extraction area. Processing may or may not take place at the mining site. Mining equipment ranges from small, simple units such as tractor-mounted high-loaders and dump trucks to more sophisticated systems involving large power shovels, draglines, bucketwheel excavators, and belt conveyors. Increasingly, mining systems are being designed to provide for more efficient and economical land reclamation.

Mining with a dredge usually involves mounting the equipment on boats or barges. Suction or bucket-type dredges are used most commonly to harvest sand and gravel from the bottom of a body of water. The sand and gravel is processed either on board or transported to land for processing.

Processing.—Although small amounts of unprocessed bank-run sand and gravel are used for fill, most of the U.S. production is processed in some way. Present methods include washing with water during the screening process, in some cases followed by crushing of the larger particles in cone or gyratory crushers. Secondary crushing may be done by roll crushers. Sizing is done in most plants by horizontal or sloped single or multideck vibratory screens. If necessary, heavy-media separation or jigging is used to remove heavy, unusable materials. Sand for use in construction is freed from clay by log washers or rotary scrubbers. The scrubbing is followed by classification, use of separatory cones or hydroseparators to remove water, and fine screening for grading. Rodmilling is often required for production of small-sized fractions of sand. Transfer of processed sand and gravel from the processing plant to stockpiles or bins is accomplished by flexible combinations of conveyor belts, bucket elevators, and screw conveyors.

Permanent installations are built when large deposits are to be operated for many years. Portable and semiportable units are used in many pits that have an intermediate working life. Several such units can be tied together to obtain large initial production capacity or to add capacity as needed. Mobile screening plants can be quickly moved from one deposit to another without undue interruption or loss of production.

Recycling.—As the Nation moves into an age of increased environmental consciousness, recycling of old concrete and asphalt, used mostly in pavements, is increasing. Local scarcity or high cost of construction aggregates in some areas as well as waste disposal problems are making recycling more attractive economically. In some States, limited recycling, especially in road construction, is either encouraged or required by law. The best utilization for recycled cement concrete is as road base material, because the matrix of concrete cannot be converted back to cement, and also

because of the lower strength of concrete compared with that of natural aggregates. Sound crushed concrete can make good coarse aggregate, but the fines produced in crushing the concrete have a higher absorption, are more friable, and will require a higher amount of asphalt in asphaltic concrete and a higher amount of mixing water in portland cement.³ The amount of asphalt roads recycled is significantly larger than that of concrete roads, mainly because asphalt can be rejuvenated with oil additives and used in pavements, significantly reducing the cost of the finished road. Experience has shown that about 35% of crushed asphalt pavement can be recycled into new asphalt mixtures. Proper testing under engineering supervision in all construction projects using recycled materials as aggregates should be performed to ensure that the technical specifications are met.

Byproducts and Coproducts

Small amounts of gold and silver are recovered as a byproduct or coproduct of sand and gravel extraction, particularly in highly sorted deposits.

Economic Factors

Construction sand and gravel is a high-volume, low-value commodity. The industry is highly competitive and is characterized by thousands of operations serving local or regional markets. Production costs vary widely depending on geographic location, the nature of the deposit, and the number and type of products produced. Constant dollar unit values have been quite steady during the past 20 years. As a result of rising costs of labor, energy, and mining and processing equipment, the average unit price of construction sand and gravel increased from \$1.1 per ton, f.o.b. plant, in 1970 to \$3.60 in 1991. However, the unit price in constant 1987 dollars fluctuated between a maximum of \$3.06 in 1980 and a minimum of \$2.58 in 1991. (See table 2 and figure 2.) Increased productivity achieved through increased use of automation and more efficient equipment was mainly responsible for

maintaining the prices at this level. Constant dollar prices are expected to rise in the future because of decreased deposit quality and more stringent environmental and land use regulations.

Accessibility is a problem for the construction sand and gravel industry. The high-volume and low-unit value of sand and gravel requires that operations be close to the market location. Markets for sand and gravel are construction sites that are mostly in areas of high population density. New operations, close to population centers, are difficult to develop because the land is often attractive for other uses such as housing, shopping centers, agriculture, parks or recreational areas, and because of public dislike for mining operations close to populated areas. Existing operations in expanding communities face increasing costs because of increasing land values and increasing restrictions on operations as suburban development comes closer. Deposits are often small and, once exhausted, the operation must be moved to a new site that invariably is farther from the market because closer sites are being used for other purposes.

The industry also faces increasing competition from crushed stone that can substitute for sand and gravel in most of its applications. Stone operations are generally longer lived, can afford greater capital investment for higher efficiency, and are often located where competing land use pressures are less severe. The topographically rugged stone-bearing areas are usually less desirable for construction purposes than sand-and-gravel-bearing areas, which are generally flatter.

A 5% depletion allowance based on gross income is allowed for construction sand and gravel. There are no import tariffs.

Operating Factors

Many States, counties, and cities in the United States have zoning laws, and land within each governmental unit is usually zoned to indicate acceptable land uses. If mining is permitted in a zone and a sand and gravel company owns or leases land

within that zone, the company may apply for a use permit or its equivalent to begin an operation. If the parcels to be quarried are on lands under both city and county jurisdiction, permits usually must be obtained from each. An acceptable reclamation plan that meets the guidelines or regulations of the appropriate governmental agency must also be approved. Environmental concerns such as noise, dust, beautification, and storage of wastes must be accounted for in a manner satisfactory to the governmental entity involved. Wastewater discharge requirements must be planned for and met. If the deposit to be worked is on a river or land controlled by a river or water or flood control agency, whether municipal, State, or Federal, that agency's requirement must also be satisfied.

In most States, permits for sand and gravel operations require an Environmental Impact Report (EIR) or Statement (EIS). A reclamation plan and a use permit application may also be required, with considerable overlap of subject matter with the EIS. A complete EIS may cover all the problem areas at once and facilitate acceptance.

Environmental Requirements.—Two main points are involved in environmental land use and reclamation factors. First, the industry must be concerned about any practices that can affect the community environment. An effective effort must be made to reduce noise, air, and water pollution; to reclaim pits after the operation is complete; and to improve the overall appearance of the operating mine, processing plant, and transportation facilities. Second, the industry and community must recognize the time and costs required to protect the environment and the importance of agreeing on fair and realistic environmental standards.

Because sand and gravel is a local commodity, the effect of supply deficiencies and cost of material will affect the local community first. Undue delay and unreasonably high cost can strongly affect the movement of sand and gravel into the marketplace. Also, stringent controls by the local government

that prevent permits being issued to operators can have adverse economic effects on the communities around them. These conditions can make it difficult to assess the timing and even the possibility of plants going on-stream and can therefore affect the supply of sand and gravel into the marketplace.

Although much progress is being made through premining planning, the sand and gravel industry continues to have problems with environmental controls, land use conflicts, and reclamation practices. Many of these problems are acute because extraction areas and plants must be reasonably near to consumers who are largely in metropolitan areas. Major environmental considerations that must be dealt with in mining and processing sand and gravel are emission of particulate matter into the air, processing water discharge, noise abatement, and employee and public health and safety.

Transportation.—Transportation is a major factor in the delivered price of construction sand and gravel. The cost of moving construction sand and gravel from the plant to the market often exceeds the sales price of the product at the plant. Because of the high cost of transportation, construction sand and gravel continues to be marketed locally. Economies of scale, which might be realized if fewer, larger operations served larger marketing areas, would probably not offset the increased transportation costs.

Truck haulage is the main form of transportation used in the construction sand and gravel industry. Many producers have their own truck fleet and deliver their own raw materials and products. A significant and increasing amount of sand and gravel, however, is being hauled by independent truckers because of the cost of maintaining a truck fleet, particularly when the market is highly variable or down. Rail and water transportation combined account for about 10% to 20% of total construction sand and gravel shipments.

ANNUAL REVIEW

In 1991, a total of 780 million short tons of construction sand and gravel was estimated to have been produced in the United States, a 14.3% decrease compared with the total production of 1990. This tonnage represents the lowest production level since 1986, indicating a significant decline in the demand for construction aggregates in the United States in 1991. During the year, productions of construction sand and gravel decreased every quarter, compared with the same period of 1990, with the largest decreases occurring in the first and fourth quarters of 1991.

Legislation

On December 18, 1991, the Intermodal Surface Transportation and Infrastructure Act of 1991 became Public Law 102-240. The new law authorized \$151 billion to be spent in the next 6 years on transportation projects, \$119.5 billion on highway work, and \$32.5 billion on mass transit. The new law defines a new National Highway System that combines interstate routes with selected State routes, creates a Surface Transportation Program that replaces categorical grants to the States, and restructures the Federal-Aid Highway Program giving State legislatures and metropolitan planning organizations more flexibility in choosing projects and transferring funds between spending categories.

On June 8, 1992, OSHA announced that it was amending its standards governing the "Occupational Exposure to Asbestos, Tremolite, Anthophyllite, and Actinolite (AT&A)"⁴ by removing nonasbestiform AT&T from the scope of the present standards affecting the general industries, including the construction industries. OSHA has determined that substantial evidence is lacking to conclude that AT&T present the same type or magnitude of health effects as asbestos or that employees would be at significant risk because nonasbestiform AT&T were not regulated in the asbestos standards. The latest Administrative Stay of

enforcement of the revised standards was also removed by OSHA effective May 29, 1992.

Issues

The implementation of the provisions of the amended Federal Water Pollution Control Act of 1977, the Clean Water Act, Section 404, dealing with "wetlands" and the establishment of a "no net loss of wetlands" policy constitutes one of the major areas of concern to the crushed stone industry. There is a significant amount of uncertainty regarding the process of designating some lands as wetlands and whether the current exemptions to the Clean Water Act section 404 permit program will be maintained in the future. Several bills were introduced in the 102d U.S. Congress to replace the current section 404 of the Federal Water Pollution Control Act. The new proposed bills plan to provide a concise and structured program for the delineation of wetlands based upon their functions and values and will balance the need for effective protection of the Nation's important wetlands with the need for essential community growth and the constitutional rights of landowners.

The removal of nonasbestiform AT&T from the scope of the present OSHA standards for regulating occupational exposure to asbestos in general industries, including the construction industries, eliminates a major area of concern for the construction aggregates industries. Based on the entire rulemaking record, OSHA has determined that substantial evidence is lacking to conclude that nonasbestiform AT&T present the same type or magnitude of health effects as asbestos. OSHA also concluded that substantial evidence does not support a finding that exposed employees would be at significant risk because nonasbestiform AT&T were not regulated in the asbestos standard.

Another issue of concern to the construction aggregates industries is the classification of crystalline silica as a probable human carcinogen by the International Agency for Research on

Cancer, an agency of the World Health Organization. OSHA-regulated sites that receive and/or use products containing more than 0.1% crystalline silica must comply with OSHA's Hazard Communication Standard. Both the classification of crystalline silica as a probable human carcinogen and the requirement to quantitatively analyze for crystalline silica at the 0.1% level are controversial.

Production

The production estimates indicate that in 1991 the U.S. production of construction sand and gravel was 780 million short tons, a 14.3% decrease compared with the total production of 1990. Of the four major geographic regions, the West again led the Nation in the production of construction sand and gravel with 285 million tons or 36.5% of the U.S. total, followed by the Midwest with 244 million tons or 31.2% of the total; the South with 171 million tons or 21.9%; and the Northeast with 81 million tons or 10.3%. Compared with that of 1990, production by major geographic regions decreased in every region, 24.3% in the Northeast, 16.1% in the South, 13.5% in the Midwest, and 10.3% in the West. (See table 3 and figure 1.)

Of the nine geographic regions, the Pacific again led the Nation with 172 million tons or 22.1% of the U.S. total. Next was the East North Central with 161 million tons or 20.7% of the total, and the Mountain with 113 million tons or 14.4% of the total. Compared with that of 1990, production decreased in all nine regions, the largest decreases being recorded in the New England region, 33.5%; the South Atlantic region, 20%; and the Middle Atlantic region with only 18.9%. (See table 3.)

The estimated production by quarters for 1991 indicated that most of the construction sand and gravel in the United States was produced in the third quarter, followed by the second quarter and the fourth quarter. Estimated production by each quarter of 1991 was also available for most of the States. (See tables 4 and 6.)

Construction sand and gravel was produced in every State, and the 10 leading States in 1991 were, in descending order of tonnage, California, Michigan, Ohio, Washington, Texas, Wisconsin, Colorado, Illinois, Minnesota, and New York. Their combined production represented 51.1% of the national total. (See table 5.)

Compared with that of 1990, production decreased in most States, including 7 of the top 10 States. The decreases, in percentage, were very large in Maine, -50.4%, New Hampshire, -40.5%, Connecticut, -36.8%, and Rhode Island, -34%, and significant in some of the major producing States like Minnesota, -27.7%, California, -22.9%, New York, -20.3%, Illinois, -18.8%, Michigan, -16.6%, and Texas, -15.8%.

Limited information about the production of construction sand and gravel in foreign countries may be found in the U.S. Bureau of Mines "Minerals Yearbook, Area Reports: International." For nonreporting countries, estimates of sand and gravel and crushed stone outputs can be based on indirect sources such as the level of cement consumption.

Fewer changes in ownership, acquisitions by foreign or domestic companies, and mergers occurred in the construction sand and gravel industry in 1991. In November 1991, Hanson PLC of London, United Kingdom, acquired Beazer PLC, of Bath, United Kingdom, the parent company of Beazer USA, Inc., the largest construction sand and gravel and the second largest crushed stone producer in the United States. In August, prior to the acquisition, in an effort to reduce its debt, Beazer announced plans to sell most of its European housebuilding, real estate, and contracting operations and focus mostly on its U.S.-based operations.

In October 1991, Redland Aggregates Ltd. of Groby, Leicester, United Kingdom, acquired Frontier Materials Co. of Denver, CO, a sand and gravel producer and a paving company.

Consumption and Uses

Sand and gravel reported by producers to the U.S. Bureau of Mines is actually material that is "sold or used" by the companies and is defined as such. Stockpiled production is not reported until it is sold to a user or consumed by the producer outside its own operation. Because no consumption surveys are conducted by the U.S. Bureau of Mines, the "sold or used" tonnage is assumed to represent the amount produced for domestic consumption and export.

The largest use of construction sand and gravel is as aggregate for the production of concrete, used in nearly all residential, commercial, and industrial buildings, and in most public works projects such as highways and roads, bridges, dams, airport runways, sewer systems, tunnels, etc.

Over the past several years, this use represented about 26% of the total. The second largest use is as base material in the construction and repair of highways, railways, runways, etc. It represented about 15% of the total. Other major uses are as aggregate in asphaltic concrete used for paving highways, streets, and parking lots, about 8%, and as fill in highway construction, earth dams, and other applications where recontouring of the original land surface is required, about 7%. The above percentages were calculated based on the information provided by the producers. It should be noted that over the past several years, about 37% of the total U.S. production was included in "unspecified uses—actual and estimated," because some producers reported only total production or did not report at all, and then their production was estimated. The percentage of estimated amounts for nonrespondents decreased from 23.5% in 1984 to 12.7% in 1990, while the percentage of production reported only as totals increased from 16.2% in 1984 to 24.1% in 1990.

Sand and gravel are usually used mixed, but some uses require only sand or only gravel. Sand is used in mortar, plaster, and gunite and for snow and ice control. Gravel is used to improve or

control drainage and as covering and stabilizer on load-bearing surfaces such as unpaved roads, driveways, and parking areas. In 1991, only production estimates were generated for construction sand and gravel, and therefore no information by end uses is available for this year.

Prices

Prices in this chapter are f.o.b. plant, usually at the first point of sale or captive use. This value does not include transportation from the plant or yard to the consumer. It does, however, include all costs of mining, processing, in-plant transportation, overhead costs, and profit. Compared with that of 1990, when the last full annual survey was conducted, the estimated 1991 average unit prices increased only 0.8% to \$3.60 per ton.

As a result of rising costs of labor, energy, and mining and processing equipment, the average unit value of construction sand and gravel increased from \$1.11 per ton, f.o.b. plant, in 1970, to \$3.60 in 1991. However, the unit price in constant 1987 dollars fluctuated between a maximum of \$3.06 in 1980 and a minimum of \$2.58 in 1991. (See table 2.)

Foreign Trade

The widespread distribution of domestic sand and gravel deposits and the high cost of transportation limits foreign trade, mostly to local transactions across international boundaries. U.S. imports and exports are small, representing less than 1% of the domestic consumption.

Exports.—Exports of construction sand decreased 6.2% to 439,000 tons, while value increased 9.4% to \$13 million. Mexico was the major destination, receiving 41.9% of the total, followed by Canada with 37.1%. Exports of construction gravel declined 17.8% to 700,000 tons compared with those of 1989, and value declined 21.6% to \$6 million, again compared with that of 1989, because no information on exports of gravel was available for 1990. Canada was the major destination with 84.6% of

the total, followed by Mexico with 4.7%. (See table 8.)

Imports.—Imports of construction sand and gravel decreased 15.9% to 1.5 million tons compared with that of 1990, while the value decreased 27.4% to \$16.6 million. Canada was the major source of imported construction sand and gravel with 65.2% of the total, followed by the Bahamas with 18.4%. (See table 9.)

Current Research

Recognizing the need for research into properties and adequate use of aggregates, crushed stone, and sand and gravel, as well as the need for reliable technical information in this area, the National Aggregates Association and the National Stone Association established in 1990 the Aggregates Foundation for Technology, Research, and Education (AFTRE.) The main purpose of the Foundation is to establish and provide the funding for the Aggregates Research Center. The Foundation and the Research Center will support scientific research and education and develop and disseminate authoritative technical information related to construction aggregates. The comprehensive and objective information on construction aggregates developed by the Research Center will promote and extend the effective and efficient use of aggregates in the construction industries. At the 1992 CON/AGG Show held in New Orleans, LA, between February 1 through February 6, 1992, the Board of Trustees of AFTRE announced the selection of the University of Texas at Austin and the Texas A&M University at College Station as the home of the new Aggregates Research Center.

The year 1991 was the fourth year of the 5-year Strategic Highway Research Program (SHRP), a program created in 1987 by the U.S. Congress. SHRP's mission is to produce usable research results targeted toward technical areas where there is potential for improvement of our highways and the materials used to build them, research that could also yield significant cost savings. SHRP's

research activities account today for more than one-quarter of all highway research conducted in the United States by the Federal agencies, the States, and the private industry.

SHRP's four areas of research are asphalt, concrete and structures, highway operations, and long-term pavement performance. To improve the quality of pavements, better materials specifications and asphalt concrete mixture design systems based on a scientific understanding of how asphalt properties influence performance are needed. SHRP made significant progress toward that goal in 1991.⁵

Based on results obtained through the use of state-of-the-art chemical and physical analysis techniques, researchers supported by SHRP have developed a chemical model of asphalt structure that, for the first time, explains how asphalt chemistry affects binder performance. Analysis of samples of asphalt using nuclear magnetic resonance spectroscopy (NMR) indicated that the molecular structures in asphalt are very small, contrary to the long-accepted "micellar" model that had pictured asphalt as relatively large lumps of materials in a sticky gel. At the same time, chemical analysis using ion exchange chromatography indicated that the molecules that gave the asphalt most of its physical properties comprised only a small portion of the total number of asphalt molecules. Based on these results, a model was produced that describes asphalt as a polar dispersed fluid and reconciles asphalt's chemical features with its physical behavior.

SHRP's concrete program is developing new engineering guidelines and materials tests that will help highway engineers produce more durable concrete consistently. Alkali-Silica Reactivity (ASR) of concrete is a damaging and difficult-to-detect problem in highway structures and a major area of concern for the highway and bridge inspectors. SHRP's Construction Technology Laboratories developed a new quick chemical field test that uses uranyl acetate fluorescence to detect whether an ASR product has been formed in concrete.

SHRP's Handbook for the Identification of Alkali-Silica Reactivity in Highway Structures provides guidance on proper diagnosis and assessment of ASR problems.⁶

SHRP's Long-Term Pavement Performance (LTPP) program addresses the issue of how best to use and protect the very large investment made every year in building and maintaining highway pavements. SHRP's LTPP program, the largest and most comprehensive pavement performance test in history, is collecting data on pavement conditions, climate, traffic, and load conditions over a 20-year period. The LTPP experiments involve testing of almost 1,000 in-service sections of the most common types of pavement design in use in the United States, as well as sections that have been specially constructed to isolate certain factors in pavement design.

The American Association of State Highway and Transportation Officials, the Federal Highway Administration, and the National Research Council have agreed upon an approach to establish an oversight of continuing activities when some of SHRP's programs expire in 1992. The SHRP Monitoring and Research Transfer Committee will be created by the National Research Council that will include representatives from a broad spectrum of organizations, including strong State highway agency representation.

Technology

A bucket-wheel dredge of a new design that can operate at depths of up to 30 to 35 meters, (97 to 107 feet), replaced a plain suction dredge in the Netherlands. In addition to being able to dredge at significantly greater depths than its predecessor, the new dredge has also doubled its production and cut fuel consumption in half. The dredge throughput can reach 1,200 cubic meters/hour, (1,570 cubic yards) of slurry at densities of up to 1.7 (70% solids). The heart of the dredge is a 1.90-meter diameter bucket-wheel driven by a 75-kilowatt hydraulic motor at speeds of up to 25 revolutions per

minute. The buckets of the bucket-wheel are closely spaced and have no bottom or rear and are a part of the suction mouth. A 250-kilowatt submerged pump on the ladder lifts the excavated slurry to a 443-kilowatt on-board booster pump for transfer through a 350-millimeter-diameter floating pipeline to the processing plant. The dredge can be operated by only one person. The Series 1400 wheel dredge was manufactured by IHC Holland NV. A new dredge of the same basic design that will be able to excavate at even greater depths of up to 54 meters is presently under construction.⁷

Specialized computer services using high technology provide fast and accurate earthwork volume estimating that are being used to calculate production and stock inventories in aggregates operations. Computer generated cross sections of the pit or quarry at very close intervals are generated, and very accurate calculations of volumes are performed. Valuable three-dimensional depth maps and two-dimensional cross sections of the operations can be also produced that can assist the plant operators or the designers of new pits and quarries.⁸

More aggregates-producing companies are automating their operations to remain competitive. Automated weighing and information processing systems in the sand and gravel and crushed stone industries are usually one of the first areas to be automated, especially in medium- to small-size operations. A properly selected and implemented computer-based data collection, storage, retrieval, and reporting system provides the operations with fewer mistakes, reduced expenses, and more timely available information. A review of present technology, software and hardware, and recommendations on how to select and implement the proper system in aggregates operations was published by Pit & Quarry.⁹

Technologically, the aggregates industry is very complex and requires professionals with skills in a variety of areas, including geology and geophysical sciences, mining, materials, and geotechnical engineering and

management. For a long time there has been a need for a comprehensive reference book covering the construction aggregates that can be used by producers, consulting and design engineers, and users. The Aggregate Handbook published by the National Stone Association in 1991 is just such a publication. The handbook covers all aspects of the sand and gravel and crushed stone industries from basic properties of aggregates, geology, exploration, extraction, and processing, to uses, standards and specifications, sampling and testing, marketing, and regulatory compliance. Numerous references are also provided for those interested for more in-depth information.¹⁰

OUTLOOK

The demand for construction sand and gravel in 1992 is expected to be about 850 million tons, a 9% increase from that of 1991. Gradual increases in demand for construction aggregates are anticipated after 1992, based on increased volume of work on the infrastructure expected to occur following the passage of the Intermodal Surface Transportation and Infrastructure Act of 1991. The new law authorized \$151 billion to be spent in the next 6 years on transportation projects, of which \$119.5 billion was on highway work and \$32.5 billion was on mass transit. It is estimated that the demand for construction sand and gravel will reach 1 billion tons in 1995. The projected increases will be influenced by construction activity primarily in the public construction sector and to a lesser extent in the private sector.

The value of public construction work as part of the gross domestic product (GDP) has declined constantly, from about 3% in the 1950's and 60's to less than 2% in the 1980's. If this trend begins to reverse in the 1990's, a significant increase in spending for public construction work could be expected that will dramatically alter the aforementioned forecasts.

Construction sand and gravel f.o.b. prices are not expected to increase

significantly, even if the demand for construction aggregates will rise over the aforementioned forecasts. However, the delivered prices of construction sand and gravel are expected to increase, especially in and near metropolitan areas, mainly because more aggregates are transported from distant sources.

INDUSTRIAL SAND AND GRAVEL

By Wallace P. Bolen

Mr. Bolen, a physical scientist, has been the commodity specialist for industrial sand and gravel since October 1988. Domestic survey data were prepared by Christopher H. Lindsay, statistical assistant; and the international production table was prepared by Ronald Hatch, international data assistant.

Probably no other nonmetallic mineral has more diversified uses than silica (industrial) sand, mainly because of its common occurrence around the world and its distinctive physical characteristics, including hardness, resistance to high temperature and chemical action, and relatively low price. Silica sand is the major component of common glasses, foundry molding and cores, abrasive blast sand, and hydraulic fracturing sand. Industrial sand and gravel is also important in ceramics, chemicals, and fillers for rubber and plastics, and also is utilized in golf courses, as a flux in smelting and chemical production, as filter media, and in many other uses.

DOMESTIC DATA COVERAGE

Production of industrial sand and gravel in 1991 decreased to 25.6 million short tons, about 10% less than 1990's production. Production decreased for the second year in a row, to its lowest level since 25.3 million tons was produced in 1967. During 1991, the following silica markets saw decreases in consumption: glass containers, fiberglass, foundry sand, blast sand, chemicals, and hydraulic fracturing sand (frac sand).

Exports of silica sand and gravel increased about 42% in quantity, but the average value per ton, compared with that of 1990, decreased 10%. Imports of industrial sand and gravel increased about 25% in quantity, but the associated value decreased 70%. Domestic apparent consumption of industrial sand and gravel in 1991 was 24.1 million short tons, a decrease of almost 12% compared with that of 1990.

Domestic production data for industrial sand and gravel were developed by the U.S. Bureau of Mines from voluntary surveys of U.S. producers. Of the 152 industrial sand and gravel operations surveyed, 119 (78%) reported to the U.S. Bureau of Mines. Their combined production represented about 86% of the U.S. total published in table 1. The production of nonrespondents was estimated mostly using employment data. Of the 152 operations, 148 (97%) were active and 4 idle. (See table 1.)

BACKGROUND

One of the first industries to use silica sand was the glass industry. At least 4,000 years ago, long before iron was smelted, glassmaking was already a known craft. Although the place and date of the first manufactured glass are not known, the oldest known specimens of glass are from Babylon (ca. 2600 B.C.) and from Egypt (ca. 2500 B.C.), where the industry was well established by about 1500 B.C. Many varieties of glass were known during Roman times. Little is known of the glassmaking methods used in Europe from the fall of Rome until the 10th century, when stained glass was produced in Venice. After this, Venice remained the leader in fine glassware for the next four or five centuries. In the 17th century, a process for casting glass was invented in France, and later, England began to make flint glass, marking the beginning of modern glass technology.

Glassmaking was apparently the first industry to be transplanted from Europe to North America, first to Mexico and

later to the British colonies. The first manufacturing establishment in what is now the United States was a glass factory at Jamestown, VA, built in 1608. The 1885 edition of "Mineral Resources of the United States," the predecessor of today's U.S. Bureau of Mines "Minerals Yearbook," reported a total of 317,000 tons of silica sand produced in 1884 in the United States, under "Glass Materials." In 1991, a total of 25.6 million tons of silica sand was produced in the United States for a variety of uses, of which 11.2 million tons was for glassmaking. Today, glass has become an invaluable product with a multitude of forms and applications.

Metals casting was probably the second industry that used silica sand. Today, the casting industry provides vital components for most modern manufacturing industries. The number of industries using silica sand is growing constantly, as are the products made by using silica sand.

Definitions, Grades, and Specifications

Sand is defined throughout the industry and by the American Society for Testing and Materials (ASTM) as granular rock particles that pass through a No. 4 mesh (0.187-inch) U.S. standard sieve, are retained on a No. 200 mesh (0.0029-inch) sieve, and are the result of natural disintegration or comminution of cemented rock. Industrial sand or silica sand is the term used by the industry for sands that have a very high percentage of silicon dioxide (SiO₂) and are essential materials in glass manufacture, in ferrous and nonferrous foundry operations, in

certain chemical and metallurgical processes, for hydraulic fracturing of oil and gas deposits, and in many manufactured products as fillers or extenders.

Most industrial sands have been named for their specific uses; for example, glass, foundry, abrasive, filler, and hydraulic fracturing sands. Almost invariably, these sands, in addition to being high in silica, consist mostly of quartz grains.

Products for Trade and Industry

Silica sand had a wide range of uses in a significant number of industries, the most important being glass and foundry. Other uses were metallurgical and as abrasives, as fillers, for filtration, and for hydraulic fracturing of rock formations to improve recovery in oil wells.

Glass sand was used as a main constituent for manufacturing glass containers, flat glass, safety glass, pressed and blown glass, fiberglass, and a wide variety of specialty glasses such as optical glass and industrial glass.

Glass sand had to meet rigid specifications with respect to purity and silica content, depending on the kind of glass being manufactured. Only a very small amount of iron oxide and chromium compounds could be tolerated, and a high percentage of aluminum, calcium, or magnesium oxides was undesirable. The standards of the American Ceramic Society for glass sand indicated that all grains should pass through a No. 20 mesh screen, between 40% and 60% should be retained on a No. 60 screen, between 10% and 20% on a No. 80 screen, and not more than 5% should pass a No. 100 screen. Sand for first-quality optical glass should contain 99.8% SiO₂ and a maximum of 0.1% aluminum oxide (Al₂O₃) and 0.02% iron oxide (Fe₂O₃). Third-quality flint glass could contain only 95% SiO₂ and as high as 4% Al₂O₃. Only in the low-quality amber glass was the content of Fe₂O₃ permitted to reach 1%.

Most glass manufacturers established their own specifications for the physical size and chemical purity of the raw

materials that have to be met by the suppliers of glass sand. Recently, glass manufacturers showed an increased interest in finer glass sands because processing of smaller particles required lower temperatures and, therefore, reduced the consumption of energy.

Foundry sands included molding sand and core sand that were used for casting iron-, aluminum-, and copper-base alloys. Required properties included cohesiveness sufficient to hold together the mold or core when moist, which is achieved by a bonding agent; refractoriness to withstand the high temperature of the molten metal; strength to resist the weight of the metal; permeability to release vapors and gases generated during cooling of the metal; and proper texture and composition to produce a smooth casting that will not react with the metal. Most metals were cast in "green sand," which is a mixture of silica and clay, although to a lesser extent, resins or oils were also used as a bonding agent instead of clays. In the case of naturally bonded foundry sands, the amount of clay minerals present affected their usefulness. Standard tests and specifications for foundry sands were published by the American Foundrymen's Society.¹

Refractory sands were used in the manufacture of silica brick and tile, quartzite (gannister) being the commonly used raw material. Required properties were "the capability of maintaining the desired degree of chemical and physical identity at high temperatures" and resistance to abrasion, impact, thermal shock, and high level of load. Refractory silica materials were classified based on their general composition and on their distinctive properties. Standard classifications and specifications for silica refractory brick were published by the ASTM.²

Quartz sands, on the Knoop scale at 820, are quite hard and are one of the oldest abrasives known. Abrasive sands were quartz sands used in stone sawing, glass grinding, metal polishing, and sand blasting. No rigid specifications existed for these sands, but sound, clean, hard, and closely sized sand grains were required. Purity and grain-shape

specifications varied with the type of abrasive action and the requirements of the final product. An angular particle shape with sharp cutting edges was generally required.

Hydraulic fracturing sand was pumped into oil or natural gas wells as a sand-liquid mixture to break up petroleum-bearing formations and act as a propping agent, allowing oil or gas to move more freely toward the producing wells. Some of the major requirements for fracturing sands were spherical, well-rounded grains of clean, dried, and well-screened quartz sand, free of any materials such as feldspar, calcite, and clay. The most common size was 20/40 mesh; other sizes included 6/12, 8/16, 12/20, 40/70, and 70/140, but these sands represented only about 15% of the total sand used as proppant. "Recommended Practices for Testing Sand Used in Hydraulic Fracturing Operations," published by the American Petroleum Institute, was used as a guide by industry.³

Ground sand or silica flour has found wide industrial application as a filler in paint, plastics, rubber, ceramics, and a variety of other products. Mainly because of the diversity of its uses, no standard specifications exist for the silica flour used in most of these applications except grain size and chemical composition.

Silicon carbide, which was used as an abrasive, for refractory uses, and in specialty ceramics, was produced by the reaction of silica sand (60%) and coke (40%) at elevated temperatures up to 2,400° C.

Metallurgical sand was used as a fluxing agent for basic oxides in various smelting operations and as a source of silicon in ferrosilicon manufacture. The ferrosilicon was a steel alloying additive. Filter sand was used extensively in filtering water for municipal and industrial use and swimming pools and in sewage treatment plants. Engine sand was used in locomotive haulage to improve traction. Other sands were used in special cements, in manufacturing silica brick and tiles for furnace linings and beds, for coal washing, and in manufacturing pottery. Industrial sand

was also used for chemical production, golf courses (both in traps and in green construction), and building products. Industrial gravel was used as the source material in the production of silicon and ferrosilicon and as a flux for the production of copper, nickel, and elemental phosphorus. Some gravel was also used as filtration media, mainly in municipal water treatment facilities.

Industry Structure

In 1991, 77 U.S. companies with 148 active operations produced silica sand and gravel. The individual industrial sand and gravel operations ranged in size from those producing about 1 million tons annually to those reporting less than 10,000 tons per year. Most of the production came from large operations that were mostly owned or operated by a small number of companies. In the past 10 to 15 years, there was a gradual trend toward larger operations, mostly because small plants were becoming less economical. The viability of small operations was dependent on demand in local markets, mining conditions, and the degree of processing required to supply the final product.

During the past 10 years, changes within the structure of the industrial sand industry occurred, primarily caused by mergers and acquisitions, some resulting from an influx of foreign capital, mostly from Europe.

Geology-Resources

U.S. resources of industrial sand and gravel were expected to be sufficient to meet domestic demand in the foreseeable future, although their geographic distribution and quality often did not match market requirements. The availability of these reserves was controlled to a significant degree by land use and/or environmental constraints. Reserves of industrial sand and gravel owned or controlled by domestic producers were estimated to total about 3 to 4 billion tons.

Although silica reserve data for the rest of the world were not available, it

could be assumed, on the basis of geologic evidence, that world reserves were sufficient to meet demand, even if not always at the locations where needed.

Industrial sand or silica sand was produced in the United States from a variety of geological formations ranging in age from late Precambrian to mid-Tertiary. About 70 stratigraphic units were known as having an economic potential for this industry. Lithologically, these deposits ranged from quartzites, sandstones with different degrees of cementation, quartz conglomerates, chert deposits, and quartz pegmatites to terrace sands and gravels, and dune sands. Most of the high-quality industrial sand was produced from a few geological formations in the Eastern United States. Oriskany sandstone, or more precisely the Ridgeley formation of Early Devonian age, was one important source of silica sand. It extended from New York State to southern Virginia and eastern Ohio, but was being mined only in central Pennsylvania, northwestern Maryland, and northern West Virginia, where the formation was thick enough to be of commercial value. It was a hard, white orthoquartzite with medium to fine, angular and subangular, and well-sorted grains. The St. Peter sandstone of Middle Ordovician age, extending from Wisconsin and Minnesota through Iowa, Illinois, and east-central Missouri, was another major source of industrial sand. The best known center of production of silica sand from this formation was the Ottawa district of La Salle County, IL, where it was known as "Ottawa sand," and to a lesser degree in southern Wisconsin and east-central Missouri. It was a soft and poorly cemented high-purity orthoquartzite with coarse, rounded grains. The weak cement holding the silica grains together was mostly a light-colored clay.

In addition to the two formations just mentioned, the most important sources of industrial sand in the United States, numerous other deposits were also being mined for silica sand in different parts of the country. Included are the Jordan sandstone of Upper Cambrian age in Minnesota and Wisconsin, a primary

source of hydraulic fracturing sand; the Raritan formation of Upper Cretaceous age in central New Jersey and the Cohansey sand of probable Miocene age in southern New Jersey; and the Tuscarora quartzite of Lower Silurian age in Pennsylvania and Virginia used for the manufacture of refractory bricks. Other deposits are the Sylvania sandstone of Devonian age in the Detroit area; the Oil Creek and McLish formations of Lower Ordovician age in Oklahoma, a southwestward extension of the St. Peter sandstone; and the Hickory sandstone of Cambrian age in central Texas that produced mostly hydraulic fracturing sand.

In the West, the most important sources of industrial sand were the Ione formation of Eocene age in northern California, the Silverado (Paleocene) and Tejon (Eocene) formations in southern California, and the Eureka quartzite of Middle Ordovician age in central California.

Approximately two-thirds of the U.S. industrial sand and gravel was produced east of the Mississippi River, especially in the industrialized areas of the East North Central, South Atlantic, and Middle Atlantic regions. Of the top five producing States that accounted for about 45% of 1991 production, three—Illinois, Michigan, and New Jersey—were in the East and the other two—California and Texas—were in the West. The concentration of the industrial sand operations in the eastern part of the United States resulted from the existence of high-quality geologic deposits close to the major consuming industries, glass and foundry. In the south and west, demand from the oil and gas industry in the Louisiana, Oklahoma, and Texas area has sustained the growth of industrial sand operations in Texas. California production remained large owing to demands from local industry, particularly the glass container industry, and the distance of California from the traditional production areas in the Midwest.

Technology

Exploration.—A large number of geologic formations with economic potential as a source of industrial sand have been mapped and described in the literature over many years and were, therefore, well known. Consequently, detailed exploration and development work for new industrial sand operations was expected to occur on some of these formations. The qualities of a silica deposit necessary for a viable operation should include proper particle size, chemical composition, degree of cementation, and deposit uniformity. Also, the nature and amount of waste material and the economic feasibility of its removal and possible use or disposal should be studied. The evaluation of the new deposit should also include an environmental impact study as required by most local or State agencies before authorizing a new mining operation.

If the raw material should prove to meet the requirements and adequate reserves are demonstrated, the development stage of the operation could be started. Economic feasibility and marketing studies should be performed by analyzing all factors important for any such mining operations. Included are the availability of power and water supply, mining and processing costs and requirements, and the condition of nearby roads and highways. Other factors include the proximity of rail haulage; the cost of compliance with local, State, and Federal regulations; and the proximity and density of local population as well as its attitude toward such a project.

Mining.—Most industrial sand was mined from open quarries, but a few underground operations existed, mostly because of an exceptionally thick overburden or environmental limitations. Surface mining methods and equipment varied with the type of the geologic formation, size and configuration of the deposit, production capacity, estimated life of the operation, and location of the deposit with respect to urban centers. The mining methods depended primarily

on the degree of cementation of the rock, although most open pit mining operations included site clearing and removal of the overburden; mining of the silica rock or sand; processing of the material, including crushing, screening, and classification; and reclamation of the extraction area. Unconsolidated sands, such as the Cohansey of New Jersey, below the ground water level were dredged. Much of the St. Peter sandstone was first loosened by light blasting and then washed down by hydraulic jets or "monitors" into sumps, from which it was pumped to the processing plants. Harder rock such as the Oriskany sandstone required blasting and primary and secondary crushing before it could be processed.

Processing.—Processing of mined silica sand required specialized operations that varied considerably with the nature of the deposit and the physical and chemical requirements of the desired product. Depending on the degree of cementation, several stages of crushing were necessary to achieve the desired size reduction. Gyratory crushers, jaw crushers, impact mills, or roll crushers were used as primary or secondary crushers, and smooth rolls, media mills, autogenous mills, high-speed hammer mills, or fluid energy jet mills were used for grinding the product down to 50 microns and finer. Dry or wet screening was used to separate particles of sizes down to about 150 microns, and wet or air classifiers processed particles from 250 microns into the submicron range. Vibratory screens and gyratory screens, in addition to mechanical, hydraulic, or air classifiers, were used, depending on the size distribution required.

Research for the silica mining industry related not only to new methods that increased output and reduced production costs but also to health and safety problems as well as exploration, land management, and reclamation. Equipment manufacturers and some Government agencies were constantly working on improving exploration, mining, and processing plant technology.

Significant technological developments instrumental in maintaining adequate production at relatively stable real costs were mostly in the processing plant technology. The use of computerized systems in plant operation and quality control increased; this, along with improved mining and processing equipment, permitted the recovery of salable fractions that were previously considered uneconomical.

Recycling.—Recycling of silica sands was limited to some foundry sands, particularly those used for making cores and molds with no-bake resin-bonded sands, some abrasive and airblasting sands, and, increasingly, post consumer glass and scrap glass that substitutes for glass sand. Most glass recycling was restricted to container glass, with green and amber being consumed at a higher rate than flint because it was more difficult to use in the batch mix. As the level of glass used increases, so does the level of quality required. Contamination of cullet by ceramics and nonmagnetic materials was an increasing concern. International trends toward increased recycling of glass and foundries sands and innovative ideas on recycling other materials should influence greater recycling of silica products.

Byproducts and Coproducts

Small amounts of gold and silver were recovered occasionally as a byproduct or coproduct from some unconsolidated silica sand deposits. Also, during the processing of some silica resources, other minerals, including clays, feldspars, mica, and quartz crystals, were produced as byproducts and coproducts.

Economic Factors

Silica sand deposits are nonrenewable resources. New mining methods combined with advances in mineral processing that were introduced during the past decade have increased the number of silica deposits that can be commercially developed.

The industrial sand industry was very competitive, largely because silica sand is a relatively abundant mineral, with supply usually exceeding demand. The delivered price of the product, in addition to quality, was a very important element in any major transaction. The producer with an operation closest to the market had a significant advantage over competitors. Combining sophisticated (and therefore expensive) processing equipment backed by technical knowledge and solid sales expertise was important. For this reason, only a small number of large companies were able to compete successfully and succeed in the silica sand business and supply a wide variety of products. Smaller, less efficient operations became uneconomical as operating costs, as well as costs associated with meeting various Federal, State, and local regulations, continued to increase. The only alternatives they had were to either limit the range of products they supplied to close markets or go out of business.

Prices.—As a result of rapidly rising costs of labor, energy, and mining and processing equipment, 1991 constant dollar prices of industrial sand rose steadily between 1973 to 1983. From 1985 to 1991, 1991 constant dollar prices fluctuated in the 15.25 to 16.25 range owing to decreased demand and tight competition in some markets. Prices should be expected to continue to fluctuate, although they should slowly rise as a result of the cost of compliance with more stringent environmental, land use, and safety regulations.

Costs.—Production costs for silica sand were determined to a large extent by the cost of labor, equipment, energy supply, water availability, and the additional burden of compliance with environmental and safety regulations. Production costs varied widely depending on the nature of the geologic deposit, the geographic location, and the type and number of products produced. Profits were relatively small for most producers, total

production costs being close to the f.o.b. selling price per ton.

Tariffs.—There has been no tariff on imported silica sand containing 95% or more SiO₂ and not more than 0.6% iron oxide from most favored nations since January 1, 1987. For all other countries, the tariff for imported silica sand remains \$1.94 per long ton.

Depletion Provisions.—The depletion allowance for industrial sand and gravel was 14%.

Operating Factors

Environmental Requirements.—Major environmental considerations that had to be dealt with in mining and processing of industrial sand and gravel were emission of particulate matter into the air, discharge of processing water, and noise abatement. Air pollution constituted a major problem in the processing plants, especially in the drying and packaging stages of finer products such as silica flour, silicosis being the major disease that can be contracted as a result of long-term exposure to silica dust. Because of the high cost of compliance with the environmental regulations designed to reduce this health hazard and possible long-term liabilities associated with it, some companies were no longer producing silica flour or did not plan to produce it in the future. Both wet and dry methods of dust control were used. The most important water pollutant was clay in suspension as a result of washing and screening silica sand. Because of the large quantities of water used to process silica sands and the need of compliance with stringent regulations, the treatment of discharge water by the sand producer was expected to require increasingly sophisticated and expensive processing methods. Significant progress was made in reducing noise pollution, both inside and outside of the operations, including noise and vibration produced by blasting and movement of heavy trucks.

Sand producers had to obtain mining permits from the appropriate

governmental agency, which sometimes also required an Environmental Impact Statement (EIS) and a reclamation plan that met its guidelines or regulations. More and more emphasis was being put by local communities on improving the overall appearance of the operating mines as well as on land reclamation after mining was completed. At the same time, industry and the communities had to recognize the time and costs required to protect the environment and the importance of agreeing on fair and realistic environmental standards. Many States, counties, and towns had zoning laws that regulated land use.

Most of the active silica sand quarries as well as the known deposits were on private land, which was either owned or leased on a long-term basis by the producers. These deposits contained high-quality silica sand and were in the best locations with respect to markets. Unlike the construction sand and gravel industry, the industrial sand industry was usually not significantly affected by increasing land values near populated areas.

Transportation.—Transportation costs for silica sand were often equal or considerably greater than the cost of the product at the processing plant. Because of the large variety and number of consumers of silica sand, long distance haulage was not uncommon. In 1991, the largest tonnage, 56% of all industrial sand, was shipped by truck because most users require a versatile and rapid delivery system. Substantial quantities, 40% of the total, were also shipped by rail, especially when large volumes were sent long distances. The remaining tonnage was shipped by barge or used at the mine.

ANNUAL REVIEW

Production

The Midwest (East and West North Central regions) continued to lead the Nation in production, with about 42% of the 25.6 million tons produced in the United States, followed by the South

(South Atlantic, East and West South Central regions) with about 36% and the West (Pacific and Mountain regions) with 14%. (See table 2 and figure 1.)

Based on the 1990 census estimations on population, 1991 U.S. per capita industrial sand and gravel production was 0.10 ton. Per capita production by major geographic region was 0.18 ton in the Midwest, 0.11 ton in the South, 0.07 ton in the West, and 0.05 ton in the Northeast.

The five leading States in the production of industrial sand and gravel, in descending order of volume, were Illinois, California, Michigan, New Jersey, and Texas. Their combined production represented 45% of the national total. Significant changes within the five major producing States included Texas, where production decreased almost 16%, and California, where production decreased by more than 14%. Production decreased in almost every State except in a few instances where production rose by a small percentage. (See tables 3, 4, and 5.)

The U.S. Bureau of Mines canvassed 77 producers of industrial sand and gravel with 148 active operations. About 74% of the industrial sand and gravel was produced by 44 operations, each with an annual production of more than 200,000 tons. The 10 leading producers of industrial sand and gravel were, in descending order of tonnage, Unimin Corp., U.S. Silica Co., Fairmount Minerals Ltd., The Morie Co. Inc., Oglebay Norton Co., Badger Mining Corp., Simplot Industries Inc., Construction Aggregates Corp., Owens-Illinois Inc., and WHIBCO Inc. Their combined production, from 63 operations, represented 72% of the U.S. total.

Consolidation of silica companies continued in 1991 as Fairmount Minerals acquired some of Manley Brothers of Indiana's operations from Hepworth Minerals and Chemicals Ltd. of the United Kingdom. The remaining Manley Brothers operation, in Illinois, was taken over by the management, which planned to maintain the Manley Brothers of Indiana name. The Securities Exchange

Commission (SEC) ruled that Fairmount Minerals would not be allowed to purchase the entire Manley operation. The SEC determined the planned takeover was anticompetitive because of the change in market share distribution. With this purchase, Fairmount Minerals strengthens its hold as the third largest producer of industrial sand and gravel in the United States. Fairmount takes over mines and mills in two locations in Michigan as well as some other Manley facilities.

Spruce Pine Sand and Gravel, Franklin County, AL, discontinued sales of industrial gravel owing to the closure of elemental phosphorus plants at Olin and Occidental Chemicals' plants in Tennessee. Other producers also saw halts or decreases in gravel sales for elemental phosphorus production.

Ideal Basic Industries Inc. sold its Hempstead County, AR, operation to Holnam, Inc., a subsidiary of Financiere Glaris Ltd.

Salt Lake Valley Sand and Gravel temporarily shut down its facility for the production of abrasive blast sand.

Feldspar Corp. sold its ultrahigh-purity silica plant at Spruce Pine, NC, to Unimin Corp. Unimin is now the sole U.S. producer of ultrahigh-purity silica (less than 30 parts per million total impurities).

Consumption and Uses

Sand and gravel production reported by producers to the U.S. Bureau of Mines was actually material used by the companies or sold to their customers. Stockpiled material was not reported until consumed or sold.

Of the 25.6 million tons of industrial sand and gravel sold or used, 44% was consumed as glassmaking sand and 22% as foundry sand. Other important uses were abrasive sand (7%) and frac sand (5%). Because some producers did not report a breakdown by end use, their total production as well as the estimated production for nonrespondents were included in "Other uses, unspecified," which represented about 4% of the U.S. total.

On the regional level, more than one-third of the glassmaking sand was

produced in the South (40%), followed by the Midwest (30%) and the West (17%). Three-fourths of the foundry sand was produced in the Midwest (74%). About three-fourths of the hydraulic fracturing sand was produced in the Midwest (73%), and the majority of the abrasive sand was produced in the South (65%). (See table 6 and figure 2.)

Northeast.—Cumberland County, NJ, continued to be the largest source for the glass and foundry sand markets in the region. Unimin, U.S. Silica, Morie, and WHIBCO Inc., all of which operated plants in the county, were among the largest producers of sand for these markets. U.S. Silica's plant in Huntingdon County, PA, also produced significant amounts of sand for the glass market. Morie's plant in Cumberland County and New Jersey Pulverizing Co.'s plant in Ocean County, NJ, produced a major percentage of the abrasive blast sand in the region.

Midwest.—Unimin's plants in LaSalle and Ogle Counties, IL; LeSueur and Scott Counties, MN; and Columbia County, WI, were among the leaders in producing sand for the glass, foundry, and frac sand markets. Fairmount Minerals, with operations in Berrien and Van Buren Counties, MI; Geauga County, OH; and La Salle County, IL, was a major producer of sand for the blast, foundry, frac, and glass sand markets in the region. U.S. Silica's plant in La Salle County, IL, and Badger Mining's plant in Jackson County, WI, were large producers for the glass and frac sand markets, respectively. Construction Aggregates Corp. in Ottawa County, MI, and U.S. Silica in LaSalle County, IL, were major producers of foundry sand in the region. Nugent Sand Co. Inc., in Muskegon County, MI, Badger Mining in Green Lake County, WI, and Sargent Sand Co. in Wexford County, MI, were also large producers for the foundry industry.

South.—Unimin and U.S. Silica Co. were two of the largest producers of sand

for the glass and foundry markets. Unimin's major plants were in Frederick County, VA; Richmond County, NC; Pontotoc County, OK; and Izard County, AR. U.S. Silica's Bullock County, AL; Morgan County, WV; Johnston County, OK, and Limestone County, TX, operations were the major contributors for these markets. Morie's Tuscaloosa County, AL, and Marion County, GA, plants were large producers of blast, foundry, and glass sand. Huey Stockstill Inc., Pearl River County, MS, Mid-State Sand and Gravel Co., Baywood and Baggett Parishes, LA, Pioneer Concrete of Texas Inc., Colorado and Liberty Counties, TX, Oglebay Norton's Texas Mining Co., McCulloch County, TX, and Specialty Sand Co., Colorado, Harris, and Newton Counties, TX, were large producers of blasting sand. W.R. Bonsal and Co., Anson County, NC, produced a large percentage of the industrial gravel used in the production of silicon and ferrosilicon. Oglebay Norton's Texas Mining Co. and Vulcan Materials Co., both in McCulloch County, TX, were the largest producers of frac sand in the region.

West.—Corona Industrial Sand Co., Owens-Illinois, Simplot Industries, and Unimin were the four largest producers of glass sand in the region, with major operations in Riverside County, CA, Amador County, CA, Clark County, NV, and Contra Costa County, CA, respectively. Lane Mountain Silica, Stevens County, WA, and Lone Star Industries Inc., Monterey County, CA, were the major suppliers for the sand blasting industry in the region. Simplot Industries also supplied a large portion of the foundry sand consumed.

Transportation

Of the total industrial sand and gravel produced, 56% was transported by truck from the plant to the site of first sale or use, unchanged from that of 1990; 40% was transported by rail, also unchanged from that of 1990; 3% by waterway; and only 1% was not transported. Because most of the producers did not report

shipping distances or cost per ton per mile, no transportation cost data were available. (See table 7.)

Prices

Compared with that of 1990, the average value, f.o.b. plant, of U.S. industrial sand and gravel decreased slightly to \$15.25 per ton. Average unit values for industrial sand and industrial gravel were \$15.39 and \$12.18 per ton, respectively. Nationally, industrial sand used as fillers for rubber, paint, and putty, etc., had the highest value per ton (\$69.77), followed by silica flour, (\$36.50), silica sand used in ceramics (\$36.28), fiberglass (ground) (\$35.70), scouring cleansers (\$29.84), and frac sand (\$27.10).

Unit values for different uses of industrial sand and gravel generally changed little from 1990 to 1991 even though total tonnage sold and used changed substantially. Despite the decreased sales for most uses, some uses underwent an increase in average value. These included sand for flat and specialty glasses, ground sand for fiberglass, foundry, filtration, frac, and sand used in roofing granules and fillers.

The average value per ton of industrial sand and gravel was highest in the West (\$17.68), followed by the Northeast (\$15.55), the South (\$15.51), and the Midwest (\$14.15). Glass sand average value per ton varied markedly, from \$17.27 in the West to \$9.74 in the Midwest. Tighter supplies and higher production costs in the West increased the cost of sand and gravel in this region.

Foreign Trade

Exports.—Exports of industrial sand, compared with those of 1990, increased 42% to 1,637,000 tons, and the value increased 27% to \$106.7 million. Of this, 73% went to Canada, 13% went to Mexico, 3% went to Japan, and the remainder went to numerous other countries throughout the world.

Imports.—Compared with those of 1990, imports for consumption of industrial sand increased 25% to 91,000 tons valued at \$932,000. More than 98% of this was lower value silica from the Federal Republic of Germany. Small amounts of specially prepared silica sand from Australia, Belgium, Canada, France, Italy, Japan, Mexico, Sweden, Switzerland, and the United Kingdom sold for very high values per ton. (See tables 8 and 9.)

World Review

World production of industrial sand and gravel, based on information usually provided by foreign Governments, was estimated to be 121.7 million short tons, a decrease of 6% from that of 1990. The Netherlands was the leading producer, followed by, in descending order, the United States, Argentina, the Federal Republic of Germany, and Japan. Most countries in the world had some production and consumption of industrial sand and gravel because of its basic uses in glass and foundries. However, because of variation in descriptions and usage for silica sand and gravel, it was difficult to get reliable information. Beyond those countries listed, many other countries were believed to have had some type of silica production and consumption. (See table 10.)

Current Research

Advances continued through 1991 into research involving glasses, glass fibers, silicon carbide, silicon nitride, silica fabrics, and fiber optics.

Corning Inc. reported that global demand for optical fiber expanded by 30% during 1990. Corning continued R&D in fiber-optic components that split, combine, or vary the intensity of optical signals. Corning urged Congress to remove barriers to competition that are inhibiting deployment of optical fiber to schools, homes, and hospitals as well as business.⁴

A new development involving rare-earth fluoride glasses found that

lanthanide-doped fluoride fibers have a unique guiding configuration that allows the materials to be used as optical amplifiers and fiber lasers.⁵

Researchers reported a breakthrough in optical signal amplification that could slash the cost of future fiber-optic systems. The new amplifiers use special fluoride glass fibers treated with rare-earth praseodymium and boosted signal strength more than 1,000 times.⁶

A leaching process reportedly converts knitted and woven glass fabrics to silica, increasing the fabrics maximum operating temperature. The temperature-resistant fabrics are used for high-temperature insulation, welding protection, and metal filtration.⁷

Toyota Motors continues research into lightweighting to improve mileage and reduce air and noise pollution. Steel was replaced in seats by fiberglass springs, which improved passenger comfort while cutting the weight of the vehicles.⁸

A particulate silicon carbide metal matrix composite was used in the manufacture of a bicycle frame. The tubing used in the frame has a specific strength and stiffness higher than any other metallic frame material.⁹

Kyocera of Japan announced a new ceramic engine parts pilot plant to be built in Vancouver, WA. A spokesman said that the company would focus on components made from sintered silicon nitride ceramic. The material, compared to alumina ceramics, was claimed to be much less susceptible to thermal shock and able to maintain its strength at higher temperatures.¹⁰

Chemists at the University of California at Berkeley have blended polymers and glass at near-molecular level. The result, they say, was a composite one-half the weight of glass, but far stronger and nearly indistinguishable in clarity and resistance to scratches and corrosion.¹¹

The construction industry is taking its first tentative steps toward what may one day be the widespread use of recycled, crushed, mixed-color glass as an aggregate fill around subsoil culverts, pipes, and drains. Increased use of

recycled glass in this manner would increase use of virgin silica sand.¹²

In health-related matters, 3M Corp. announced a new respirator, 8825, which is believed to be the first dust, mist, and metal fume respirator to meet the requirements of TM14 Part 9.1, FFP2 Solid and Liquid. 3M stressed function and comfort in the design of this respirator, which is said to offer protection that exceeds exposure limits in most countries.¹³

In a related area, the U.S. Bureau of Mines recently carried out two studies that evaluated workers' dust exposures in automated-pallet-loading processes. The first study involved a dust control system using a push-pull ventilation technique that reduced dust exposure 76%. The second study evaluated different commercial automated-pallet-loading systems. A review was published in Mining Engineering Magazine.¹⁴

OUTLOOK

Demand

The forecast range of total U.S. demand in the year 2000 was expected to be 28 to 39 million short tons for industrial sand and gravel. Probable demand was expected to be about 34 million tons, which corresponded with an average annual growth rate of 3.4%. All forecasts were based on previous performances for this commodity within various end uses and contingency factors considered relevant to the future of the commodity. (See tables 11, 12, and 13.)

Glass Sand

Since 1987, annual demand for glass sand had fluctuated between 11.1 and 12.3 million tons. Sand consumed for container glass has decreased since 1987 mainly because some glass containers were being replaced by aluminum cans and plastic containers and also because the amount of glass being recycled was increasing. Additionally, many manufacturers of container glass were using thinner walls in glass containers, and this process had cut down the amount

of sand used. Also, a new thinner and lighter safety glass was used in automobiles, and its use was growing. As a result of these contingency factors, demand for glass sand was expected to grow slowly until the year 2000. Probable demand for glass sand for the year 2000 was forecast to be 13 million tons, with a range of 12 to 15 million tons. The probable forecast indicated an annual growth rate of 1.8%.

Foundry Sand

The probable forecast for foundry sand was expected to be 8.5 million tons, and the range was expected to be 7 to 10 million tons. The probable forecast indicated an average annual growth rate of 5.4%. The use of foundry sand was seen to be dependent mainly on automobile production. Recently, many foreign automakers have opened plants in the United States, and this should support growth in sales of foundry sand as a greater percentage of cars sold in the United States will also be made in this country.

Hydraulic Fracturing Sand

This end use declined greatly in 1991, sinking to less than 1.4 million tons. Although the amount of hydraulic fracturing sand used in each oil and gas well increased, drilling activity decreased. This occurred because of lower than hoped for prices for oil and gas attributed to the stabilization of world oil markets after the Gulf War. However, demand was expected to grow for this end use during the decade, partially due to increased exports of frac sand. Probable demand for hydraulic fracturing sand for the year 2000 was expected to be 2.3 million tons, with a range of 1.7 to 2.7 million tons. The probable forecast indicated an annual growth rate of 4%.

Adequacy of Supply

Domestic production was expected to continue to meet more than 99% of demand through the year 2000. Imports,

mostly from Australia and Canada, were expected to remain minor.

The United States was the second largest producer and consumer of silica sand among the market economy countries and was self-sufficient in this commodity. Most of it was produced in the eastern part of the United States, where the largest deposits and major markets are. A significant amount of silica sand was also produced in the West and Southwest, mostly in California and Texas.

Because the unit price of silica sand was relatively low, except for a few end uses that required a high degree of processing, the location of silica sand deposits in relation to the market was an important factor that may work for or against a sand producer. Consequently, a significant number of relatively small operations supplied local markets with a limited number of products.

The constant-dollar price of domestic silica sand had fluctuated since 1983 and was expected to continue fluctuating because of strong competition among producers for retention of dwindling markets.

Possible Supply-Demand Changes

Several factors could affect supply-demand relationships for silica sand. Further increases in the development of substitute materials for glass and cast metals could reduce demand for glass sand and foundry sand but would increase demand for silica flour, which is used as a filler in plastics, and for glass fibers, which are used in reinforced plastics. Also, increased efforts to reduce waste and increase recycling could hinder glass sand demand. However, with advances in high-technology materials, silica sand may see increased consumption for ceramics, fiber optics, and other silicon and glass compounds. Although developments could cause demand for silica sand to decrease, the total value of production could increase because of the increased unit value of the new specialized sands.

An increase in the price of oil on the international market would stimulate

domestic drilling and extraction from new and old oil deposits. This would increase demand for domestic hydraulic fracturing sand.

Concern over the use of silica as an abrasive due to health concerns and the imposition of stricter legislative and regulatory measures concerning silica exposure could decrease demands in many silica markets. Silica sand for use in the abrasive blast industry was being attacked as a health hazard as marketers of competing materials, including garnet, slags, and olivine, pushed the use of their "safer" abrasive medium.

Development of more efficient mining and processing methods are expected to continue. This will enhance development of lower grade silica sand deposits closer to markets but not presently mined. Such developments are expected to increase silica sand reserves.

SELENIUM AND TELLURIUM

By Daniel Edelstein

Mr. Edelstein is a physical scientist (geologist) with more than 17 years of combined experience working for the U.S. Bureau of Mines in minerals processing research, process evaluation, and mineral commodities. He has been a commodity specialist for selenium, tellurium, and copper for 9 years.

Domestic demand for selenium declined slightly in 1991. Though domestic production also declined, shipments by domestic producers increased and inventories, which had risen in 1990, declined, resuming the downward trend of the past decade. However, world supply and demand for selenium were nearly in balance, and selenium prices remained remarkably stable throughout the year, with apparently little speculative interest expressed by the market. Environmental concern over high-selenium agricultural drainage water and cadmium sulfoselenide pigments continued.

Following several years of decline, U.S. production, shipments, and consumption of tellurium appeared to stabilize. Imports continued to decline from the high 1988 level.

DOMESTIC DATA COVERAGE

Domestic data for selenium and tellurium are developed from a voluntary survey of the stocks, production, and shipments at the three known domestic producers of selenium and one producer of tellurium. Although all producers responded to the survey, some of the data are withheld to prevent disclosure of company proprietary data.

BACKGROUND

Uses and Products for Trade and Industry

Selenium demand by end use can be divided broadly into four categories: electronic (includes photoconductor uses), glass manufacturing, pigments and chemicals, and other, including

agricultural and metallurgical. In electronics, the largest end-use market, high-purity selenium is used principally as a photoconductor on the drums of plain paper copiers. Other electronics uses include rectifier and photoelectric application. In glass manufacturing, selenium is used principally as a decolorant in container glass and other soda-lime silica glasses. The addition of selenium under weak oxidizing conditions adds a pink color to the glass that combines with the green color imparted by ferrous ions to create a neutral grey color that has low perceptibility to the human eye. Selenium is also used to reduce solar heat transmission in architectural plate glass.

In pigment applications, selenium is used to produce color changes in cadmium sulfide-based pigments. With increasing substitution of selenium for sulfur, the yellow cadmium pigment becomes redder. Sulfoselenide red pigments have good heat stability and are used in ceramics and plastics, as well as paints, inks, and enamels. Because of the relatively high cost and toxicity of cadmium-base pigments, their use is generally restricted to applications requiring long life, brilliance, and high thermal stability and chemical resistance.

Chemical uses of selenium include industrial, pharmaceutical, and biological uses. Small quantities of selenium are used as human food supplements, selenium having been recognized as an essential nutrient for human health. The principal pharmaceutical use of selenium is in antidandruff hair shampoos. Miscellaneous industrial chemical uses include lubricants, rubber compounding, and catalysts.

Dietary supplements for livestock are the largest agricultural usage for selenium. Selenium may also be added directly to fertilizer as a means of increasing selenium content of forage and feed, a practice that is more prevalent outside the United States.

In metallurgical applications, selenium is added to copper, lead, and steel alloys to improve machinability and casting and forming properties. Selenium is added to low-antimony lead alloys used in the support grids of lead-acid storage batteries. The addition of 0.02% selenium by weight as a grain nucleant improves the casting and mechanical properties of the alloy. The quantity of selenium consumed in this application has been greatly affected by technological changes in battery grid manufacture. Development of low-maintenance batteries in the early 1970's encouraged the use of low-antimony grid alloys requiring selenium. Since 1975, lead-calcium maintenance-free automotive batteries have captured a greater share of the automotive battery market. More recently, hybrid batteries, which employ low-antimony lead positive plates and lead-cadmium negative plates, are gaining in usage.

Tellurium is used principally as an alloying element in the production of free-machining low-carbon steels, where additions of up to 0.1% tellurium, usually in conjunction with lead, greatly improve machinability. Similarly, the addition of tellurium to copper and other nonferrous alloys improves their machinability, strength, and corrosion resistance. Tellurium catalysts are used chiefly for oxidation of organic compounds, but are also used in hydrogenation, halogenation, and chlorination reactions. Tellurium

chemicals are used as curing and accelerating agents in rubber compounding. Electronic semiconductor applications for high-purity tellurium include its use with selenium as a photoconductor in plain paper copiers, in thermoelectric and photoelectric devices, and in optical disk storage systems. Mercury-cadmium-telluride (MCT) is used as a sensing material for thermal imaging devices.

Geology-Resources

Selenium and tellurium are relatively rare elements, having estimated crystal abundances of 0.05 part per million and 0.5 to 10 parts per billion, respectively.¹ Selenium and tellurium are frequently found in base metal sulfide minerals. Selenium can isomorphously replace sulfur in the crystal lattice while tellurium is usually found in discrete minerals or microsegregations in the host sulfide mineral.² The most common occurrence of tellurium is as a gold and/or silver telluride.

The concentrations of selenium and tellurium in nature are insufficient to allow for their economic recovery as principal products. Recovery of these elements is therefore dependent on their concentration during the processing of nonferrous ores, principally copper-bearing ores. World reserves of selenium and tellurium are difficult to assess on a deposit by deposit basis. A simplified estimate may be obtained by applying assumed recovery factors to world copper reserves. Total reserves of selenium and tellurium thus estimated were 80,000 metric tons and 22,000 metric tons, respectively. A higher recovery factor was applied to Canada owing to the unusually high selenium content of eastern Canada copper reserves. The aforementioned estimates exclude resources of selenium and tellurium contained in lead, zinc, and gold reserves, which at times have served as sources of these materials, and in coal reserves.

The selenium content of coal averages about 1.5 parts per million. Various studies have indicated that between 5%

and 90% of the selenium contained in coal is released to the atmosphere in either vapor form or as fine particles that escape pollution control devices. Coal combustion is the major anthropogenic source of atmospheric selenium. It has been estimated that combustion of fossil fuels, especially hard coal, accounts for about 35% of total anthropogenic atmospheric selenium emissions of 6,300 tons per year. However, anthropogenic sources account for only 40% of estimated annual global emissions, the balance coming from natural sources such as dust, volcanos and hot springs, sea salt spray, and vegetative emissions.³

Technology

In processing copper ores, selenium and tellurium accumulate along with the precious-metals values in the anode slimes generated during electrolytic refining. Anode slimes typically contain only 10% selenium and 2% tellurium, but may contain up to 30% and 8%, respectively. Decopperized anode slimes are treated by one of several chemical and pyrometallurgical process schemes, first to segregate the selenium and tellurium from the precious-metal residues and secondly to refine the crude selenium and tellurium intermediates. In one process, decopperized slimes are roasted with soda ash to produce water-soluble selenates and selenides. If present, insoluble tellurium may be acid leached from the residue. A second method involves sulfatization, where slimes are digested in sulfuric acid at elevated temperature to sulfatize the base metals and oxidize the selenium. Thin layer roasting of the sulfatized slimes volatilizes the selenium dioxide, which is then precipitated upon cooling.

Most of the selenium and tellurium initially present in the sulfide ores is never recovered, because process circuits are optimized for recovery of copper in the concentration, smelting, and refining stages and precious metals in the slimes processing circuits. In the case of selenium, only 25% to 60% of the selenium in the smelter feed is recovered in the blister, and only 30% to 80% of

the selenium concentrated in the anode slimes is recovered, compounding losses as the processing progresses. Assuming an emissions factor of 120 grams per ton of primary smelter production, copper smelters emit about 1,000 tons per year of selenium to the atmosphere.⁴

ANNUAL REVIEW

Legislation and Government Programs

Since the early 1970's, the Food and Drug Administration (FDA) has been dealing with the issue of selenium addition to animal feeds. Selenium is an essential dietary micronutrient, and much of the forage and grain grown in the United States contains insufficient selenium to meet dietary needs. Since 1974, when the original food additive regulation for selenium was approved, regulations concerning selenium animal feed supplementation have been amended eight times. In April 1987, the permitted supplementation levels were increased from 0.1 or 0.2 part per million, depending on the animal, to 0.3 part per million in complete animal feed. In issuing that amendment, the FDA found that the increased supplementation level would have no significant environmental impact. However, several organizations filed objections to that "finding of no significant impact" (FONSI), and requested a hearing and/or stay of the 1987 amendments. At issue was whether or not increased excretion of selenium by animals ingesting the higher levels of selenium would be of sufficient quantity and bioavailability to cause significant adverse environmental impacts, particularly in aquatic systems. This was of particular concern given that animal feces are used for soil supplementation; some areas where supplementation might occur are contaminated with selenium from existing water-management practices, and wildlife from those areas have already been adversely affected.

In July 1989, the Center for Veterinary Medicine (CVM) of FDA published its preliminary analysis of objections to the 1987 amendments and invited further comments before issuing a final

conclusion. In its issue analysis, CVM affirmed the nutritional justification for selenium supplementation and concluded that its initial FONSI grossly overestimated the potential mobility and bioavailability, and therefore, the potential negative impact of selenium entering the environment as a consequence of the 1987 amendment. At yearend 1991, CVM had yet to finalize its analysis and continued to operate under the guidelines of the 1987 amendment.

Issues

The impact on selenium consumption that limitations on cadmium use could have was a major issue of concern to selenium producers. The principal use of selenium in pigments is to modify the color of yellow cadmium pigments. Cadmium sulfoselenide pigments (CSP's) are widely used in plastics because of their high thermal, chemical, and ultraviolet stability. Worldwide, about 10% of selenium demand was for pigments and about 80% of CSP's was used in plastics. The toxicity of cadmium and concerns over leachability of CSP's has already led to restriction of usage in some applications, particularly those associated with foodstuffs and toys. A European Community directive intended to harmonize CSP restrictions within member countries, which was scheduled to take effect on January 1, 1993, but which was believed to be impacting CSP usage already, restricts CSP use in those resins and polymers where their use is not seen to be essential. The 1993 restriction was limited to polymers for which pigment substitutes were already available. The directive also proposed a future ban, beginning in 1996, for a list of polymers for which it anticipated that it might be possible to demonstrate satisfactory substitutes. Though tests have shown cadmium leaching from plastics to be low, further restrictions, such as banning landfill disposal of CSP-containing plastics, could further impact this segment of the selenium market.

Production

Primary selenium was recovered in the United States at three electrolytic copper refineries: ASARCO Incorporated at Amarillo, TX; Phelps Dodge Refining Corp. at El Paso, TX; and Rio Tinto Zinc Corp. Ltd. at its Kennecott refinery at Magna, UT. Commercial-grade tellurium metal and tellurium dioxide were produced only by Asarco. Selenium- and tellurium-containing anode slimes or residues generated at other domestic primary copper refineries were exported for processing. In addition to commercial-grade tellurium, Asarco produced some high-purity electronics-grade material (99.999% tellurium) at its refinery in Globe, CO. Detector-grade tellurium (99.99999% tellurium), suitable for use in infrared imaging devices, was produced by Cabot Corp., Boyerstown, PA.

Most domestic selenium was produced as commercial-grade material, averaging a minimum of 99.5% selenium and available in various forms, including shot, powder, and lumps, or as pigment-grade powder having a minimum 99.8% selenium content. The largest end use for domestic selenium was in glass manufacturing. There was no domestic production of high-purity selenium suitable for electronic applications. Selenium contained in scrap derived from the manufacture of photoconductor drums and from used photoreceptor drums was exported for processing. There was no domestic production of secondary selenium.

Domestic production of refined selenium declined in 1991 despite record mine production of copper. The discrepancy resulted from a decline in primary smelter and electrolytic refined copper production, the increase in mine production coming from leaching/solvent extraction-electrowinning. The decline is also a reflection of the "bottleneck" in global and domestic copper smelting capacity. U.S. net exports of copper concentrates increased by about 25,000 tons from the already high level of 1990. Production by Kennecott was negatively

impacted by smelter curtailments imposed by State environmental regulations.

Consumption and Uses

Domestic demand for selenium fell slightly, continuing a 3-year decline, owing to poor photoreceptor demand, weakness in the automotive industry, and environmental pressure to reduce the use of cadmium-containing materials. Demand for selenium in glass manufacturing was reported to be strong. Demand for selenium by end use was estimated as follows: electronics, 35%; pigments and chemicals, 20%; glass manufacturing, 30%; and other, including agriculture and metallurgy, 15%.

Excluded from the 1991 apparent consumption estimate of 520 tons were about 14 tons of selenium contained in imported selenium dioxide and an undifferentiated quantity of imported sodium selenite and miscellaneous compounds. In 1988, the last year for which trade data on sodium selenite were available, 41 tons of selenium contained in selenite was imported, principally for use as an animal feed additive. Apparent domestic demand for tellurium in 1991, as calculated from production, stock, and trade data, increased slightly, reversing a downward trend and was increasingly met by domestic production. The war in the Persian Gulf may have served to boost demand for high-purity tellurium used in MCT thermal imaging devices for night vision. High-purity tellurium, however, accounted for only a small part of the tellurium market.

Markets and Prices

The merchant price for commercial-grade, 99.5% selenium metal, quoted by Metals Week on a weekly basis, remained remarkably stable throughout the year, with only a slight decline at midyear when the quoted price fell from the yearend 1990 quoted range of \$5.40 to \$5.70 per pound to \$5.10 to \$5.35 per pound. Intermerchant prices in Rotterdam warehouses, as reported by Metals Bulletin, were also stable. Quotations fell within the \$4.80 and

\$5.40 range throughout the year. The upper limit came down slightly to \$5.30 at midyear. Pigment-grade material, minimum 99.8% selenium, traded at about a \$0.50 per pound premium to commercial-grade material. Significant premiums, \$10.00 to \$20.00 per pound, were charged for higher purity forms of selenium.

The price for commercial-grade tellurium metal remained essentially unchanged during the year despite overall easing in the availability tightness that had caused a near tripling of prices between 1986 and 1988. The yearend price quote for tellurium by the only domestic producer was \$32 per pound.

World Review

World production of refined selenium remained at about the same high level as in 1990. According to data compiled by the Selenium Tellurium Development Association, Inc. (STDA), Western World supply and demand for refined selenium were nearly balanced during 1991, though inventories rose slightly at reporting companies owing to outside purchases. STDA data reflect shipments and inventories from companies that accounted for between 70% and 80% of Western World supply. While apparent demand declined in the United States and Europe, apparent demand in Japan, as calculated from production and trade, increased, and exports to China rose to more than 150 metric tons. Exports to China during the previous 3 years averaged only 85 tons per year.

World production and consumption data for refined tellurium were limited. According to STDA data, shipments of refined tellurium by producers outstripped production, and stocks fell slightly during the year. STDA data reflect shipments and inventories from companies that accounted for between 60% and 70% of Western World supply. Ferrous and nonferrous alloys accounted for most of the identifiable market.

Capacity.—While many market economy countries mine copper, only about 15 countries and 20 refineries

reported recovery of primary selenium, and about one-half the latter reported tellurium production. Several primary refiners of selenium also recovered selenium from scrap, though breakout of their primary and secondary production is not well documented. Several companies, including Pacific Rare Metal Industries Inc. (formerly International Recoveries Inc.) in the Philippines, Shinko Chemicals Co. Ltd. and Asia Bussei Zairyo in Japan, and Mineral and Chemical Products Ltd. in the United Kingdom, were believed to produce selenium exclusively from secondary materials. Capacity estimates for principal primary producers are shown in table 8.

Canada.—One company, Noranda Inc., accounted for all of Canada's refined selenium production. Inco Ltd. discontinued production of refined selenium in 1988 and began exporting crude selenium and tellurium. According to Energy Mines and Resource Canada, Inco can produce 45 tons and 4.5 tons per year of selenium cake and tellurium dioxide cake, respectively. In addition to its own material, Noranda processes anode slimes at its Canadian Copper Refiners (CCR) Div. from Hudson Bay Mining and Smelting Co. Ltd. and Kidd Creek Mines Ltd. The Kidd Creek ore body is reported to be the world's largest single source of selenium. While anode slimes from electrolytic refining of copper typically contain between 2% and 10% selenium, Kidd Creek slimes contain about 20% selenium. CCR is the world's largest producer of selenium and has an estimated capacity of about 400 tons per year. CCR commissioned a new slimes treatment plant in 1988.

Japan.—Primary selenium and tellurium are produced by four companies in Japan having a combined estimated capacity of about 500 and 100 tons per year, respectively. At yearend 1989, Mitsubishi Metal Corp., Japan's largest producer, commissioned a new precious-metals refinery at Naoshima, reportedly closing its Osaka slimes recovery unit. Annual capacities for selenium and

tellurium at the new facility were reported to be 200 tons and 18 tons, respectively. Capacities at the Osaka plant had been reported to be 250 tons and 60 tons, respectively. Nippon Mining Co. Ltd. was Japan's second largest producer, followed by Sumitomo Metal Mining Ltd. and Mitsui Mining and Smelting Co. Ltd.⁵

OUTLOOK

Production and consumption of selenium have fluctuated over time. Because primary selenium is recovered as a byproduct of other nonferrous metals, its availability is influenced by the supply-demand cycles of the principal metals. High demand-production for the principal material has led to excess production of selenium. Similarly, owing to its limited application in specialized areas, technological changes or government regulation have caused rapid shifts in demand. For example, apparent domestic demand for selenium in 1970 and 1991 were both about 500 tons. However, demand slipped during the 1970's to below 400 tons owing to replacement of selenium by silicon in most rectifier applications. The development and growth in the photocopier market led to a resurgence in electronics demand for selenium. The domestic copper production cycle, however, was out of phase with selenium demand. High copper production of the late 1970's corresponded to weak selenium demand, and depressed copper production in the early 1980's corresponded to a growth period in selenium demand. Consequently, stocks of selenium rose to a peak level in 1981, before beginning a 10-year slide. The selenium supply-demand balance entered a transition period in 1990, when demand fell, production increased, and the slide in inventories was halted. World production and consumption were balanced in 1991.

The outlook for selenium demand, based on existing application, is not encouraging. As noted before, demand for selenium in pigment applications has already begun to show the impact of

increased environmental concern over the use of cadmium-base pigments. Similarly, photocopier markets for selenium are expected to decline or remain stable owing to competition from other technologies, including organic photoreceptors and laser printing. On the positive side, demand for selenium compounds in agricultural uses is expected to remain stable or even increase, though environmental concerns could limit its increase. Demand in this application increased significantly, along with imports of sodium selenite, in 1987, following the new FDA regulations. The market for selenium in glass is expected to remain strong.

The U.S. Bureau of Mines forecasts a significant increase in world copper mine capacity for the next 5 years. Several major refiners of selenium have modernized their facilities over the past few years, and several new selenium refineries have opened. Since 1985, world capacity has increased by about 200 tons. Thus, production of refined selenium is expected to meet or exceed world demand. New technologies, such as photovoltaic solar cells and free-machining brass alloys as a replacement for leaded brass in plumbing systems, could create new markets and alter the supply-demand balance. Increased exports to China could further boost demand.

Though tellurium, like selenium, is recovered strictly as a byproduct of other nonferrous metals, principally copper, its production cycle has shown significant independence relative to copper production. World production of tellurium has trended downward since 1979, following the downward trend in world demand. Excess supply, an extended period of weak prices, and reduced tellurium content of ores processed have contributed to lost production. By the end of 1987, available supplies fell short of even the reduced world demand, and prices climbed to their current levels. Since that time, the supply and demand for refined tellurium has maintained a tight balance.

The near-term outlook is for a continuation of the tight balance between

tellurium supply and demand. Tellurium's high price is expected to moderate future demand for it in traditional metallurgical applications and stimulate the substitution of alternative materials. Demand for high-purity tellurium for use in thermal imaging and optical storage devices is expected to grow but not have significant impact on overall demand. If new thin-film technologies stimulate the demand for tellurium in electronic applications, such as solar energy conversion or thermoelectric power generation, supply pressures could increase. Though no significant new tellurium capacity is expected, low-grade tellurium residues from anode slimes that are not currently processed could become economic to treat. Also, anticipated growth in copper mine and electrolytic refinery production will increase slimes generation and could result in increased tellurium production. Little public information is available on the selenium and tellurium content of new ore bodies scheduled for development.

³Tellurium dioxide and tellurium metal; tellurium content.

SILICON

By Larry D. Cunningham

Mr. Cunningham, a physical scientist with 12 years U.S. Bureau of Mines experience, has served as the commodity specialist for silicon since February 1992. Domestic survey data and trade data were prepared by Ms. Robin Johnson, statistical assistant.

Silicon (Si) is a light chemical element with both metallic and nonmetallic characteristics. In nature, silicon combines with oxygen and other elements to form silicates. Silicon in the form of silicates constitutes more than 25% of the Earth's crust. Silica is a silicate consisting entirely of silicon and oxygen. Silica (SiO₂) as quartz or quartzite is used to produce silicon-base products for the iron, steel, aluminum, and chemical industries.

Silicon metal prices improved from those of the previous year, but the price for ferrosilicon continued its decline as supply continued to exceed demand. Based on contained silicon, overall domestic production fell to about 365,000 metric tons, and consumption of silicon decreased to 500,000 metric tons.

Overall U.S. trade volume of silicon exports was down by 8%, while overall trade volume of silicon imports decreased by more than 30%. Dumping tariffs were levied against U.S. imports of silicon metal from Argentina, Brazil, and China. U.S. net import reliance for silicon products was estimated to be 27%.

The metric system is the official system of measurement of most countries. The U.S. Bureau of Mines, in an effort to provide statistical data on silicon that are consistent with international usage, reports data in kilograms and metric tons unless otherwise noted. For comparison to data published in short tons prior to 1990, metric tons can be converted into short tons by multiplying the published number by 1.10231.

DOMESTIC DATA COVERAGE

Domestic production data for the silicon commodity are developed by the U.S. Bureau of Mines by means of monthly and annual voluntary surveys. The "Silicon Alloys" survey canvasses the operations listed in table 2. The figures in table 1 represent 100% of the production and shipments from these operations.

BACKGROUND

Definitions, Grades, and Specifications

Silicon metal and ferrosilicon are referred to by the approximate percentage of silicon contained in the material and by the maximum amount of trace impurities present. There are two standard grades of ferrosilicon, with one grade approximately 50% silicon and the other 75% silicon by weight. In addition to the standard grades of ferrosilicon, there are miscellaneous silicon alloys that contain silicon and other elements. The most common of these alloys are magnesium ferrosilicon and calcium silicon. However, other elemental additions include barium, boron, manganese, strontium, and titanium.

Metallurgical-grade and polycrystalline silicon metal are referred to by their minimum silicon content and maximum impurity level. Typical impurities cited for metallurgical silicon metal are aluminum, calcium, and iron. Typical polysilicon impurities include carbon, boron, and phosphorus and are commonly

measured at the parts per million and parts per billion levels.

The American Society for Testing and Materials (ASTM) publishes standards for ferrosilicon and silicon metal. ASTM Specification A100 covers seven regular grades of ferrosilicon for steelmaking and foundry uses designated A, B, C, D, E, F, and G, and subgrades designated as low-aluminum, boron-bearing, and calcium-bearing. ASTM Specifications A518 and A861 covers high-silicon cast iron castings and high-silicon iron pipe and pipe fittings for corrosion-resistant uses. ASTM recommends that the producer furnish with each shipment an analysis showing the silicon content and, on request, also include aluminum, carbon, manganese, phosphorus, and sulfur contents. Semiconductor Equipment and Materials International (SEMI) has published standards for both polycrystalline and single crystal grades of silicon.

Products for Trade and Industry

Several grades of ferrosilicon are produced and sold in the United States. However, most of the ferrosilicon consumed domestically in 1991 was either 50%- or 75%-grade material, the majority being 50%-grade. The domestic silicon industry supplies nearly all of the 50%-grade material and about 70% of all ferrosilicon products. Miscellaneous silicon alloys consumed in the United States consist primarily of magnesium ferrosilicon. Almost all ferrosilicon products are consumed by the iron and steel industries.

Metallurgical-grade silicon metal is used by the primary aluminum, secondary aluminum, and chemical industries. The products sold to these industries vary considerably in their specifications. The chemical and primary aluminum industries generally require more stringent specifications than those of the secondary aluminum industry. In addition, the chemical industry requires that the metal be ground into a fine powder rather than the lump form used by the aluminum industries.

Geology-Resources

The United States has an abundance of silica deposits for the production of ferrosilicon and silicon metal. For the production of these materials, 98% to 99% purity is preferred. However, trace amounts of aluminum and iron are also acceptable. Physically, the material should not contain fines and should not crumble easily.

Technology

Silicon metal and ferrosilicon are produced by the reduction of silica (SiO_2) to silicon (Si) in a submerged arc electric furnace. A typical charge consists of silica as beneficiated quartz or quartzite; coal, coke, or charcoal as a reductant; wood chips for porosity; and, when producing ferrosilicon, iron in the form of steel scrap or iron ore. During the furnace operation, raw materials are periodically charged into the top of the furnace, and the molten metal or alloy is periodically tapped at the bottom of the furnace and cast into chills or ingots. The material is then crushed to specific size requirements starting at about 20 centimeters down to 200 mesh.

Metallurgical-grade silicon metal is the starting material for high-purity silicon consumed by the electronics industry. First, silicon metal is used to produce an intermediate product such as silicon trichlorosilane (TCS). A vapor deposition process is then used to form a rod or boule of high-purity polycrystalline silicon (polysilicon) from the TCS. A single crystal boule is made from

polysilicon by two methods. The Czochralski (CZ) method uses a seed crystal to grow a rod of single crystal silicon from a molten crucible of polysilicon. The Float Zone (FZ) method uses an induction coil to produce a molten zone within a rod of polysilicon. The coil starts at one end of the boule where a seed crystal starts the crystal growth. The coil moves slowly down the boule, allowing a single crystal to be formed. After being sliced into wafers, the silicon is used by the electronics industry to produce integrated circuits.

Byproducts and Coproducts

Silicon metal and ferrosilicon furnaces produce a material that is referred to as silica fume, silica dust, or microsilica. Originally, this material was considered of little or no value. However, microsilica is now used as an additive in a number of different products, including high-strength concrete. Research is ongoing to find additional uses for this material.

Economic Factors

Production of silicon metal or ferrosilicon is extremely power intensive, requiring a power input of about 8,000 kilowatt-hours per ton of 75%-grade and 12,000 kilowatt-hours per ton of silicon metal. Power costs represent approximately one-third of operating costs for silicon producers. Subsequently, most new producers of silicon products have been where favorable electrical power availability and cost situations exist. Norway has traditionally been a major producer and exporter of silicon products because of its vast hydroelectric power resources. More recently, Brazil, China, and Venezuela have emerged as major exporters of silicon products largely because of their low power costs.

Operating Factors

Silicon metal is a raw material for the production of many silicone-base products, including silicone breast implants. Silicone-base products are

often used because they are considered nonreactive with other materials. However, silicone breast implants were being scrutinized for possible health problems caused by leakage and/or rupture. After being on the market for 30 years, use of silicone implants has been seriously questioned. Doctors have reported that implant patients have a variety of symptoms suspected to be caused by silicone gel leaks. Complaints reportedly began to surface about the safety of the devices in the early 1980's. The complaints alleged that leaky and/or ruptured implants were possibly contributing to an increased incidence of autoimmune diseases such as rheumatoid arthritis, lupus, and scleroderma (hardening of the skin) in implant patients.

Silicone breast implants were first introduced in the United States in the early 1960's. At that time, the Food and Drug Administration (FDA) had no authority to regulate medical devices. Congress granted the FDA authority to regulate medical devices in 1976; however, those medical devices already on the market were grandfathered under the law with the provision that FDA had the power to ask for safety data. In 1990, FDA reportedly started requesting that manufacturers file for formal approval. Manufacturers had until July 1991 to supply data showing that their devices were safe and effective.

In November 1991, an FDA advisory panel found the data submitted by the manufacturers to be insufficient to establish the safety of the implants. However, the panel recommended that the manufacturers be given more time to collect additional safety information under an FDA-imposed deadline. Additionally, the panel recommended that the implants be allowed to remain on the market during this period under certain restrictions. FDA estimates on the number of women in the United States who have had silicone breast implants is as high as 1 million.

By yearend, the FDA reportedly was increasingly concerned about how long the implants last in the body, how often they may leak or rupture, and the

possible harmful effects to the body that could be caused by leakage of silicone from ruptured or damaged devices.

ANNUAL REVIEW

Legislation and Government Programs

The U.S. Department of Commerce (DOC) and U.S. International Trade Commission concluded their investigations of silicon metal imports from Argentina, Brazil, and China. Domestic producers of silicon metal had filed for antidumping and countervailing duties against imports of silicon metal from these countries. The Agencies determined that silicon metal imports from these countries were sold at less than fair value and caused material harm to the domestic industry. Subsequently, dumping tariffs were levied against imports from the respective countries. The DOC assessed the dumping duty for Argentina at 8.65% and China at 139.49%. Duties for Brazilian imports were assessed against individual producers over a range of 87.79% to 93.2%. Silicon metal imports from Brazil and China dropped substantially following the determinations.

The Department of Energy reports that Federal funding appropriated for photovoltaic research amounted to \$46.1 million in 1991 compared with \$34.3 million in 1990.

Strategic Considerations

High-purity silicon is a strategic element of advanced electronic systems for commercial and military applications. Although the United States is a leader in the development of these systems, many of the components and devices within these systems are provided from foreign sources. Recent studies indicate Japan leads the United States in world semiconductor chip production.

Production

Overall gross production of silicon products decreased 16% compared with that of 1990. Production of silicon metal

rose by 3%, while production of ferrosilicon and miscellaneous alloys declined by more than 20%. The most significant change occurred in the production of 50%-grade ferrosilicon, which was down by 28%. Overall shipments of silicon-containing products decreased by 8%. Producer stocks of silicon-containing materials decreased by 18% overall. Ferrous scrap used in the production of these products was estimated to be 180,000 tons.

Simetco Inc., Montgomery, AL, made plans to restart its third and final silicon metal furnace during the fourth quarter. The furnace reportedly had been idle since midyear 1989 owing to low silicon metal prices and increased imports.¹

Applied Industrial Materials Corp. (AIMCOR) announced that the company had merged the management of its metals and minerals activities into one Pittsburgh-based office. AIMCOR's minerals unit relocated from the company's headquarters in Deerfield, IL.² In November, the United Steelworkers Union ended a 4-week strike at AIMCOR's Bridgeport, AL, facility. During the strike, the plant's single ferrosilicon furnace was under a maintenance shutdown, and delivery commitments were made through inventory stocks. Following the settlement, the furnace was reported to have restarted.

In June, Elkem Metals Co. opened a new 3,716-square-meter research and development center near its Pittsburgh, PA, headquarters. Elkem Metals, the U.S. subsidiary of Norwegian aluminum and ferroalloys producer Elkem AS, is the largest producer of bulk ferroalloys in the United States. Elkem's product line includes silicon-containing alloys as well as silicon metal. The new \$4.1 million facility replaces the company's aging research center in Niagara Falls, NY, which had operated for more than 50 years. The focus of the research at the new operation reportedly will be the development of new alloys and the improvement of existing products to meet the changing needs of the company's primary customers—the aluminum, chemical, and iron and steel industries.

The center planned to employ about 40 people when fully staffed.³

Union Carbide Chemicals and Plastics Co., Danbury, CT, acquired McGhan NuSil Corp., Carpinteria, CA, a developer and manufacturer of silicone materials for advanced technology applications. NuSil's products are used in medical, aerospace, defense, and electronic applications. The acquisition reportedly expanded Carbide's business in specialized organosilicone polymers, elastomers, gels, and resins for high-tech markets.⁴

Dow Corning Corp., Midland, MI, reportedly signed an agreement with Himont Inc., Wilmington, DE, to jointly develop and produce improved silane catalyst for polyolefin production. Dow is a major producer of silicon-base products, including silanes, while Himont is a producer of polypropylene resins, alloys, and advanced materials. Under the agreement, Himont expects improvement in catalyst technology that will boost the performance of its current catalyst. The agreement also creates marketing opportunities for Dow Corning.⁵

Dow Corning also announced plans for a \$262 million expansion at its silicones manufacturing complex in Barry, Wales. The investment program was expected to incorporate the latest silicone technology and reportedly more than double the plant's manufacturing capabilities for silicone intermediates. Dow's program to increase capacity reportedly is due to the favorable outlook for the silicones market.⁶ Completion of the expansion is expected in 1995.

In addition, Dow Corning was reported to be building a silicones facility at Lat Krabong, northeast of Bangkok. When completed, the facility would be operated by Dow Corning Thailand and would produce silicone rubbers, emulsions, and sealants.⁷

GE Silicones, the silicone products division of General Electric, reportedly plans to expand capacity at its silicone production facility in Waterford, NY. Work was scheduled for completion by the first quarter 1993. The expansion was part of a reported \$53 million

program that included the addition of an applications development center in Japan.⁸

Consumption and Uses

Apparent consumption of silicon-containing ferroalloys and silicon metal was estimated to be about 500,000 tons of contained silicon. Consumption of silicon metal was estimated at 175,000 tons, while consumption of ferrosilicon and miscellaneous silicon alloys was estimated to be about 325,000 tons. Compared with that of 1990, consumption of silicon metal decreased 10%, and consumption of ferrosilicon and other alloys decreased 17%. Ferrosilicon and miscellaneous silicon alloys accounted for about two-thirds of all the silicon materials consumed, based on silicon content.

The aluminum industry used silicon metal in the production of wrought and cast products, while ferrosilicon was used primarily as a deoxidizing and alloying agent in the production of iron and steel products. Metallurgical-grade silicon metal was also used as the basic raw material in the manufacturing of many chemical products and intermediates such as silicones and silanes. Silanes were used in the production of high-purity silicon for semiconductor devices, solar cells (photovoltaic cells), and infrared detectors. The U.S. Bureau of Mines did not collect data on electronic grades of silicon. (See table 3.)

Markets and Prices

Table 4 shows the average annual import price for 50%- and 75%-grade ferrosilicon as well as silicon metal. Prices are posted in cents per pound of contained silicon. The price for ferrosilicon continued the downward trend that started in 1989, as supply exceeded demand, forcing prices down. The import price for 50%-grade ferrosilicon started the year at 37.5 to 38.5 cents per pound, with a May high of 40.0 to 42.0, then fell steadily to a low of 35.0 to 36.0 by yearend. The import price for 75%-grade ferrosilicon followed a similar curve, starting the year at 36.0

to 36.5 cents per pound, peaking in May at 39.5 to 40.5, then falling thereafter to a low of 31.8 to 32.3 by yearend. Silicon metal prices improved for the year in the wake of DOC's assessment of antidumping duties for Brazil and China. The import price for silicon metal started the year at 54.0 to 57.0 cents per pound, peaked in early August at 66.0 to 66.5, then fell to 58.5 to 59.5 by yearend.

Foreign Trade

U.S. exports of ferrosilicon were relatively unchanged in 1991 compared with those of 1990, based on gross weight. (See table 6.) The total value of ferrosilicon exports decreased by 2%. More than 40% of the exported material was shipped to Canada. Silicon metal exports decreased by 8% based on gross weight, while the total value of the exports increased by more than 20%. More than 50% of the silicon metal exported was shipped to Canada, Japan, and Mexico.

U.S. imports of silicon-containing alloys decreased significantly compared with those in 1990. Imports of ferrosilicon categorized as "55% to 80% silicon, other" decreased 14% based on gross weight, with the total value for this category decreasing by 16%. A substantial decrease occurred in ferrosilicon categorized as "Other," which included all ferrosilicon of less than 55% silicon content. Imports of "Other" ferrosilicon decreased 35% based on gross weight and 44% by total value. Overall imports of silicon metal products decreased 35% based on gross weight and 12% by total value. Imports of silicon metal categorized as "99.00 to 99.99% silicon" decreased by more than 50% based on gross weight and almost 40% by total value. Imports from Brazil and China for this category were down dramatically, owing in part to dumping tariffs levied against the two countries. The U.S. net import reliance for ferrosilicon and silicon metal products were estimated to be 33% and 17%, respectively, compared with 30% and 27% the previous year. The overall

import reliance for silicon products was estimated to be 27%.

World Review

Capacity.—The data in table 8 are furnace capacity for the production of silicon-containing ferroalloys and silicon metal. Capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgement of the author, can be brought into production within a short period of time with minimum capital expenditure. Capacity is based on published reports, maximum production statistics, and estimates where capacity information is either incomplete or unavailable.

Australia.—Pioneer Silicon Industries Pty. Ltd. announced plans to close its Electrona silicon metal facility in southern Tasmania in August. However, (See tables 5 and 7.) the facility was to be kept on a care-and-maintenance basis pending review of the global silicon metal market. The single-furnace plant was reported to have capacity to produce approximately 10,000 metric tons per year (mt/yr) of silicon metal. Material produced at the facility was sold primarily to Asian markets.⁹

Brazil.—Cia. Brasileira Carbureto de Cálcio (CBCC) reportedly halted silicon metal production at its Santos Dumont plant for several months following the U.S. DOC's preliminary decision to retroactively impose a dumping tariff on silicon metal imports from Brazil. DOC's final decision in July imposed an 87.79% dumping tariff on CBCC, but was not retroactive. Subsequently, CBCC reportedly restarted silicon metal production at one of the facility's two furnaces.

Eletrivale S/A Indústria e Comércio reportedly was scheduled to complete construction of a 30-megawatt (MW) ferrosilicon furnace facility by the end of the year. The furnace was originally scheduled for completion in July. The new furnace will produce 75%-grade ferrosilicon and will add an additional 21,000 mt/yr to the company's existing 24,000-mt/yr ferrosilicon production capacity.¹⁰

In May, Cia. de Ferro Ligas da Bahia (Ferbasa) reportedly had reactivated one of its three idled ferrosilicon furnaces. One furnace was shut down in October 1990, and the other two furnaces had been idle since March. The combined production capacity for the three furnaces is reported to be 45,000 mt/yr.

Anuário da Indústria Brasileira de Ferroligas (ABRAFE), the Brazilian ferroalloy producers association, reported 1991 production as follows: 45%-grade ferrosilicon, 5,486 tons; 75%-grade ferrosilicon, 185,937 tons; calcium-silicon, 21,708 tons; and silicon metal, 106,002 tons. ABRAFE reported 1991 exports as follows: 45% (50%)-grade ferrosilicon, 13,853 tons; 75%-grade ferrosilicon, 141,226 tons; calcium-silicon, 19,328 tons; and silicon metal, 85,863 tons.

Bhutan.—Elkem Technology Norway and Elkem Engineering India reportedly was contracted to supply equipment for the 15,000-mt/yr ferrosilicon plant planned for construction by Bhutan Ferroalloys Ltd. The contract is said to be valued at about \$17 million. Supplies to be provided under the contract include furnace equipment and equipment for the handling of raw material and for pollution control.¹¹

Canada.—In May, Timminco Metals halted ferrosilicon production at its Beauharnois, Quebec, plant. The company had been operating only one of its two furnaces prior to the shutdown. Timminco was producing ferrosilicon for use at its magnesium operations and for outside sales.¹²

Metallurgie Silicium Echo International (MSEI), a subsidiary of Spain's Echevaria Group, made plans to construct a 28,000-mt/yr silicon metal plant at Amqui, Quebec. Metallurgie reportedly signed a tentative agreement to purchase power for the 40-MW two-furnace facility. The facility was scheduled for operation by November 1992. However, the plan required Government approval, and construction of the facility was not definite.¹²

Late in the year, Dow Corning indicated plans for the completion of its 6-MW silicon metal pilot plant in Manitoba. Completion of construction was scheduled for December with production to commence in January 1992. The plant will produce 2,000 to 3,000 mt/yr of silicon metal. The company is expected to make a decision in 1993 regarding the construction of a commercial-size facility.¹³

China.—An investigation by the U.S. International Trade Commission and the U.S. DOC found that silicon metal imports from China had been sold at less-than-fair market value and had caused material harm to the U.S. silicon metal industry. Subsequently, DOC assessed an antidumping duty of 139.49% on silicon metal imports from China. U.S. imports of silicon metal from China in 1991 decreased dramatically from that of the previous year.

In an apparent effort to raise ferrosilicon prices, the Chinese Government restricted the issue of ferrosilicon export licenses to three major companies: Minmetals, the China Metallurgical Import and Export Corp., and the China National Non-Ferrous Import and Export Corp. In addition, the Government also revised the endorsement system for licenses. The new policy attempts to limit export sales by smaller producers and coordinate producers' prices.¹⁴ Exports of Chinese ferrosilicon in 1991 totaled about 320,000 tons, an alltime high, and were about 30% greater than exports in 1990.¹⁵

European Community (EC).—After concluding an investigation that began in November 1989, the European Commission took action against imports of ferrosilicon from Brazil. In February 1991, six Brazilian producers agreed to a minimum reference price for ferrosilicon. In May, the Commission set a 39% antidumping duty against Brazilian ferroalloy producers whose prices did not meet the minimum reference price. However, Rima Electrometalurgia and CBCC were excluded from the 39% duty. CBCC was not determined to be dumping, and an import duty for RIMA was set at 12.2%. Brazilian imports reportedly supplied 4% of the European market in 1990.¹⁶

The EC was also reported to be investigating the alleged dumping of ferrosilicon by Egypt and Poland. In addition, allegations that Chinese exporters were absorbing the antidumping duty imposed on Chinese silicon metal imports to the EC would be investigated. It was alleged that the import price of the metal fell after the imposition of the duty.

Hong Kong.—In August, it was reported that Mainland Metals and Minerals would commence production at its silicon metal facility in the near future. Production of up to 500 mt/yr of metal was anticipated.

India.—Owing to the competitiveness of the ferrosilicon market, some producers shifted to the production of other ferroalloys. Nava Bharat Ferroalloys Ltd. reportedly was operating only one of its three 16.5-megavolt-ampere furnaces for the production of ferrosilicon. One furnace had been converted from ferrosilicon production to the production of ferrochromium. The remaining furnace was converted for silicomanganese production. VBC Ferro Alloys Ltd. suspended ferrosilicon production and converted its 16.5-megavolt-ampere furnace for high-carbon ferrochromium production.¹⁷

Indonesia.—In January, PT Ferrotama Alloys was reported to have created a

new subsidiary, PT Indo Alloy Dutanusa, to construct a new 24,000-mt/yr ferrosilicon plant in South Sumatra. Full operation of the plant was expected by early 1993. Ferrotama operates an existing 10,000-mt/yr ferrosilicon plant near Jakarta.¹⁸

Japan.—It was reported in July that Japan Metals and Chemicals (JMC) had contracted to sell electric power at its Matsukawa 22,000-kilowatt powerplant. The plant supplies power to JMC's Minami-Iwate ferrosilicon facility. JMC's ferrosilicon production had been reduced, leaving the company with excess power for consumption.¹⁹

The TEX Report reported that imports of ferrosilicon into Japan totaled 470,600 tons. Chinese imports accounted for 232,000 tons of ferrosilicon imports, an alltime high. Imports of silicon metal into Japan were reported to be 136,103 tons, an alltime high. Silicon metal imports from China and Brazil totaled 68,913 tons and 30,899 tons, respectively.

Norway.—In October, it was reported that Elkem AS and Fesil KS were both planning to curtail their output of ferrosilicon products. The production cutbacks were attributed to poor market conditions, increased competition from Eastern European producers, and for the purpose of inventory adjustment. Overall, Elkem planned a 10,000-metric-ton reduction for its Norwegian operations at Salten, Thamshavn, Bjolvefossen, and Sauda.²⁰ Fesil planned for similar cutbacks at its five domestic ferrosilicon plants. One of Fesil reductions was a 6-week shutdown of the 75,000-mt/yr Rana Metall plant. Fesil's cutbacks would reduce its rated capacity of 275,000 mt/yr by about 40%.²¹

U.S.S.R.—In September, Elkem of Norway and SA des Minerais of Luxembourg reportedly signed a letter of intent to form a joint venture to supply technology, equipment, and services to the ferroalloys industry in the U.S.S.R. The joint venture, Elsumin, was to be

incorporated in Luxembourg. Elsumin was expected to have a branch in Moscow that by yearend would be fully operational.²²

OUTLOOK

Demand for silicon metal will continue to be driven by consumption in the aluminum and chemical industries. Consumption by these industries is expected to undergo slow growth during the next 5 years. The automotive sector will contribute to this growth through increased aluminum content within each vehicle, as automobile producers seek to make vehicles lighter and more fuel efficient. Within the chemical industry, silicon metal is used to produce a wide variety of silicone-base products and intermediates. The worldwide silicones business is expected to continue to grow at a rate of about 7% annually. Industry sources suggest that overall consumption of silicon metal will grow at about 5% annually for the near term.

Ferrosilicon is consumed primarily by the iron and steel industries. The industries use ferrosilicon for both deoxidation of molten metal and as an alloying agent. The outlook for steel is discussed in the annual report for "Iron and Steel." The International Iron and Steel Institute has predicted that consumption of steel by industrialized countries will decline by an average of 0.1% per year for the period 1985 to 1995. Thus, based on this forecast, domestic ferrosilicon consumption is expected to remain at or be somewhat lower than the current level for this period. Factors that could influence consumption of ferrosilicon by the steel industry include technological changes and trade agreements.

SILVER

By Robert G. Reese

Mr. Reese, a physical scientist with the Branch of Metals, has been the commodity specialist for silver for 10 years. Domestic survey data were prepared by Lisa Conley and Dwayne Penn, mineral data assistants; and international data tables were prepared by Virginia Woodson, international data coordinator.

Domestic silver production decreased for the first time in 5 years. A number of mines, including both primary and byproduct silver producers, either reduced their level of operation or ceased mining entirely. The domestic economic recession and low prices for silver and some other metals were cited by company officials when discussing their decisions regarding production levels.

The Government continued to reduce its silver holdings. The Bureau of the Mint produced three commemorative coins during the year. The National Defense Stockpile (NDS) was the source of the silver used in the three coin series.

The average annual domestic silver price fell for the fourth consecutive year. The low price for the year as quoted by Handy and Harman was the lowest daily price since January 1974. Analysts attributed the continued weak price to a lack of investor demand combined with a drop in industrial demand.

The domestic apparent demand for refined silver was 3,846 metric tons in 1991. Apparent demand measures both the quantity of silver required by domestic manufacturers and the quantity of silver demanded by U.S. investors. The decrease in apparent demand was attributed primarily to the domestic recession and a lack of investor demand. An estimate of domestic consumption derived by the CPM Group for the Silver Institute was published in mid-1992. According to analysts at CPM, domestic silver consumption in 1991 was lower than that in the previous year.

DOMESTIC DATA COVERAGE

Domestic mine production data for silver were developed by the U.S. Bureau of Mines from four separate, voluntary surveys of U.S. operations. Typical of these surveys was the lode mine production survey of copper, gold, lead, silver, and zinc. Of the 141 silver-producing lode mines to which a survey form was sent, 129 responded, accounting for an estimated 94% of the total U.S. mine production shown in tables 1, 2, 3, 5, 6, and 7.

BACKGROUND

Silver has played an important role in peoples' lives since ancient times. Early people used silver for ornaments and utensils and as a substance that could be bartered for other goods and services. This concept of the "value" of silver eventually led to its use as the standard in monetary systems, such as that of the Roman Empire, and as a means of paying for international trade. Silver continued to be the standard for most currencies until the discovery of major silver deposits in Mexico and Peru. As more silver deposits were discovered in the 18th and 19th centuries, countries gradually abandoned silver as the standard for their currencies in favor of a gold standard.

Expanding industrial use of silver eventually led to the elimination of silver in U.S. coinage. In the early 1960's, the U.S. Department of the Treasury became a major supplier of silver to industrial consumers. The Treasury, however, had insufficient stocks both to meet industrial

demand and to maintain an adequate supply of circulating silver coinage for a prolonged period. When the silver price reached \$1.29 per ounce, the value of the silver in a silver dollar equaled \$1 in currency. At silver prices greater than \$1.29, the silver in a silver dollar would have been worth more than \$1 in currency, and as a result, it could have been advantageous to melt silver dollars for their silver content, thereby decreasing the amount of circulating coinage. Similarly, if the silver price rose above \$1.38 per ounce, the silver in dimes, quarters, and half-dollars would have been worth more than the coins' face value. To avoid a possible meltdown of the circulating coinage, the Treasury attempted to control the silver price through increased silver sales and increased minting operations from 1964 to 1967. A reduced silver content half-dollar, along with silverless dimes and quarters, were introduced in 1965 to help maintain the supply of circulating coinage, and in 1967, the Treasury announced that all silver coins were being withdrawn from circulation.

Silver occurs as native metal, but is usually found combined with sulfur. Until the 16th century, the ratio of silver to gold produced in Europe was about 10:1. Most of the silver was obtained from the lead sulfide ore galena. With the discovery and exploitation in the 16th and 17th centuries of silver deposits in the Americas, silver production shifted away from Europe. As production increased in Bolivia, Mexico, and Peru, the world ratio of silver to gold production increased because silver was relatively more abundant than gold in the New

World. Following the 1859 discovery of the Comstock Lode in Nevada, the United States was the world's leading silver producer from 1871 to about 1900. Mexico was the leading producer from 1900 to 1968, yielding to Canada from 1968 to 1976. In 1976, Mexico regained the position of the world's leading silver producer, a position that it held through 1991.

Definitions, Grades, and Specifications

The purity of silver in bullion, coinage, jewelry, or other items is usually expressed by its "fineness," or parts per thousand. Pure, or "fine," silver is 1,000 parts fine or 100.0% silver. Sterling silver is 925 fine, or 925 parts (92.5%) silver and 75 parts (7.5%) copper. Domestic coin silver is an alloy that was used in minting coinage until 1964 and contained 900 parts silver and 100 parts copper. Commercial silver bullion ranges from 999 to 999.9 fine. For any fineness of silver bullion, the principal impurities are gold or copper. Doré silver is unrefined silver bullion generally containing a variable percentage of gold as an impurity. Silver for the NDS is required to be 999 fine; free of slag, dirt, or other foreign material; and in bars weighing approximately 31 kilograms.

Uses and Products for Trade and Industry

The most important use of silver is in photographic materials. Silver is used in the manufacture of film, photographic paper, photocopying paper, X-ray film, photo-offset printing plates, and in some other minor light-sensitive products. Photographic materials are produced by depositing thin layers of silver salts, gelatin, and dyes onto a support material. Silver salts, although not extremely sensitive to light when first exposed to illumination, produce a greatly intensified image when subsequently treated with photographic chemical developers. The developer reduces a portion of each silver salt grain to metallic silver, depending on the intensity of the light to which the

grain was exposed. The resulting gray to black metallic silver forms a negative image of the original object.

Silver is used in electrical and electronic products because of its high electrical and thermal conductivity and its resistance to corrosion. Silver has the highest thermal and electrical conductivities of any metal. Silver, in general, can be characterized as strongly resistant to atmospheric and ordinary oxidation and exceptionally resistant to corrosion by weak acids. Although silver commonly reacts with sulfur-containing atmospheric gases to form a sulfide tarnish, the tarnish itself offers little electrical resistance and does not prevent the use of silver as an electrical contact material. Pure silver is generally used in low- and medium-current switching devices. In other applications where the device requires higher strength, more wear resistance, better resistance to arcing, or lower costs, silver is usually alloyed with another metal such as copper or palladium to produce the desired characteristics.

Batteries constitute another electrical use for silver. Silver batteries produce a high-energy output per unit size and weight, but are generally characterized by a short life and high per unit cost. Primarily because of the short life and high costs, the use of silver batteries has been confined to defense and space applications where battery weight, size, and reliability are major concerns. There is, however, a growing use for small silver-zinc button cells in such commercial applications as calculators and hearing aids.

The use of silver for decorative purposes can be divided into three main applications. Probably the oldest use of silver is its use in jewelry. Silver or a silver alloy, usually silver and copper, is flattened and shaped into objects that can be worn for personal adornment. Sterlingware, the second decorative use, consists of articles such as bowls and flatware that are often functional as well as decorative. Sterling silver is an alloy of silver (92.5%) and copper (7.5%). The third decorative use for silver is electroplated ware. Electroplated ware

generally consists of the same types of objects produced as sterlingware, the difference being that electroplated ware is made by depositing a thin silver layer on a base metal object, whereas the sterlingware object is formed entirely of the silver-copper alloy. Because less silver is used in a piece of electroplated ware than is used in a similar piece of sterlingware, the price of the plated piece is less than the price of a corresponding sterlingware piece.

The refrigeration and air-conditioning industry uses silver in the form of brazing alloys because of the ability of silver brazing alloys to wet various base metals at temperatures below their melting points. In general, silver brazing alloys do not dissolve or attack steel in normal usage, are ductile, maintain their strength over a wide range of temperatures, and will join a variety of materials. Silver is added to some solders to improve their flow properties, corrosion resistance, and wettability.

Silver is also used in mirrors, catalysts, medicinals, dental amalgams, bearings, coins, medallions, and a variety of commemorative objects. Silver is used in mirrors because of its high reflectivity in the visible portion of the spectrum. Silver catalysts are used in oxidation reactions such as the production of formaldehyde from methanol and the conversion of ethylene to ethylene oxide. Medicinal compounds include the soluble salts, such as the nitrates and citrates, and insoluble compounds such as the oxides, halides, and proteinate. In dentistry, silver is an important component of amalgam fillings.

Refined silver is available in the form of bars, grain, sheet, strip and foil, wire, rod and tubing, powder, and flake. Bars produced at refineries generally weigh about 31 kilograms and are about 30.5 centimeters long by 12.7 centimeters wide and 10.2 centimeters thick. Grain silver is produced by pouring molten silver into water, creating irregularly shaped silver particles less than 1.3 centimeters across. Silver sheet and foil are available in widths of up to almost 2.1 meters and as thin as 0.01 millimeter. Generally, the thinner the sheet or foil, the narrower it

is in width. Silver rod and wire can range from 5 centimeters in diameter to 0.1 millimeter in diameter. Openings in silver tubing can range from capillary size through 15 centimeters in diameter. Silver powders are generally powder-size (0.5 to 2 micrometers) spherical particles, although coarsensized particles can be produced.

Geology-Resources

About two-thirds of the world silver reserves and resources is contained in copper, lead, and zinc deposits. Ores in which silver or gold is the main component account for the remaining one-third of total world reserves and resources. U.S. silver resources are estimated to be about 190,000 tons.¹ Total world silver resources are estimated to be about 780,000 tons.

The chief silver minerals found in U.S. reserves are native silver (Ag), argentite (Ag₂S), cerargyrite (AgCl), polybasite (Ag₁₆Sb₂S₁₁), proustite (Ag₃AsS₃), pyrargyrite (Ag₃SbS₄) and tetrahedrite (Cu₃(Sb, As)S₃). Other ore minerals of silver are the tellurides, stromeyerite, and pearceite.

U.S. silver reserves are usually found associated with intermediate felsic rocks such as andesites and rhyolites, in veins ranging from a few centimeters to several meters in width. Ores from which silver is produced as a byproduct are usually found in copper porphyries, massive sulfide deposits, or in copper-lead-zinc vein deposits. Historically, most of the U.S. silver production has been from the Rocky Mountain States. It is likely that if major new reserves are discovered, the deposits will be in this region.

Technology

Mining.—Silver is mined using well-established open pit and underground methods. Open pit mining consists of removing overburden, drilling and blasting the exposed ore, loading the broken ore, and hauling the ore to the processing plant. Overburden removal is done with draglines or bulldozers, depending on the depth of the ore body.

The broken ore is loaded by either power shovels or front-end loaders, and the ore is shipped to the processing plant by truck, train, conveyor belt, or some combination of these transport modes, depending on the distance to the plant.

Underground mining of silver is generally done using one of several stope mining methods. Stope mining consists of the development of a series of horizontal workings, or stopes, into the ore body from a shaft or tunnel. The stopes are above each other and can be vertically separated by as much as 60 meters of ore. The ore between the stopes is removed through the use of explosives.

Beneficiation.—Current treatment of silver-containing base metal ores is almost entirely by a flotation process. The concentrates contain the silver along with the copper, lead, and zinc. The silver is recovered from intermediate products resulting from smelting the concentrates. In predominantly lead ores, silver is carried down with the lead in smelting and separated from it by the addition of zinc to the molten silver-lead mixture. The mixture is allowed to cool, and the virtually insoluble silver-zinc alloy separates from the molten lead and rises to the surface where it is skimmed. In addition to the silver, this first crust contains some lead and any gold contained in the original ore. The zinc is distilled in a retort for reuse. The retort residue is roasted to recover the gold and silver as doré metal and the lead as litharge.

In predominantly copper ores, the silver is carried down with the copper in smelting. In the electrolytic refining of copper, the silver accumulates in the anode slime, from which it is recovered as silver bullion by smelting.

Gold and silver ores are generally treated by cyanidation. The ores are crushed by grinding in rod or ball mills and then leached with a dilute cyanide solution. Zinc dust is used to precipitate the gold and silver from the cyanide solution. The precipitate is melted in a furnace to produce a doré metal.

Silver bullion is generally refined using an electrolytic process. In the process, electricity is applied to a standard electrolytic cell in which the impure silver bullion is used as the anode, silver nitrate and nitric acid is used as the electrolyte, and either a pure silver strip or graphite is used as the cathode. Passage of an electrical current results in dissolution of silver in the anode and its subsequent deposition as silver crystals on the cathode. The silver crystals are periodically stripped from the cathode and collected, melted, and cast into bullion bars.

Economic Factors

Costs of mining silver ores vary greatly with depth, ground control problems, ventilation, width of vein, continuity of ore bodies, location, presence of byproduct metals, and the availability of electricity, water, labor, and equipment. Low-grade deposits can usually be mined profitably if sufficient quantities of other metals are contained in the ore. Accurate information on capital costs is difficult to obtain, not only because of variability in the factors enumerated above, but because of differences in accounting methods and definitions used by the mining industry. In general, the cost of mining silver ranges from less than about \$30 per kilogram (\$1.00 per troy ounce) to more than \$260 per kilogram (\$8.00 per troy ounce). Underground mining is, in general, more expensive than surface mining.

U.S. tax laws permit silver-producing companies a depletion allowance of 15% for domestic operations and 14% for foreign operations. There are no tariffs on the importation of silver ores, concentrates, doré, scrap, or refined bullion. Tariffs on semimanufactured silver can be as high as 27.5% ad valorem for countries receiving most-favored-nation classification and can be as high as 110% ad valorem for imports from those countries classified as non-most-favored nation, depending on the item.

Operating Factors

Silver mining is, in general, no more hazardous than other mining, but because of the depths reached in the Coeur d'Alene district, rock bursts there are relatively common. Temperatures are uncomfortable at these depths, and air conditioning must be used in ventilation systems. Gains in productivity are difficult to achieve because the possibilities for mechanization are limited by the relatively narrow veins mined. In recent years, companies have attempted to increase productivity through modification of labor agreements to allow more flexibility in work assignments and compensation and by improved mining plans.

Although in most circumstances silver is not a toxic substance in other than very large doses, a standard has been established for worker exposure to airborne particulate silver. The Occupational Safety and Health Administration currently requires that the concentration of either silver metal or soluble silver compounds be less than 0.01 milligram per cubic meter of ambient air in workplaces.

Nearly all silver-bearing ores are processed after grinding by flotation or cyanidation. Pollution of downstream waters by fine solids from flotation plants is a problem that requires adequate ponding and retention of tailings. Disposal or stabilization of the accumulated tailings can be a problem at some mines. It can be partially solved in those deep mines where ground support is needed by pumping the tailings back into the mine. In cyanidation operations, extreme care must be exercised to avoid contamination of the ground water, nearby watercourses, or surrounding areas through losses of leach solution. As a result, the solution collection system for returning the leachant to the storage tanks and the system for monitoring water in the surrounding area must be adequate to prevent pollution.

Achieving adequate air pollution (sulfur dioxide) control and disposing of slag and other wastes (iron and silica) are the problems encountered in smelting

silver ores. Refining presents little environmental concern because the bulk of noxious impurities are removed during the smelting step; however, spent solutions from electrolytic refining present a disposal problem because of toxic materials in the solutions.

ANNUAL REVIEW

Legislation and Government Programs

The Bureau of the Mint produced three commemorative coins during the year. Public Law 101-332 authorized the production of gold, silver, and copper-nickel-clad coins in honor of the 50th anniversary of the Mount Rushmore National Memorial. Public Law 101-404 authorized the production of silver coins to commemorate the 50th anniversary of the United Services Organization (USO). Public Law 101-495 authorized the minting of a silver coin to commemorate the 38th anniversary of the ending of the Korean War.

All three silver commemorative coins had the same specifications. Each coin was made from a 90% silver-10% copper alloy, weighed 26.73 grams, and had a diameter of 3.8 centimeters. Inscribed on each coin was its face value (\$1.00) and the words "Liberty," "In God We Trust," "United States of America," and "E Pluribus Unum." Also included on the Mount Rushmore and USO commemorative coins was the year of production (1991). Inscribed on the Korean War coin though, was the time period, 1953-1991. All three coins were legal tender. The NDS was the source of the silver used to manufacture the three coins. The enabling legislation limited the number of coins to be issued to 2 million for the Mount Rushmore commemorative coin and 1 million each for the USO and Korean War coins.

Included in the sales price of each coin was its face value and the labor, materials, dies, machinery, and various expenses, including overhead, marketing, and shipping required to design and issue the coins. Also added to the price of each coin was a \$7.00 surcharge. Surcharges collected from the sale of the

Mount Rushmore coins were divided, with one-half used to reduce the National debt and one-half given to the Mount Rushmore National Memorial Society to improve, enlarge, and renovate the Mount Rushmore National Memorial. One-half of the surcharges collected from sales of USO coins went to reduction of the National debt and one-half to the USO to fund its various programs. The Korean War Veterans Memorial Fund received all the surcharges collected from sales of the Korean War commemorative coins. The fund was to provide for the construction and maintenance of a Korean War Veterans Memorial in Washington, DC.

Production

Silver was produced from precious-metal ores at 120 lode mines and from base metal ores at 21 lode mines. Silver was also produced at eight placer operations. In 1991, 17 mines each produced more than 30 tons of silver; their aggregated production equaled 75% of total domestic production.

In October, Magma Copper Co. signed an innovative labor agreement with its unions. The new agreement conditionally covered a 15-year period and prohibited strikes and lockouts for at least 7 years. Hourly workers were to receive wage increases of \$0.25 to \$0.35 per hour during the first 5 years of the agreement, with some increases tied to company earnings. After the initial 5-year period, the agreement would continue in force for another 10 years unless either party proposed to modify it. If the company and the unions could not agree on the proposed modifications, then the suggested modifications would be submitted to arbitration. After the initial 5 years, the use of arbitration twice in any subsequent 5-year period would terminate the contract. The termination would occur on the anniversary of the second arbitration award.

Alaska.—During the year, workers at the Greens Creek Mine mined and processed about 390,000 tons of ore and recovered almost 242 tons of silver.² As

in the previous year, reserves at the mine increased significantly. At yearend 1991, Greens Creek's estimated proven and probable reserves were about 12,560,000 tons grading 414 grams of silver per ton.

Performance improved at the Red Dog Mine following some mill modifications and as workers gained a better understanding of the various ore types. The operation processed almost 1,451,000 metric tons of ore in 1991 compared with 904,000 tons during the mine's first full year of operation. Average silver content of the ore was 87 grams per ton.³ The company solved an unanticipated mine drainage problem during the year. Although the natural drainage at Red Dog was acidic and contained high metal levels, mining operations at the site reportedly aggravated the situation. To solve the problem, Cominco spent U.S.\$14.0 million to divert the major water course in the area around the pit. The company also began to treat contaminated water generated in the pit and divert it to the tailings pond.

Arizona.—Magma Copper purchased the McCabe Mine during the year. The underground mine produced about 523 kilograms of silver and 121 kilograms of gold.⁴

In July, Magma signed a Memorandum of Commitment with its unions. The memorandum identified various processes first used at the San Manuel Mine that resulted in significant productivity gains and cost reductions. Included in the memo was the formation of high-performance teams. The teams, encouraged to suggest and implement more efficient production techniques, operated with greater autonomy and less supervision than previously. Magma planned to introduce these processes throughout its underground operations.

Idaho.—In early April, ASARCO Incorporated, operator and 50% holder of the Coeur Mine, temporarily ceased operations at the mine. Company officials, citing low silver prices for the decision, placed the mine on a care-and-

maintenance basis. Reportedly, exploration to locate new ore reserves was to continue. On December 31, Coeur d'Alene Mines Corp. acquired Callahan Mining Corp. With the acquisition, Coeur's interest in the Coeur Mine increased from 45% to 50%. In 1991, Asarco milled about 34,000 tons of ore and recovered 12 tons of silver at the Coeur Mine. The previous year's production was 16 tons of silver.⁵

At its DeLamar Mine, NERCO Minerals Co. began a two-phase program to detoxify the mine's tailings pond. The company undertook the program, at least in part, in response to a bird mortality problem at the mine. The company planned to lower the cyanide concentration of the pond by injecting it with hydrogen peroxide which would destroy the residual cyanide. Additionally, the company planned to construct a cyanide recovery facility to remove the cyanide from the tailings before their deposition in the pond. The DeLamar Mine produced 1 ton of gold and 53 tons of silver during the year.⁶

With its acquisition of Callahan Mining, Coeur d'Alene Mines obtained a 50% nonoperating interest in the Galena Mine. Asarco, the mine's operator, milled about 166,000 tons of ore during 1991 and recovered 102 tons of silver.⁷

Near the end of June, Hecla Mining Co. acquired CoCa Mines Inc. CoCa's major asset was the Grouse Creek project, a gold-silver deposit in southern Idaho. With the acquisition of Grouse Creek, Hecla increased its reserves significantly. Hecla announced plans to proceed with development of the project, and production could begin by late 1993. At yearend 1991, reserves at the Grouse Creek project were 13,600,000 tons grading 1.5 grams per ton gold and 37.3 grams per ton silver.⁸

Cost reductions continued to benefit the Lucky Friday Mine. Despite operating at a loss, production continued throughout the year. Hecla, which owns and operates the mine, cited the continuing productivity improvements in the decision to keep the mine open. Corporate officials stated that because of the improvements the mine was now

among the lowest cost domestic primary silver producers. According to the literature, the reduced operating costs have made it less costly to keep the mine operating than to place it on care and maintenance. For the year, the Lucky Friday Mine produced 58 tons of silver from 138,000 tons of ore.⁹

MinVen Gold Corp. acquired the 50% interest held by its joint-venture partner in the Stibnite Mine. MinVen took over operation of the mine in April. Production at the heap-leach operation reportedly improved following the resumption of crushing the ore before leaching.

In early June, Sunshine Precious Metals Inc. reduced the operating rate at the Sunshine Mine from 162 tons per year to about 81 tons per year as a consequence of the low silver price and the need to preserve cash. The new operating plan reportedly was less expensive than either full operation or placing the mine on care and maintenance. Company officials stated that the new plan would allow the mine to respond quickly to rising prices. In early July, the company negotiated new labor agreements covering most of the unionized workers at the Sunshine Mine. The new agreements cover a 3-year period, and were not expected to result in any significant increase in labor costs. Sunshine Precious Metals was a wholly owned subsidiary of the Sunshine Mining Co., whose major asset was the Sunshine Mine, mill, and refinery. During 1991, the Sunshine Mine produced 115 tons of silver.¹⁰

During the year, Hecla Mining Co. mined the remaining oxide ore at the Yellow Pine Mine. The heap-leach operation produced 255 kilograms of silver in 1991.¹¹ The Yellow Pine Mine won the State of Idaho's "Excellence in Operation Award" for its environmental work. Corporate officials expected leaching at the site to be completed in 1992.

Montana.—Unseasonably heavy precipitation hindered operations at the Beal Mountain Mine during the first half of 1991. The rains inhibited crusher

operation and diluted the mine's leach solutions, thereby reducing gold and silver production. Increased production during the second half made up most of the first half production shortfall. To guard against a recurrence, Pegasus Gold Inc. doubled the mine's solution treatment capacity by installing five new carbon columns in the plant. During 1991, Beal Mountain recovered 1,472 kilograms of gold and 243 kilograms of silver.¹²

Canyon Resources Corp. mined approximately 1,362,000 tons of ore at its Kendall Mine. The Kendall Mine, an open pit, heap-leach operation produced about 2 tons of gold and 333 kilograms of silver.¹³

Near mid-June, Pegasus took over mining at its Montana Tunnels Mine. Prior to that time, a contractor mined the deposit and Pegasus ran the processing plant. By performing the mining itself, Pegasus expected to realize a significant reduction in its operating costs. During the year, Montana Tunnels mined 3,875,000 tons of ore and recovered 2 tons of gold and 36 tons of silver.¹⁴

As with its Montana Tunnels Mine, Pegasus also took over the mining operations at its Zortman-Landusky Mine. The transition to in-house mining began in October. For 1991, the Zortman-Landusky Mine recovered 4 tons of gold and 30 tons of silver.¹⁵

Nevada.—At its Battle Mountain Complex, Battle Mountain Gold Co. recovered approximately 8 tons of gold and 13 tons of silver from the Fortitude, Labrador, and Surprise deposits.¹⁶ The 1991 output of gold and silver was slightly lower than that for the previous year and probably was attributable to lower ore grades. The company processed more than 1 million tons of ore through its on-site carbon-in-pulp mill and leached an additional 660,000 tons. The Fortitude deposit probably will be depleted in early 1993, but Battle Mountain expects to develop other small, nearby deposits.

Cominco American Inc. halted mining at the Buckhorn Mine in May and crushing operations in June owing to ore depletion. Leaching was believed likely

to continue into 1992. The company began site reclamation during the year and expected to complete its reclamation work in 1992.

In June, workers at the Bullfrog Mine began driving a drift into the North Zone reserves. The mine expected to begin underground production in 1992 using a drift-and-fill mining method. In 1991, the open pit mine produced 6 tons of silver.¹⁷

Although mining ceased at the Candelaria Mine in November 1990, continued leaching resulted in the production of almost 53 tons of silver and 93 kilograms of gold.¹⁸ NERCO Minerals Co., operator of the Candelaria Mine, was proceeding with development of smaller gold deposits near the mine site.

Silver production at the McCoy-Cove Mine increased significantly. The mine consisted of two deposits, with production from two pits and two underground operations. In 1991, the mine produced 175 tons of silver, compared with 62 tons during the previous year.¹⁹ Gold production also increased slightly. Company reports attributed the increases to several developments. One was a new effluent treatment plant completed in 1990. During that year, the company had been forced to reduce the concentration of chemicals used in the mill to help neutralize the mill effluent. With completion of the effluent treatment plant, the mill resumed the use of concentrated chemicals, and gold and silver recovery improved. Another factor for the significant jump in silver production was the increased mining of the Cove deposit. The Cove deposit contained significant quantities of silver, while the McCoy deposit contained only minor amounts. Also cited were increases in the underground mining rates and reduced waterflows in the Cove pit owing to the pit dewatering program. In early 1991, mining depleted the known ore reserves in the bottom of the McCoy pit. Exploration subsequently discovered some additional reserves. These additional reserves probably will be exploited following completion of underground mining in the deposit.

At the Paradise Peak Mine, silver production declined significantly. Gold production was about 6 tons and silver production about 72 tons.²⁰ In 1990, the mine produced 6 tons of gold and 170 tons of silver. Declining ore grades and the depletion of the high silver portion of the Paradise Peak deposit during 1990 were the primary factors in the lower production. To help offset the effects of the declining grades, FMC Gold Co. increased mill throughput at the mine and expanded its heap-leaching activities. The company milled approximately 1.4 million tons of ore and added about 2.9 million tons to the leach pads. The previous year, the company had milled 1.3 million tons and leached about 700,000 tons. During the second half, the company began mining operations at the County Line deposit. Previously, production had been from the original Paradise Peak and Ketchup Flat deposits. FMC began a gain-sharing program aimed at reducing operating costs. Savings from the program were expected to be about \$1.3 million per year.

The Rawhide Mine completed its first full year of operation. The mine, owned and operated by Kennecott Corp., a wholly owned subsidiary of The RTZ Corp. PLC, produced gold and silver.

Magma Copper expanded its property holdings near the Robinson Mine. Among the properties acquired was the Taylor Mine, a former gold-silver producer. NERCO Minerals Co., which owned the Taylor Mine, exchanged its interest in the property for a net smelter royalty on the Robinson copper-gold property. Although the Taylor Mine had been inactive since 1984, the mine's mill had operated since then. Company officials expected the mine to produce copper, gold, and silver. Permitting and various studies were underway at yearend. In 1991, mining near-surface deposits on the Robinson property reportedly resulted in the production of 645 kilograms of gold.²¹

Gold and silver production at the Rochester Mine increased in 1991. Mining operations produced about 6.3 million tons of ore, and silver recovery at the heap-leach operation rose from 149 tons to 178 tons.²² Gold production

increased slightly. Company officials attributed the increased production to the adoption of a new extraction technique called "counter-current leaching." This technique consisted of using the same batch solution to leach the ore on more than one leach pad. After passing through several heaps before processing the pregnant solution contained additional gold and silver. Reportedly, counter-current leaching reduces the volume of solution that must be processed by increasing the concentration of gold and silver in the pregnant solution.

Production at the Sleeper Mine declined, owing in part to a decline in ore grades. To help offset the lower ore grades, Amax Gold Inc. added a larger grinding mill to the operation, thereby increasing its mill capacity to about 2,000 tons per day. The increased capacity will allow the company to mill some lower grade ore previously heap leached, resulting in improved recoveries. For the year, the Sleeper Mine milled 565,000 tons of ore and added 7.5 million tons of ore to its leaching pads. Production at the mine included 9 tons of silver and 6 tons of gold.²³

At the Wind Mountain Mine, Amax Gold Inc. mined about 13 million tons of ore. The heap-leach operation produced 13 tons of silver and 3 tons of gold.²⁴ Mining ceased at the open pit mine near the end of January 1992 owing to the depletion of ore reserves. Reclamation of the site began after that, although leaching continued.

Other States.—Mining resumed in the Cripple Creek mining district in Colorado. Pikes Peak Mining Co. began mining in the Globe Hill area of the district in June. Pikes Peak was a wholly owned subsidiary of NERCO Minerals. With the resumption of mining by Pikes Peak, NERCO Minerals reopened its Victor Mine. The Victor Mine, also in the Cripple Creek district, last produced in January 1986.

Production began at the San Luis Mine in July. The mine, near the town of San Luis, CO, was a typical open pit operation. The mine used a carbon-in-pulp leach circuit to process

approximately 674,000 tons of ore. Although experiencing some startup problems, the mine produced 684 kilograms of gold and 435 kilograms of silver.²⁵

Prior to its acquisition by Coeur d'Alene Mines Corp., Callahan Mining decided to abandon its Ropes Mine, near Ishpeming, MI. The Ropes Mine was an underground operation that produced gold and silver and had a history of ground control problems. Ground control problems near the mine's main shaft, along with low gold and silver prices, resulted in its closure in late September 1989. The mine never reopened. Company officials cited the continually escalating costs of reopening the mine and the continuing low gold prices when announcing their decision.

The Magmont Mine in Missouri reduced its work force by 20% to 151 employees during the year. Company officials cited lower metal prices and the need to remain competitive for the decision. Despite the reduced work force, the mine maintained its production levels and milled more than 1 million tons of ore.

At its copper refinery in El Paso, TX, Phelps Dodge Corp. recovered 60 tons of byproduct silver.²⁶ Feed material for the El Paso refinery came from its copper mines and smelters in Arizona and New Mexico and the Santa Gertrudis Mine, in Mexico. At the Morenci Mine in Arizona, Phelps Dodge mined about 40.4 million tons of ore. At its Chino and Tyrone Mines in New Mexico, the company mined about 16.4 million and 14.3 million tons of ore, respectively.

In Utah, gold and silver production at the Bingham Canyon Mine increased owing in part to an increase in mill throughput and to higher ore grades. The ore mined at Bingham Canyon reportedly contained about 112 tons of silver.²⁷

Consumption and Uses

Apparent U.S. demand for silver in 1991, calculated as refinery production from primary materials and from old scrap plus net imports of refined bullion, was 3,846 tons. Included in the apparent

demand calculation was the amount of silver absorbed by investors and the amount of silver required by the domestic fabricating industry. For the second consecutive year, apparent demand decreased, reflecting the continued lack of investor demand and the effects of the domestic recession.

Near mid-1992, the Silver Institute published estimates of silver consumption in 1991 by end use.²⁸ CPM Group, private consultants, developed the estimates for the Silver Institute. These estimates are reproduced in table 9. According to CPM, domestic silver consumption in 1991 declined from that of the previous year. Probably a major reason for the lower consumption was the economic recession.

Stocks

Total accountable stocks at yearend 1991 had increased by about 79 tons over those of yearend 1990. Continued buildup of stocks held by futures exchanges combined with an increase in industry-held stocks more than compensated for decline in Government-held stocks. Analysts cited the slowdown in the domestic economy and the lack of investor demand as the primary reasons for the continued stock buildup.

The total quantity of Government-held silver continued to decline. The U.S. Mint, as authorized by Congress, used NDS silver for various coinage programs. (See the "Legislation and Government Programs" section of this report.) Since 1985, Government-held stocks have declined by more than 1,600 tons. Various Government coinage programs have consumed nearly all the silver represented by the decrease.

Markets and Prices

The domestic silver price, as quoted by Handy & Harman, declined for the fourth consecutive year despite the lower domestic mine production and the lower quantity of silver recovered from old scrap. Analysts attributed the continued weak price primarily to lower industrial demand, combined with lack of investor

demand. The price began the year at \$4.13 per troy ounce and generally trended downward until the end of February. The low for the year of \$3.58 on February 26 was the lowest daily price since January 1974. Following the end of the Iraq-Kuwait conflict, the price rallied until it reached the high for the year, \$4.53, near mid-June. Although the price subsequently declined, it remained near \$4.00 per troy ounce for the remainder of the year. The London spot price followed a pattern similar to that of the Handy & Harman price. The U.S. dollar equivalent of the London spot price, as quoted in Metals Week, began 1991 at \$4.16 per troy ounce and ended the year at \$3.86. The low and high prices of \$3.54 and \$4.57 occurred on February 25 and June 10, respectively. The average for 1991 was \$4.05.

The amount of silver represented by the future contracts traded on the Commodity Exchange Inc. (COMEX) increased in 1991 to 646,129 tons from 608,634 tons in 1990. At the Chicago Board of Trade, the quantity of silver corresponding to the futures trading volume decreased to 3,654 tons in 1991 from 5,912 tons in 1990. On the Mid-America Commodity Exchange, silver futures trading volume increase to 408 tons in 1991 from 342 tons in 1990.

Foreign Trade

U.S. silver exports decreased in 1991 for the first time in 7 years. The lower domestic mine production and the economic recession, both domestically and in other industrialized countries, may have been contributing factors to the lower exports. The countries with the largest increases in quantities of silver imported from the United States were the United Kingdom and the United Arab Emirates. Shipments to these countries increased about 148 tons and 108 tons, respectively. Increased shipments of refined bullion accounted for the increased trade with both countries. The largest drop in U.S. silver exports were those to Japan, which decreased by 432 tons from those of the previous year. Cumulatively over the past 10 years, the

United States has exported about 10,748 tons of silver. Japan (2,467 tons), Canada (2,397 tons), the United Kingdom (2,166 tons), and France (1,189 tons) have received most of the U.S. silver exports.

Although U.S. silver imports increased in 1991 for the fourth consecutive year, shipments from Canada and Mexico continued to decline. Canadian and Mexican exports to the United States fell by 230 tons and 205 tons, respectively, primarily the result of lower shipments of refined bullion. During the past 10 years, Canada has supplied 11,271 tons and Mexico 12,617 tons of the total U.S. imports of 38,166 tons during that period. The increased imports were due to increased exports by the United Kingdom (453 tons), Peru (204 tons), the Federal Republic of Germany (182 tons), Chile (169 tons), and Malaysia (152 tons).

World Review

The data in table 13 were rated production capacity in mines as of December 31, 1991. Rated capacity was defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable, long-term operating rate, based on the physical equipment of the plant and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

As with U.S. consumption, the Silver Institute publication World Silver Survey 1992 contained estimates of world silver consumption. These estimates are reproduced in table 16.

Australia.—Completion of a project to push back the pit walls reduced the stripping ratio at the Pajingo Mine and provided access to deeper reserves. The mine milled 171,000 tons of ore and produced 2 tons of gold and 4 tons of silver.²⁹ Company officials stated that at current mining rates, the mine's known

reserves would be depleted in 1992. The mill, however, would continue to process stockpiled ore through 1994. Battle Mountain let a contract to ACM Gold Ltd. for future exploration work near the Pajingo Mine.

Aberfoyle Ltd. closed the Que River Mine near yearend owing to exhaustion of the mine's reserves. The zinc-lead-silver operation mined almost 100,000 tons of ore containing an average 156 grams of silver per ton.³⁰

Near mid-March, Niugini Mining Ltd. completed the purchase of the Red Dome Mine in Queensland. The open pit operation used heap leaching, flotation, and carbon-in-leach to recover gold, silver, and copper. In 1991, the mine produced about 1 ton of gold and 4 tons of silver.³¹

Bolivia.—In May, Battle Mountain increased its interest in Empresa Minera Inti Raymi S.A. to 85% from 51%. Battle Mountain acquired 24.5% of Inti Raymi's stock through the acquisition of Westworld Resources Inc. The company obtained the remainder of its share from Zeland Mines S.A. Inti Raymi operated the Kori Kollo heap-leach operation in Bolivia. The company began construction of a new carbon-in-pulp cyanide leach mill, which will be used to treat the sulfide portion of the deposit. In 1991, Kori Kollo recovered 2 tons of gold and 10 tons of silver.³²

Canada.—MinVen Gold Corp. closed the Blackdome Mine following the exhaustion of known ore reserves in mid-January. The company reportedly sold some equipment at the mine and used the proceeds to help carry out reclamation of the site.

Completion of various projects during 1990 and 1991 increased the mill capacity of the Con Mine to 1,000 tons per day from about 700 tons per day. Nerco began installation of an autoclave during the year. The autoclave will be used to treat and stabilize arsenic sludge produced by the mine's former owners as a byproduct of their gold operations. Officials expected the autoclave to

recover some gold from the sludge and be operational by yearend 1992. The mine received an environmental award during the year for this cleanup effort.

Placer Dome Inc. reported the production of 175 tons of silver at the Equity Silver Mine in British Columbia.³³ In 1990, the mine had recovered 229 tons of silver. Company reports attributed the decline in production to the mining and processing of lower grade ores. Future silver production will continue to decline as the mine reaches the end of its planned life.

At its Kidd Creek Div., Falconbridge Ltd. reported the production of 168 tons of silver during 1991.³⁴ The byproduct silver production declined from that of the previous year owing in part to low zinc prices, which caused zinc production to decline. The company reduced both the number of employees in the division and the amount of contract labor used for capital projects as steps toward becoming a lower cost, more competitive operation.

Brunswick Mining and Smelting Corp. Ltd. settled a 10-month strike at its No. 12 Mine in early May. Through the strike, the company reportedly maintained operations at 25% of the normal levels with staff employees. During the year, the mine produced 127 tons of silver by milling 2,531,000 tons of ore.³⁵ Brunswick's smelter produced almost 51.3 tons of silver doré.

Kerr Addison Mines Ltd. closed its Opemiska Mine in June following exhaustion of its remaining reserves. For the year, the mine produced 4 tons of silver.³⁶ The silver production at Kerr's other operations was 9 tons from its Lac Dufault Div., 114 tons from its Samatsum Div., and 6 tons from its Winston Lake Div.

At the Sullivan Mine, Cominco Ltd. milled 1,688,300 tons of ore grading 39 grams of silver per ton, compared with 399,600 tons grading 28 grams of silver per ton the year before.³⁷ The company attributed the higher production primarily to essentially full year continuous operations at the mine. During 1990, low zinc prices and high operating costs had resulted in the mine's closure from January to November. Also cited was the

new labor agreement negotiated the previous year.

Highland Valley Copper Co. negotiated a new 2-year agreement with workers at its Valley Mine. The new agreement provided for wage and benefit improvements. During the year, the mine produced about 33 tons of silver contained in concentrate, compared with about 31 tons the previous year.³⁸

Chile.—Production at the El Indio Complex declined, owing in part to a 26-day strike and the mining of lower grade ore. The El Indio Complex consisted of the El Indio and Tambo Mines. During the year, the operation milled about 982,000 tons of ore and leached 646,000 tons to recover 43 tons of silver.³⁹

At the La Coipa Mine, a new processing plant began operating in October. The new plant had a capacity of 15,000 tons per day and could result in the mine producing more than 6 tons of gold and 500 tons of silver in 1992. The new plant, a conventional cyanide leaching gold and silver recovery plant, replaced an existing 1,000-ton-per-day mill. In 1991, La Coipa recovered 159 tons of silver.

Production began at the San Cristobal Mine in July. The mine was a typical open pit operation using heap leaching to recover gold and silver. Production during the year was lower than expected, owing in part to startup problems. Employees had corrected most of startup problems by yearend. For the year, the mine produced 653 kilograms of gold and almost 2 tons of silver.⁴⁰

Mexico.—Silver production at the Real de Angeles Mine declined in 1991 to 263 tons of silver in response to lower ore grades and lower recoveries.⁴¹ In response to low prices, Placer modified the mine's long-term mining plan to extract the highest grades available and postponed stripping activity.

Near midyear, operations commenced at the Santa Gertrudis Mine, a 2,000-ton-per-day heap-leach operation. Phelps Dodge had a 49% interest in the mine,

with the remainder shared by a group of Mexican investors.

New Zealand.—The Golden Cross Mine began operations during the year. The initial doré pour occurred in December, and commercial production commenced in February 1992. Cyprus Minerals Co. has an 80% interest in the gold-silver operation.

Amax Gold increased its interest in the Waihi Mine from 28.35% to 33.53%. During the year, the open pit gold-silver mine milled 872,000 tons of ore, recovering 2 tons of gold and 11 tons of silver.⁴²

Papua New Guinea.—Production at the Misima Mine increased despite the mining of lower grade material at the original deposit. The company was able to increase the average ore grade processed by blending the lower grade ore with higher grade material from the recently discovered Quartz Mountain zone. Increased mill throughput was an additional factor in the increased production. In 1991, the Misima Mine produced 80 tons of silver.⁴³

At the Porgera Mine, workers completed construction of a pressure oxidation circuit in the third quarter. Production at the mine increased owing to higher mill throughputs and higher recoveries. Future production was believed likely to increase as the pressure oxidation circuit began treating stored tailings.

OUTLOOK

The dominant component of domestic silver supply is silver recovered as a byproduct of the processing of other nonferrous metals such as copper, gold, lead, and zinc. Most nonferrous ores contain some silver. Processing the ores concentrates the silver either in a waste stream or with the principal product. Once concentrated, the additional cost to recover the silver is minimal.

Therefore, the quantity of silver supplied to the market is somewhat independent of the silver price. It is

likely that during the period 1992-94, domestic silver mine production will remain about 2,000 tons per year. Worldwide, mine production of silver should remain about 15,000 tons per year.

Future industrial demand for silver is harder to forecast owing to its many diverse uses. Over the next few years, the industrial demand for silver will likely follow the general economy, either upwards or downwards, but remain about 3,700 tons. Worldwide, silver demand will grow slightly with the gradual opening of new markets in lesser developed countries.

World:						
Mine production	metric tons	'14,019	'14,517	'15,057	'15,122	14,723
Consumption:⁴						
Industry and the arts	do.	15,443	16,671	'16,899	17,409	17,465
Coinage	do.	933	799	'1,141	799	840

¹Revised.
¹Defined as refinery production from primary materials plus refinery production from old scrap plus imports of bullion minus exports of bullion. Represents not only the quantity of silver required by the domestic fabricating industry, some of which may be placed in stocks, but also the quantity of silver demanded by U.S. investors.

SLAG—IRON AND STEEL

By Cheryl Cvetic Solomon

Ms. Solomon, a physical scientist with 6 years' U.S. Bureau of Mines experience, has been the commodity specialist for iron and steel slag since 1990. Domestic survey data were prepared by Shirley Miller and Robin Kaiser, mineral data assistants.

Iron and steel slags are byproducts of the iron and steel industry and are used in numerous commercial applications in construction and roadbuilding. Slags are used in road bases, various types of concrete aggregates and products, glass manufacture, mineral wool, railroad ballast, sewage treatment, and soil conditioning.

In 1991, the Federal Environmental Protection Agency (EPA) concluded that regulation of iron and steel slags as a hazardous waste under the Resource Conservation and Recovery Act (RCRA) was inappropriate. This decision presented the final regulatory determination that iron and steel slags were not subject to Federal regulation as hazardous wastes. (See Legislation and Government Programs section of this report.)

Research during the year emphasized the use of granulated slag as an additive to cement. The slag provided the cement with greater durability, strength, and resistance to sulfate attack among other qualities. Other research indicated that slag could be used to immobilize radioactive waste. (See Current Research section of this report.)

Domestic consumption of iron slag showed a moderate decrease when compared with that of 1990, while the consumption of steel slag increased slightly from that of 1990.

Beginning with this Iron and Steel Slag Annual Report, all quantities are given in metric tons. In 1960, an International System of Units was adopted by the 11th General Conference of Weights and Measures. This system is called the MKS system, or metric system, and most

countries of the world have adopted it as their official system of measurement.

Congress enacted the Metric Conversion Act of 1975 on December 23, 1975. The act was amended on August 23, 1988, by the Omnibus Trade Act of 1988, which was to enhance the competitiveness of the Nation's industries and to improve the management of the U.S. trade strategy. The Metric Conversion Act declared that the national policy was to prefer the metric system in U.S. trade and commerce and called for the U.S. Government to convert to the metric system.

On July 25, 1991, the President of the United States signed Executive Order 12770 to implement the congressional designation of the metric system of measurement as the preferred system of weights and measures for U.S. trade and commerce.

The U.S. Bureau of Mines, in an effort to provide statistical data on iron and steel slag in units most consistent with international usage, has converted all numbers in the iron and slag tables to metric tons and will henceforth report iron and steel slag data in metric tons (mt) unless otherwise noted. To convert from metric tons to short tons, the quantity should be multiplied by the conversion factor 1.10231. To convert short tons to metric tons the quantity should be multiplied by the conversion factor 0.907185. To convert from kilometers to miles, the quantity should be multiplied by the conversion factor 0.6215. To convert miles to kilometers the quantity should be multiplied by 1.609.

DOMESTIC DATA COVERAGE

Data for sales, use, and transportation of iron and steel slag are developed by the U.S. Bureau of Mines from a voluntary survey of U.S. processors. Of the 105 operations canvassed, 97 responded and the rest were estimated, representing 100% of the total sales or use quantity data shown in table 1. Value data had to be estimated for several operations using reports from prior years adjusted by industry trends.

BACKGROUND

Definitions, Grades, and Specifications

Slags are produced in many metallurgical operations, but this publication deals exclusively with iron slag and steel slag produced during the ironmaking and steelmaking processes.

In the production of iron, the blast furnace is charged with iron ore, flux stone (limestone and/or dolomite), and coke for fuel. Two products are obtained from the furnace: molten iron and slag. The slag consists primarily of the silica and alumina from the original iron ore combined with calcium and magnesium oxides from the flux stone. It comes from the furnace as a liquid at temperatures of about 2,700° F, resembling molten lava.

The blast furnace operation is a continuous process. The raw materials are fed into the top, and the products, molten iron and liquid slag, are drawn off at regular intervals throughout the entire day. Slag is produced at an average worldwide rate of 250 to 350 kilograms

of slag per ton of hot metal (kg/thm) or pig iron.¹ The slag is usually run into iron ladles for conveyance to the cooling pit, or it may run straight into a cooling pit close to the furnace. When the material cools and solidifies the gases create voids within the structure. These voids impart special engineering properties when the slag is used as an aggregate.²

The density and porosity of the slag are affected by the conditions of cooling as well as by its chemical composition. Depending upon the manner in which the molten slag is cooled and solidified, three distinct types of blast furnace slag can be produced: air-cooled, expanded, and granulated.

Air-cooled slag is allowed to run into a pit adjacent to the furnace or is transported in large ladles and poured into a pit some distance away. Solidification takes place under the prevailing atmospheric conditions, after which cooling may be accelerated by water sprays on the solidified mass. After a pit has been filled and cooled sufficiently to be handled, the slag is dug, crushed, and screened to desired aggregate sizes.

Expanded slag is formed by controlled processing of molten blast furnace slag with water, or with water and other agents such as steam or compressed air, or both. The formation of gases and steam increases the cellular or vesicular nature of the slag, producing a lightweight product. Several methods of expanding the slag are employed involving the pouring of molten slag in open pits or the use of mechanical devices, one of which produces particles in pellet form. Expanded slag is a strong lightweight aggregate suitable for making lightweight concrete, either as building blocks or as structural elements for buildings or for bridge decks, for example.

Granulated slag is produced when molten slag is cooled rapidly by means of high-pressure water jets and solidifies into a glassy, granular product. This is the most rapid cooling process, producing little or no crystallization. The granulated slag may be crushed and

screened or pulverized for various applications.

The steel industry also produces steel slag during the steelmaking process. The manufacture of steel involves the removal from the iron of excess quantities of carbon and silicon by oxidation. Steel slag is composed of roughly 50% lime. The other two main constituents are silica and iron oxide. The steel slag contains significant iron quantities and few voids making it a tough, hard, heavier material. Different types of steel slag are generated from the open-hearth, basic oxygen, and electric arc furnaces.

Air-cooled and expanded slag are defined by ASTM standard C 125-88.³ Granulated slag is specified by ASTM C 989-88, "Standard Specification for Ground Iron Blast Furnace Slag for Use in Concrete and Mortars," which was first published in 1982.⁴

The specifications for steel slag aggregate used in asphaltic concrete are covered by ASTM D 5106-91, "Standard Specification for Steel Aggregates for Bituminous Paving Mixtures."⁵

Industry Structure

In general, most slag processors operate under contracts of 3 to 10 years with steel companies. The services the slag processors typically offer to the steel mill industry are hauling and transport of the slag away from the mill site, processing of the slag, and recovery and distribution of metallics and nonmetallics. Because slag hauling and processing facilities are capital intensive, the slag processors usually try to negotiate a long-term initial contract with the steel company to recover the capital investment. Subsequent contracts may be shorter.

Depending upon the specific situation at the mill site, the slag processor may assume ownership of the slag at the point of discharge or process for a fee and/or market the finished product and pay royalties to the steel company on sales. Some steel companies may allow the processor to share in royalties on these sales. Although there are many variations in the way a particular slag processor and steel mill will set up their

agreement, two possible options are considered here. The slag company may be paid to haul and transport the slag, process it, and market the finished product. The steel company, in turn, receives a royalty on the completed sale and a purchase discount on material recycled to the mill. In a minority of the contracts, the slag processor takes ownership of the material and pays little or no royalties to the mill. In this situation, the slag processor would be assuming 100% of the site development and capital costs, including facilities for screening, metallic separation, and crushing and heavy equipment, such as slag pot haulers, to move the material around.

Technology

Processing.—Slag processing systems include those outlined below, in A.W. Cooper's "Slag Handling in the Ironmaking Industry."

Pit Granulation.—Molten slag is poured, either from a slag ladle or directly from the furnace, into a pit filled with water, or is hit with sprays of water to rapidly quench it. The blast furnace slag forms granules that have a glassy or vitrified structure. The slag granules are then separated from the granulation water and transported to the drying and grinding plant.

Gravel Layer Filter Bed System.—Pit granulation is developed further with the gravel layer filter bed system. The slag is granulated at the furnace in a granulation head by high-pressure water sprays. The slag slurry flows down a runner to an agitating tank where water is injected to keep the slag in suspension. The slag is dewatered and then excavated by a computer-controlled bucket crane. The gravel layer filter bed keeps the water in the system in a closed circuit thus preventing water pollution. Atlantic Cement (now Blue Circle) has operated a gravel layer system since 1981.

Filter Hopper System.—Filter hopper systems use large dewatering silos lined with screens to dry the slag. This system extends the filtering system upward to conserve plant space. However, since the filtering is less efficient in the filter hopper system, pumping the slurry is necessary in the filter hopper.

Slag Pelletizer.—The slag pelletizer was developed by National Slag Ltd. in Hamilton, Ontario, as a means of bringing very high hydrogen sulfide gas emission levels typical of the "pit foaming" process under control.⁶ Pelletized slag is produced by expanding molten blast furnace slag under water sprays and then passing the flow of this pyroplastic material over a spinning drum on which fins are mounted. The fins break up the slag, which then forms into pellets owing to surface tension. While previous expanding processes have been of the batch type, this is a continuous process so that gaseous emissions are effectively diluted by generation over a long period of time. Because of this rapid cooling, the pelletizer can be thought of as an "air granulator."

The pelletizer has been installed in at least eight countries. Currently in Canada, about 400,000 mt of slag is pelletized annually and separately ground for use as a cementing material by the St. Lawrence Cement Co., Lafarge Canada Inc., and St. Mary's Cement. The pelletizers are installed near Hamilton, Ontario, where the major steel producers are located.

Operating Factors

Environmental Requirements.—Slag processors have had to be aware of environmental considerations, in much the same manner as have other mineral processing or manufacturing industries. During the past decade, concerns about the environment as embodied in the Clean Air Act of 1990 or Solid Waste and Clean Water legislation have grown. Concurrently, recycling and reuse of materials have become firmly established.

In keeping with public and private emphasis on improving the environment and preventing environmental harm, the slag industry has taken an active stance toward environmental responsibility in slag plant operations. Installation of new equipment, incorporation of improved operating procedures, and increased emphasis on such slag processing as slag granulation and other types of processing have all favorably impacted the slag industry.

At the same time, the emphasis on reuse of materials has meant that slag, which has been used as far back as Roman times, has been given renewed interest as a useful byproduct that serves as a substitute for mined aggregates. In addition, the use of slag as a commercial product is vastly more useful to the environment than it would be if it were landfilled.

Because of some of the different ways in which iron and steel slags can be utilized and the variety of steel slags available in the market, the slag processor can advise the user of iron and steel slags as to the best possible use for any given slag.

ANNUAL REVIEW

Legislation and Government Programs

On June 13, 1991, the EPA published its final regulatory determination, required by RCRA, for iron and steel slags and for 20 other special wastes from the processing of ores and minerals.⁷ The EPA concluded that regulation as a hazardous waste under subtitle C of RCRA is inappropriate for iron and steel slag and the other special wastes. The EPA planned to address iron and steel slags under subtitle D, possibly in the program being developed for mining wastes.

Pennsylvania Residual Waste Regulations were anticipated in early 1992 to expand the category of coproduct to include iron and steel slags after they were processed. Such slags, therefore, would no longer be considered waste products.⁸

Production

Koch Minerals Co., a division of Koch Industries of Wichita, KS, started up a grinding and granulation plant in June 1991 to process blast furnace slag produced from the Weirton Steel blast furnace, Weirton, WV. The grinding plant had a capacity of 180,000 mt, and the granulator has a capacity of 245,000 mt. Koch Minerals also started up the granulator at the USX Gary, IN, works in July 1991 and completed the cement grinding plant in December 1991.

The Levy Co. of Portage, IN, supplied expanded slag aggregate for the more than 900,000 lightweight concrete blocks used in building the new Comiskey Park stadium in Chicago, IL. (See cover photo of this report.) Chicago Block manufactured the blocks, and construction of the White Sox stadium was completed in early 1991.

Levy also supplied expanded slag for the 250,000 lightweight concrete blocks that were used in the Sears Corporate Headquarters, completed in 1991. Other buildings in the Chicago area that used expanded slag supplied by Levy were 900 N. Michigan, the Watertower Place, the Downtown Chicago Sheraton, City Front Center, and Ameritech Headquarters.

The Standard Slag Co., Eastern Div., based in Coraopolis, PA, supplied approximately 318,000 mt of slag for the new Greater Pittsburgh International Airport in 1991. Standard used air-cooled slag coarse aggregate extensively to construct the airport. The entire project was expected to be completed by 1992.

Consumption and Uses

If slag was not dug, crushed, screened, and sized, it would go to a disposal or processing facility. Moreover, use of various kinds of iron and steel slags can provide desirable features when used as construction aggregates and as a replacement for portland cement.

Sales of slag products generally reflected demand from the construction industry. The Department of Commerce reported that value of new construction

estimated in 1991 as \$380.4 billion declined by 6% compared with that of 1990.⁹ The value of highway and street construction was estimated to have increased slightly from 1990 to 1991.

Blast furnace slag can be used as a ground product to replace portland cement in concrete, as a special lightweight aggregate in blocks and highrise buildings, as a concrete aggregate replacing common concrete aggregates and sands, as a highly skid-resistant asphalt aggregate, and as a road base where the rough, interlocking surface and shape and cementitious properties enhance its load-bearing values.

Air-cooled blast furnace slag continued to be the predominant form of iron slag processed in the United States, accounting for more than 80% of blast furnace slag sales in 1991. The most significant end use in 1991 for air-cooled slag was as a road base. Air-cooled blast furnace slag was also used as an asphaltic concrete aggregate, fill, mineral wool, and glass manufacture. (See table 5 for related data.)

Consumption of combined expanded and granulated slag increased by approximately 80% from that of 1990 to 2,404,000 mt valued at \$43,484,000. Granulated slag was predominantly used in the manufacture of cement and expanded slag in the manufacture of lightweight concrete blocks.

Steel slag is principally used for highly skid-resistant asphalt road surfaces, road bases, and asphalt aggregates.

Reported steel slag consumption increased slightly compared with that of 1990 (see table 6). Steel slag used in asphaltic concrete and road bases increased moderately from that of 1990.

Transportation

Most slag is used within about a 50-kilometer radius of its source. Trucking costs make slag uncompetitive with mined aggregates when transportation distances exceed about 50 kilometers. Some slag may be delivered over greater distances to areas that do not have other aggregates for use in construction and roadbuilding.

Of all the iron and steel slag products sold in 1991, 85% traveled by truck, with an average marketing range of 45 kilometers; 4% traveled by waterway, with an average range of 404 km; and 3% traveled by rail, with an average range of 400 km. The remaining 8% was used at the plant where it was processed (see table 4).

Markets and Prices

The average price, f.o.b. plant, for all blast furnace slag was approximately \$8.27 per mt, approximately 20% more than that of 1990 (see table 7). The price of air-cooled blast furnace slag increased from \$5.67 to \$6.10 per mt in 1991. Granulated and expanded slag price information was withheld to avoid disclosing company proprietary data. The unit value for steel slag increased by 5% from that of 1990 to \$3.41 per mt.

Foreign Trade

Statistics developed by the U.S. Department of Commerce, Bureau of the Census, indicated that approximately 114,000 mt of granulated blast furnace slag was imported from Canada into the country during 1991. The 114,000 mt of Canadian imports reportedly entered into the country primarily through Buffalo, NY, Cleveland, OH and Baltimore, MD. The Canadian imports may be expanded or pelletized slag.

World Review

It is estimated that 40 million mt of slag is used annually.

In 1991 considerable interest was shown in many countries throughout the world to recycle and reuse materials produced in a wide range of metallurgical processes. Iron and steel slags have been among the mineral products thus reused.

Australia.—There are six blast furnaces in Australia, one in Whyalla, two in Newcastle, and three in Port Kembla. The latter produced approximately 7,000 mt of iron and 2,500 mt of slag per day. Approximately 3 to 4 million mt of slag was produced in Australia in 1991.¹⁰

Approximately 30,000 mt of granulated blast furnace slag was imported from Japan over the past 2 years. Granulated slag was exported to Hawaii, the Philippines, and Korea. A small amount of air-cooled blast furnace slag was sold to Malaysia for manufacture into wool insulation. There were three companies that generated steel slags, including two generating electric arc furnace slag.

According to the Australasian Slag Association, slag was not treated as a waste or considered hazardous in Australia; there were minimal environmental concerns with iron and steelmaking slags. It was expected that all slag generated in Australia would be used with the aim to add value to the slag.

Blast furnace slag cement marketed in Australia conformed to Australian Standard AS 1317. AS 1317 permitted slag to represent 20% to 65% of the total cementitious content.¹¹

BHP Steel of Melbourne, Australia, generated 2.0 million mt of blast furnace slag and 1.2 million mt of steelmaking slag from its three integrated steelmaking plants at Port Kembla, Newcastle, and Whalla. Approximately 800,000 mt of the blast furnace slags was granulated: 75% was used in cement production, 5% went to glass manufacture, and 20% went to construction sands. The remaining 1.2 million mt of blast furnace slag was air-cooled and marketed into aggregates and road construction.

The Australasian Slag Association sponsored various seminars in Port Kembla, New South Wales, including a Technical Seminar held in July 1991 and an Environmental Seminar held in September 1991. (See the Current Research section of this report.)

According to the Australasian Slag Association, a contract involving slag products was made in 1991 for the construction of piles and pile caps to be used in the tower foundations of the Glebe Island Bridge in Sydney, Australia. Marine cement containing 65% ground granulated blast furnace slag was used in the concrete. The State road authority, the Roads and Traffic Authority of New South Wales, proposed that the marine cement be used because of the harsh

environment and also to reduce heat of hydration.

The New South Wales State Rail Authority used 1.5 million mt of uncrushed air-cooled slag to stabilize land under the main rail link between Sydney and the South Coast of New South Wales.

Japan.—Thirty-six million mt of iron and steel slag was produced in Japan. Blast furnace slags were used as material for cement, aggregate for road and railroad construction, concrete mixing aggregate, material for building and building foundations, and for civil engineering. Eighty percent of the basic oxygen furnace slag and 65% of the electric arc furnace slag were used.

The Law for the Promotion of the Utilization of Recycled Resources was enacted on October 25, 1991.¹² Iron and steel slags were included in the category of industrial byproducts that were required to be reutilized under this law. Iron and steel slag was to be used as a raw material for cement and as a roadbed material. To efficiently use iron and steel slag, the ironmaking, steelmaking, and steel-rolling industries were to promote the manufacture of products from recyclable resources in accordance with standards and specifications, install facilities for effectively processing recyclable resources, and promote technological development that increases the use and improves the quality of recyclable resources. In Japan, a material that is reused is not considered to be a waste product.

Admixtures using blast furnace slag in cement for use in ready-mixed concrete have already been adopted into Japanese Industrial Standards.¹³

Korea, Republic of.—Keo Yang, an affiliate of Pohang Iron and Steel (POSCO), planned to process slags into powder for sale to Korean cementmakers.¹⁴ It opened a slag processing plant with an annual capacity of 600,000 mt at Kwangyang at a cost of 22.2 billion won. Korean cementmakers bought crude slag from POSCO for 11,000 won per mt, but powdered slag

cost 20,000 won per mt, excluding the transportation cost. Also, the Korean cementmakers were forced to use covered trucks for transportation of powdered slag and to establish storage facilities in their plants.

Netherlands.—A conference was held concerning the use of wastes in construction. (See Current Research section of this report.)

New Zealand.—According to the Australasian Slag Association, the New Zealand Government passed a Resource Management Bill on October 1, 1991. Use of renewable resources was promoted over new enterprises. Laws were also passed to control runoff from farms into streams and rivers. Blast furnace slag was the preferred material for these wetland filter beds required under the Resource Management Bill.

Blast furnace slag was cleared by the New Zealand Health Department as not containing free silica and was therefore suitable for grit blasting. Slag was also used for agriculture for crops such as kiwi fruit.

The demand for steel slag increased and it began to replace lime in the Auckland area. It was also used as a flocculent at mine sites to settle contaminated water and as a stabilizing agent.

Research was conducted using slag to neutralize toxic wastes.

United Kingdom.—It was estimated that 3 to 3.5 million mt of blast furnace slag was produced in the United Kingdom. This slag was either pelletized or granulated. The total capacity for granulation in the United Kingdom was approximately three-quarters of a million tons per year. The United Kingdom has five slag grinding plants operated by four companies. Two of the plants use pelletized slag and three use granulated slag. Of these three, one of the plants was commissioned in 1991. There are five blast furnace slag producing locations in the United Kingdom: Ravenscraig, Redcar, Scunthorpe, Port Talbot, and Llanwern. Slag from four of these was

processed for cementmaking. Approximately 400,000 mt of slag was imported.

The majority of ground granulated blast furnace slag was produced according to the British Standard 6699 for supply directly to the concrete manufacturer, ready-mixed, site-mixed, or precast for production of portland blast furnace cement concrete (PBFC). Small quantities were dry blended with portland cement and supplied in PBFC form.

A research report published in 1991 examined the supply of mineral and construction wastes, considered their suitability for use as construction aggregates, and suggested a tax on primary aggregates as a means of encouraging an increase in the use of waste material.¹⁵ Researchers examined blast furnace slag among other materials.

Current Research

Various seminars and conferences were held that focused on or included slag papers. The Australasian Slag Association held an International Seminar in July in Port Kembla, New South Wales, Australia, entitled, "Slag—the Material of Choice." "An Overview of Slag Usage in North America and Australia" by K.W. Spencer, Edw. C. Levy Co., Detroit, MI, discussed slag production in North America and Australia. Dr. Vute Sirivivatnanon of CSIRO, North Ryde, New South Wales, Australia, in "Durability Performance of Blast Furnace Slag Blend Concrete Structures" included a discussion of the long-term durability performance of concrete structures built of portland cement and binder systems that incorporated slag as well as the visual appearance, chloride diffusion and carbonation characteristics, and the reinforcing steel corrosion behavior of the sampled structural elements. Kevin Maw of the Slag Reduction Co. Ltd. in Rotherham, England, examined the successful utilization of steelmaking slag for more than 99 years by Steel Reduction Co. "Steel Slag—Its Use and Development in the United Kingdom by the Slag Reduction Co." is an excellent

primer covering the ways of making and cooling iron and steel slags with emphasis on steel slag formation. Steelworks and roads surfaced with steel slags in the United Kingdom were listed. K.P. Woodbury of the Wollongong Division Roads and Traffic Authority (RTA), New South Wales, presented "Trials and Use of Slag in Heavily Bound Pavements." The RTA tested a variety of slag pavement types that incorporated iron and steel slags. The RTA concluded that blast furnace slag can be used for high-quality road base, and slag or slag mixes could be used for heavily bound pavements provided that they are designed to take tensile strains. Because of the current trend toward heavily bound pavements due to lower costs for medium to heavily used roads, there is a need to determine what slag mixes would be suitable for these types of pavements.

The WASCON Conference was held November 10-14, 1991 in Maastricht, the Netherlands, to discuss the environmental implications of construction with waste.¹⁶ The use of various types of slags including foundry, incinerator, copper, and magnesium types was discussed in conjunction with road and other construction projects.

A number of studies carried out in 1991 highlighted the use of slag in waste disposal. Waste repositories for the below-ground disposal of low-level radioactive waste rely greatly on the durability of concrete for their required 500-year service life. A research program in Canada studied laboratory testing of concretes containing either Type 1 cement or cements containing 65% and 75% of blast furnace slag, each at four water-cement ratios.¹⁷ It has been established that the degradation of the concrete depended on the entrance rate of the corrosive agents, chlorides, sulfate ions, and CO₂. The improvements in concrete durability due to blast furnace slag additions were illustrated.

The application, development, design, installation, and operation of two electric arc furnaces to produce mineral wool were outlined at the electric furnace conference held in New Orleans, LA.¹⁸ These furnaces were supplied and

commissioned by Lectromelt and operate in Eastern Europe. Each produced up to 6.6 mt of melt per hour that was spun into mineral wool fibers for use as structural insulation. At this capacity, the furnaces were the largest mineral wool furnaces in the world that supplied vitrified melt to mineral wool spinners. Production from both furnaces was realized in 1985. The approximate production of the plant was 50,000 mt of mineral wool in 1988, and the expected production for 1989 was 60,000 mt. With the success of these furnaces, it was believed that this technology may not only be used by mineral wool manufacturers but could also be readily adapted to vitrify waste products.

The Nigerian steel industry has also attempted to alleviate the problem of waste disposal. Use of steel slag as an aggregate for concrete mixes and in powder form as a stabilizer for soil was investigated. The short-term results have encouraged further investigation.¹⁹

A large part of the research conducted in 1991 involved granulated blast furnace slag. Granulated blast furnace slag has been shown to be a useful component in forming blended cement in a study emphasizing world byproduct gypsum utilization.²⁰ When it reacted with gypsum in the presence of water, calcium sulfoaluminate hydrates (CSH) were easily formed, which functioned as a binder for concrete materials. The cement industry was able to use this property to manufacture supersulfate cement, expansive cement, and regulated-set cement. The main ingredients in slag-gypsum boards are 30% to 60% pulverized granulated blast furnace slag, 20% to 70% gypsum, and 5% to 15% fibrous materials. In addition, slaked lime or portland cement is added as an activator. Slag-gypsum boards are incombustible and water resistant.

The strength properties of triple-blend cements were studied at the Queensland University of Technology in Australia.²¹ Triple-blend cements are blends of ground granulated blast furnace slag, fly ash, and normal portland cement. Triple-blend stabilized road construction materials were able to withstand longer

periods of delay in compaction due to their slow strength gains. This phenomena made the stabilized material less susceptible to construction stoppages during base and subbase construction.

Work concerning steel slag blended cement (SSBC) and results of preliminary work utilizing Australian-produced steel slag were presented.²² The strength contribution, volumetric stability, and grindability of SSBC with and without incorporation of ordinary portland cement clinker were studied.

A research study used approximately 480,000 cubic meters of cemented materials to backfill mined-out stopes at one mine in Australia.²³ This was expected to increase in subsequent years. This study compared the potential strength development of binders containing granulated blast furnace slag with an existing fly ash/portland cement binder. It was shown that, based on binder performance, slag mixes can provide suitable strength development over the required time.

The effect of microsilica and blast furnace slag on pore solution composition and alkali silica reaction was studied at the King Fahd University of Petroleum and Minerals in Dhahran, Saudi Arabia.²⁴ Pore fluid analysis and 6-month expansion tests were carried out on plain, 10% and 20% microsilica, and 60% and 70% blast furnace slag cements. A few of the objectives were to study the correlation between expansions and hydroxide concentrations in the pore solution and alkali-removing capacity of blast furnace slag. Incorporation of 10% to 20% microsilica and 60% to 70% slag reduced expansions from nine times the permissible expansion to safe values ranging from one-tenth to one-half the allowable expansion. Although there are other concurrently occurring mechanisms in addition to alkali removal action, blast furnace slag was shown to be an active remover of alkalis and was especially effective in medium-alkali cements.

One study featured matrices including various cement replacement levels of ground granulated blast furnace slag (GGBFS), fly ash, and microsilica that had steel reinforcement electrodes

embedded in them.²⁵ The steel reinforcements were exposed to simulated marine splash zone exposure for about 600 days after initial curing in air for 14 days. The corrosion potentials and polarization resistance were monitored at regular intervals to determine the state and rate of corrosion. The results show that maximum protection against rebar corrosion is provided at 60% replacement of cement by blast furnace slag and at 10% and 15% replacement by microsilica.

Roller compacted concrete was being used increasingly as a material for concrete dam and concrete pavement. The construction method for these structures required no slump concrete because the concrete was transported by dump trucks and compacted by vibrating rollers. The usage of portland blast furnace slag cement has increased for concrete construction in Japan because the cement has contributed to energy saving and improvement of concrete durability. In a study carried out in Japan, the mixing tests for roller compacted concrete using the portland blast furnace slag cement were used to determine the optimum mix proportion by examination of various properties of concrete, such as flexural strength, length change, freeze-thaw cycle resistance, and fatigue strength.²⁶ Consequently, the use of portland blast furnace slag cement was found to be very effective as the cementitious material for roller compacted concrete. The exception to this was the case when early strength was required. The properties of the hardened roller compacted concrete were found to be very much influenced by the compaction degree of concrete.

To improve the durability of concrete, it has been recommended that blast furnace slag be incorporated into concrete. On the other hand, it can be expected that the use of a superplasticizer is effective to improve the workability of this type of concrete. A study at the Tottori University in Japan was conducted for the purpose of establishing appropriate mix designs for superplasticized concrete incorporating blast furnace slag, as well as for

understanding the properties of fresh and hardened concretes.²⁷ A superplasticizer and two types of high-range water-reducing agents were used in the study. The slag contents were 0%, 50%, and 70%. The effects of these additives were measured by slump test, rheological test, segregation test, and strength test, among others. The results showed that the flowability of cement paste increased with an increase in slag content. Also, the slump loss of superplasticized concrete increased with an increase in slag.

The properties of concretes containing instant-chilled steel (I.C.S.) slag as aggregate were studied at the University of Wollongong in Australia.²⁸ The I.C.S. slag possessed good physical and mechanical properties and had sufficient stability for use as a coarse aggregate in concrete. Compressive, indirect tensile and flexural strengths of I.C.S. slag concretes were greater than those of corresponding control concretes containing limestone aggregate.

Formulation and commercial utilization of solid waste incinerator slag byproduct was the focus of a research study carried out in Japan.²⁹ Particular attention was given to iron aluminosilicate melts having compositions similar to that of basalt. An ideal slag consumes flux additives at acceptable cost, is compatible with furnace refractory, flows readily from the furnace, and has physical properties suitable for its commercial utilization. Examples of successful solid waste slagging practice, including tonnage, utilization, and pricing, were provided from metallurgical and waste treatment operations of North America, Western Europe, and Japan.

Trial underwater concretes were prepared in Japan by mixing high-fineness slag with ordinary portland cement.³⁰ The strength development and segregation resistance properties of the concrete were studied for laboratory and concreting in site tests. The results of the tests were that the underwater concrete composed of ultra-high-fineness slag show good segregation resistance properties, good pumpability, high self-leveling, and good mechanical properties.

The Magnitogorsk Metallurgical Combine (MMK) in Magnitogorsk, U.S.S.R., developed a technology and perfected the production of building brick from granulated blast furnace slag and fireclay. Granular blast furnace slags from MMK had a low crystallization degree.³¹

Alkali-activated slag cement (AASC) was studied as a matrix for immobilization of radioactive wastes.³² Experimental results show that AASC is the best among other cements studied, and that AASC-based waste forms had high strength, low porosity, high resistance to chemical corrosion and to heat, and low solubility as well as leachability.

Kawasaki Steel Corp. in Japan developed a new pavement method with cement utilizing blast furnace slag.³³ A dry mixture, which consisted of crushed blast furnace slag, a volume of cement and water, was spread by an asphalt finisher and then compacted by a macadam or vibratory roller. This method, when used for surface course paving, radically reduced the duration of the construction period, including curing time, in comparison with the normal concrete paving method. The rigidity and strength also satisfied design requirements.

Commercial production of gold, silver, and copper from 1882 to 1984 at Mount Morgan, Queensland, Australia, resulted in the generation of blast furnace, reverberatory, and flash-furnace slags.³⁴ Large stockpiles on the order of 4 million tons of these slags were available at the site. The CSIRO Division of Building, Construction and Engineering was approached by Mount Morgan Ltd. to investigate the feasibility of using reverberatory slag in brickmaking and for making ceramic tiles. The results indicated that it was possible to use the reverberatory slag for making bricks and pavers from coarse slag-blended clay mixes and wall and floor tiles from fine slag-clay mixes, with the required physical properties. The products made from the coarse slag-clay mixes do not exhibit firing shrinkage if fired below the sintering temperature. The dense

products made from fine slag-clay mixes have relatively small shrinkage of 6% to 7%, very low values of apparent porosity and water absorption, and could be used without glazing in some tiling applications.

Slags generated by the ferrous metals industry can be used to produce high-value ceramic materials. The properties of these ceramics can be controlled by composition, additives, and processing parameters. Standard methods of materials handling, such as comminution, and mixing are as applicable to slag as to any other mineralogical raw material. In a study conducted in the U.S. Army Materials Technology Laboratory, foundry slag was ground, homogenized, melted, and formed to produce a glass and then heat-treated to crystallize it into a high-strength glass ceramic.³⁵ The product showed promise as a low-cost, wear-resistant tile material that could be custom cast. This and similar materials made from slags could be used as construction materials, acid-resistant piping, and shock-resistant sheathing.

OUTLOOK

Production of blast furnace slag and steel slag is expected to rebound after a slight decrease in 1991, owing to increased iron and steel production. (See Iron and Steel Annual Report, 1991.)

The ratio of granulated slag tonnage to all blast furnace slag is expected to grow due to environmental and cost considerations.

Electric arc furnace slags are expected to increase and other steel slags to decrease proportionately. The last open hearth furnaces closed in 1991, and large integrated steelworks may be faced with more competition from minimills, which use scrap, thus leading to a higher ratio of electric arc furnace slag to basic oxygen furnace slag.

There is a continued trend for slag companies to be a part of larger domestic and international companies that are diversified in construction and other industries. These larger companies can use the slag for their own downstream markets as well as provide support to the

slag processors with respect to environmental matters that are expected to increase in importance through the end of the decade and beyond. Marketing slag in higher value end uses such as in cement will continue to play an important role in the slag industry.

SODA ASH

By Dennis S. Kostick

Mr. Kostick, a physical scientist with 13 years of U.S. Bureau of Mines experience, has been the commodity specialist for soda ash since 1979. Domestic survey data were prepared by Carleen Militello, statistical assistant; and international data tables were prepared by William Zajac, Chief, Section of International Data.

Continuing with this report, all data are reported in metric units in order to comply with Public Law 100-418 of August 23, 1988. This Federal law requires all Federal agencies to use the metric system of measurement by the end of fiscal year 1992. Although the use of the metric measurement standards was authorized by law since 1866 (Act of July 28, 1866; 14 Stat. 339) and the United States was an original signatory party to the 1875 Treaty of the Meter (20 Stat. 709), the United States has been the only industrially developed nation that has not universally converted to the metric system from the English system of measurements. As foreign trade of soda ash increases and foreign participation in U.S. joint ventures continues, communicating information with an international standard of measurement becomes more important.

DOMESTIC DATA COVERAGE

U.S. soda ash production data are collected by the U.S. Bureau of Mines from monthly, quarterly, and annual voluntary surveys of U.S. operations. Of the six soda ash operations to which a survey request was sent, all responded, representing 100% of the total production data shown in this report.

Data pertaining to soda ash consumption by end use is collected quarterly from the industry. Trade statistics are obtained from the U.S. Department of Commerce, Bureau of the Census. The export data collected by the Census Bureau may not correspond to the export data provided by the soda ash

producers in the quarterly survey of soda ash sales. The discrepancy between the export data sets is because Census data reports the transaction on the date the cargo physically departed from the U.S. port whereas soda ash producers consider a shipment as exported when it leaves the plant. Overland transit time between the plant and port and any carryover export inventory are not taken into consideration.

Most people have never heard of soda ash, yet it is used in many familiar consumer products found in virtually every home—glass, soap and detergents, paper, textiles, and food. Chemically, soda ash is known as sodium carbonate. It is the 11th largest inorganic chemical in terms of production of all domestic inorganic and organic chemicals, excluding petrochemical feedstocks. Internationally, there are two types of soda ash—natural and synthetic. The United States is the world's largest soda ash-producing nation with the world's largest natural deposit of trona, the ore from which soda ash is refined. Because the majority of world output is made synthetically, which usually is more expensive to manufacture, U.S. natural soda ash is extremely competitive in world markets. (See table 1.)

BACKGROUND

Although soda ash represented about 2.4% of the total \$35 billion nonfuel mineral industry that was surveyed by the U.S. Bureau of Mines in 1991, its use in many familiar household products consequently contributes substantially to

the gross national product of the United States. Soda ash is one of the basic inorganic chemicals produced in the world. Most countries do not have economic deposits of sodium carbonate-bearing minerals and must produce soda ash by various manufacturing techniques, which are labor-, capital-, and energy-intensive. In addition, the processes generate byproduct sodium chloride and calcium chloride, which are usually discharged as waste effluent that contribute to environmental problems.

Natural soda ash was probably first obtained as evaporite incrustations along the edges of alkaline lakes in Lower Egypt. It was used about 3,500 B.C. to make ornamental glassware, as evidenced by many of the early Egyptian glass artifacts. The Egyptians also mixed lime and soda ash to make caustic soda. The caustic soda was combined with silicate minerals obtained from the Sinai desert. This made a soluble silica, which was added to aluminum-rich Nile River silt, producing a silica-aluminate cement mortar with superior bonding properties. In the Old Testament, it was referred to as neter but has also been known as natrium, kali, trona, and natron. Until the 18th century, soda ash was obtained mainly by burning seaweeds and marine plants, leaching the soluble material from the ashes, and evaporating the solutions to dryness. About 13 tons of ash yielded 1 ton of sodium carbonate and 14 kilograms (30 pounds) of iodine as a byproduct. The final material was very impure but could be used in the manufacture of glass and soap and detergents. Pliny, a Roman historian,

listed soda ash in the manufacture of glass, as a medicine for colic pains and skin eruptions, and for making bread in the first century A.D.

In 1791, Nicolas Leblanc, a French chemist, developed a process for making soda ash from "salt cake" (from salt and sulfuric acid), coal, and limestone. The French Revolution interfered with its development, and his patent and factory were confiscated with him receiving only token compensation. Napoleon returned his factory to him but Leblanc was not able to raise enough capital to reopen it, and he committed suicide in 1806. More than 30 years passed before the process first became successful in Liverpool, England. The process was not used successfully in the United States except during a short period from July 1884 to January 1885 at Laramie, WY.

Ernest and Alfred Solvay developed an improved method for making soda ash from salt, coke, and limestone, with ammonia as a catalyst in the early 1860's. That process was first used in the United States in 1884 at Syracuse, NY, in a plant that continued to produce soda ash until 1986. It was the first of about 10 synthetic Solvay plants that were in operation by 1939 in the United States, and, ironically, the last one to close. The Solvay process gained in popularity over the years and is now the basic method used throughout the world for making synthetic soda ash. In addition to the Solvay plants, there were three electrolytic process plants in Tyrone, PA, Covington, VA, and Luke, MD, that were operated by West Virginia Pulp and Paper Co. in 1939.

The site of the first commercial production of natural soda ash in the United States was from two deposits known as the Soda Lakes near the present town of Fallon, NV. Asa L. Kenyon acquired title to Little Soda Lake in 1855 and sold it to Higgins and Duffy in 1868, when the first 300 tons of natural soda ash was produced. Production of adjacent Big Soda Lake began in 1875 and reached its peak in 1887. The brines became diluted as the lake levels rose in 1907 because regional dam construction affected the local water table. Searles

Lake in California was originally mined for borax as early as 1874. Soda ash production began in 1926 by the West End Chemical Co. American Potash Corp., formerly the American Trona Corp., was the second company to produce soda ash at Searles Lake in 1931. (See figure 1.)

Definitions, Grades, and Specifications

The following terms are used in the soda ash industry:

Ammonia-Soda Process.—Also known as the Solvay process and lime-soda process.

Dense Soda Ash.—Has a bulk density of 0.96 to 1.06 grams per cubic centimeter (60 to 66 pounds per cubic foot). It is produced by hydrating light soda ash followed by dehydration through calcination to produce denser crystals. In Eastern Europe, dense ash is made by compressing light ash between rollers to increase the density, followed by screening.

Light Soda Ash.—Has a bulk density of 0.51 to 0.62 grams per cubic centimeter (32 to 39 pounds per cubic foot). It is produced by calcining the sodium sesquicarbonate precipitate recovered from the carbonation towers or vacuum crystallizers.

Natural Soda Ash.—Soda ash produced from trona ore, sodium carbonate-bearing brines, or surface mineralization.

Soda Ash.—Synonymous with sodium carbonate. It is a general term that can apply to soda ash produced from natural sources or from various chemical processes.

Sodium Sesquicarbonate.—Can refer to the name for the chemical composition of trona or the chemical process that produces a light- to intermediate-grade of soda ash having an average bulk density

of 0.8 gram per cubic centimeter (50 pounds per cubic foot).

Synthetic Soda Ash.—Term for soda ash produced from one of several chemical processes, such as the Solvay process.

Trona.—The principal ore from which soda ash is made. It is composed of sodium carbonate, sodium bicarbonate, and water. The monoclinic crystals are prismatic to tabular, with colors ranging from translucent (spar variety) to shades of brown, which vary depending on the amounts of contained organic matter. Trona has a specific gravity of 2.17 with a hardness of 2.5 to 3 on the Mohs scale. About 1.8 tons of trona is required to produce 1 ton of soda ash.

The terms "soda ash" and "sodium carbonate" are used interchangeably. The material manufactured from Wyoming trona normally contains more than 99.8% sodium carbonate, and the sodium chloride content ranges between 0.01% to 0.02%. The amount of iron is less than 10 parts per million. Searles Lake brines are processed to yield a product of similar high quality, with salt and sodium sulfate as the principal trace impurities. The average material produced by a Solvay soda ash plant is about equal to the natural product in sodium carbonate content, but often contains a larger quantity of salt. Dense soda ash, because of its greater bulk density, may command a higher price than the light variety and is preferred for glass manufacture because the light soda ash leads to frothing in the glass melt. Light soda ash is preferred by many chemical and detergent industries because it dissolves more readily. Sodium sesquicarbonate has an intermediate bulk density and is used in some detergent and bath salts.

Typical official specifications for soda ash include American National Standard K60, 11-1956 (R1969) "Standard Specifications for Soda Ash," which appears as the American Society for Testing and Materials (ASTM) Designation D458-74 (Reapproved 1979); and British Standard (BS) 3674: 1963 "Specification for Sodium Carbonate

(Technical Grades)." The British Standard specifies, among other requirements, not less than 57.25% Na₂O and not more than 0.005% Fe₂O₃; the ASTM, a minimum of 99.16% Na₂CO₃. Both standards specify methods of testing.

Industry Structure

The U.S. soda ash industry is composed of six companies; five in Wyoming and one in California. All produce natural soda ash only either from sodium carbonate-rich brines or from underground mining of trona ore. Foreign investment in U.S. soda ash operations has risen from 10% of capacity in 1981, when Societe Nationale Elf Aquitaine of France bought Texasgulf Chemical Co., to 37% in 1991. Five of the six U.S. companies have either Australian, French, Japanese, or Korean partners. FMC remains the only U.S. producer without any foreign ownership. (See tables 2 and 3.)

Geology-Resources

The definitions of resources, reserves, and reserve base are published in U.S. Geological Survey Circular 831, Principles of a Resource/Reserve Classification for Minerals. Briefly, "resources" describe the quantity of ore present, regardless of grade or ease of extraction. The "reserves" are the portion of the resource that are economic to mine using the current technology and value of the commodity.

There are more than 60 identified natural sodium carbonate deposits in the world, the largest of which is the trona deposit in southwest Wyoming. Although several of these deposits have been quantified, most are economically insignificant or too remote to be commercially developed. Table 3 lists the countries with known soda ash deposits. All soda ash deposits can be classified in one of five modes of occurrences. In decreasing order of economic importance, they are as follows: buried, surface or subsurface brines, crystalline shoreline or

bottom crusts, shallow lake bottom crystals, and surface efflorescences.

The trona found in the Green River Formation in southwest Wyoming is an excellent example of a buried trona deposit. The Wilkins Peak Member contains 42 beds of trona, 25 of which have a thickness of 0.91 meter (3 feet) or more. Eleven of these exceed 1.83 meters (6 feet) in thickness covering an area more than 3,100 square kilometers (1,200 square miles). The trona beds were deposited about 50 million years ago in the early to middle Eocene epoch in an ancient freshwater lake, named "Lake Gosiute" by Clarence King in 1878. The sodium and carbonate constituents of trona owe their respective origins to the leaching of the extensive pyroxene-andesite volcanic ash layers and the seasonal influxes of carbonate-rich sediments into the local depositional basin. In addition, subterranean thermal springs contributed a significant quantity of dissolved alkaline carbonates as well as sodium, calcium, silica, and bicarbonate ions. Trona can precipitate only in the presence of abundant carbon dioxide, which probably was supplied from the atmosphere and/or the biogenic decay of Eocene plant and aquatic remains. For 4 million years, Lake Gosiute went through many stages of filling and evaporation, thereby depositing more than 42 beds of trona on the lake bottom along with repetitive beds of marlstone, limestone, oil shale, and sandstone-mudstone. The decrease of the inflow to the lake was probably in response to climatic changes that resulted in the final evaporation of the waters. The former Lake Gosiute is the present Green River Basin.

Assuming 1.8 tons of trona yields approximately 1 ton of soda ash, about 47 billion tons (52 billion short tons) of identified soda ash resources could be obtained from the 56 billion tons (62 billion short tons) of bedded trona and the 47 billion tons (52 billion short tons) of interbedded or intermixed trona and halite that are in beds greater than 1.22 meters (4 feet) thick. Approximately 34 billion tons (37 billion short tons) of reserve base soda ash could be obtained from the 36 billion tons (40 billion short tons) of

halite-free trona and the 25 billion tons (27 billion short tons) of interbedded or intermixed trona and halite in beds more than 1.83 meters (6 feet) thick. Although about 15 million tons (16 million short tons) of trona is presently being mined annually, with these minable reserves Wyoming could supply all domestic requirements for more than 3,100 years at the 1991 demand level. As technology improves in the future, mining of the subeconomic grades of ore would further extend the life of the trona deposit to more than 5,100 years. With Wyoming reserves estimated at 20 billion tons (22 billion short tons), the United States, through this one deposit, could supply the world all the soda ash to meet the current demand levels for about 630 years. (See table 4.)

The U.S. Government established a Known Sodium Leasing Area (KSLA) in Wyoming within the perimeter of the trona depositional basin. The trona within the KSLA is subject to Federal and State leasing regulations and private lease agreements. Although most of the leasable trona averages 93% sodium sesquicarbonate, several areas contain lower grade trona because of local depositional contamination along the lake margins, thereby reducing the reserve estimates of that particular area.

A series of Pleistocene playa lakes rich in evaporate minerals found in California comprise the second largest reserves of sodium carbonate in the United States. Subsurface sodium carbonate-bearing brines and crystalline material comprise the resource at Searles Lake, which is a nearly dry playa 15 kilometers (9 miles) long by 11 kilometers (7 miles) wide with an area of about 104 square kilometers (40 square miles). Surface sodium-bearing crystalline minerals predominate at Owens Lake, which was first mined in 1885 by the Inyo Development Co. Both deposits have combined reserves of about 817 million tons (900 million short tons).

Two potential sources of soda ash—nahcolite (natural sodium bicarbonate) and dawsonite (sodium-aluminum-carbonate)—are associated with oil shale in the Piceance Creek basin in northwest Colorado. Identified resources of 29

billion tons (32 billion short tons) of nahcolite and 17 billion tons (19 billion short tons) of dawsonite, equivalent to 18 billion tons and 6 billion tons (20 billion short tons and 7 billion short tons), respectively, of sodium carbonate resources, would be available as a byproduct of oil shale processing or as single mineral extraction. These deposits were formed in middle Eocene time with the nahcolite occurring as aggregates (62%), disseminated crystals (24%), and impure beds (14%).

The only other commercial natural soda ash deposit in the Western Hemisphere, excluding those in the United States, occurs at Lake Texcoco, near Mexico City, Mexico. Two caliche layers at a depth of 46 meters (150 feet) act as a filter and reservoir for the sodium carbonate-rich brine resource. With an average concentration of about 7% sodium carbonate, the resource contains about 180 million tons (200 million short tons) of available soda ash.

The Rift Valley of eastern Africa has several alkaline lakes resembling those of California. Only Lake Magadi in Kenya is presently in production. The soda ash reserves of these lakes are renewed annually from natural active volcanic sources. Other African countries that may become future suppliers of soda ash are Chad, Ethiopia, Niger, the Republic of South Africa, Tanzania, and Uganda. Botswana is developing its Sua Pan salt and soda ash deposit, and final completion of the project is scheduled for 1991. Elsewhere, deposits of natural soda ash occur in Bolivia, Brazil, Canada, India, Pakistan, the U.S.S.R., and Venezuela. Plans are underway to develop deposits in China at Xilin Gol and in the Wulan Buh desert area. A trona deposit in Turkey near Beypazari is also under consideration for development.

Technology

Soda ash from Wyoming trona is mined, crushed, dried, dissolved, filtered, recrystallized, and re-dried. In California, soda ash from sodium carbonate-bearing brines is solution mined, carbonated,

filtered, dried, decomposed, bleached, and recrystallized to dense soda ash.

Exploration.—Because of the scarcity of economic soda ash deposits in the world, many nations continue to search for new prospects. Smaller and less well known deposits are often reevaluated by different groups at different times and with usually the same results. As new techniques of exploring are developed and used, such as Landsat satellite remote sensing imagery and side-scanning radar, new deposits may be discovered.

In the United States, exploring for soda ash continues. An area near the junction of the Black's Fork and Green River in southwest Wyoming has potential. Some of the ground water near Farson contains dissolved trona and organic matter creating a "black trona water." BWAB, a Denver-based company, planned to develop this area and extract the sodium carbonate from the black water and convert the organic material to fungicides, pesticides, and pigments.¹ In Oregon, a few companies have expressed interest in evaluating the sodium carbonate deposits at Summer Lake and Abert Lake, which are near several pulp and paper manufacturers. These manufacturers have traditionally obtained their soda ash and caustic soda pulp-bleaching chemicals from Wyoming and Washington producers, respectively. As soda ash and caustic soda prices increase and overland transportation costs rise, these Oregon deposits may have commercial significance because their locations are nearer to the pulp markets.

Mining.—Commercial mining of Wyoming trona began in 1948, with the first mining on Federal land commencing in 1950. Between 1950 and 1991, more than 223 million tons (245 million short tons) of trona (equal to about 134 million tons or 147 million short tons of soda ash) has been mined. Only about 0.6% of the 36 billion tons (40 billion short tons) of halite-free trona reserve base has been used since mining began.

Underground mining of Wyoming trona is similar to coal mining, except that trona is a harder mineral than coal. The

five present Wyoming soda ash producers use room-and-pillar, longwall, shortwall, and solution mining techniques individually or in combination. The room-and-pillar method has an ore extraction efficiency rate of about 45% (55% of ore remains as pillars for structural integrity), the longwall and shortwall methods each have efficiency rates of about 75%, and solution mining has an efficiency rate of about 30%. These rates are important when calculating the amount of reserves that are minable. Based on the types of mining techniques, the author used a 60% average extraction efficiency rate to calculate reserves (remaining 40% stays in-place as pillars for structural integrity and unavailable for present extraction). The ore is undercut, drilled, blasted, mucked, crushed, and transported to the surface by well-established methods and various state-of-the-art mining equipment. The conventional blasting method using prilled ammonium nitrate and fuel oil (ANFO) is a standard and reliable method. Continuous mining uses vehicles equipped with a rotating cylindrical cutter. Continuous miners are used by Tg Soda Ash, Inc., in its shortwall technique. The longwall technique was used by General Chemical Corp. and is now used by FMC Wyoming Corp. Adopted from coal mining use, the longwall method uses a special track-mounted shearer that moves in front of a hydraulic-operated roof support system.

FMC has pioneered the use of solution mining to dissolve and recover deeply buried trona. Using an array of injection and recovery wells, a solvent (dilute sodium hydroxide) is introduced under pressure to dissolve the underlying trona. This technique has had moderate success since its first commercial debut in 1985. Beginning in 1990, FMC used the majority of the output from its solution mining for manufacture of caustic soda, from which some sodium cyanide was produced.

To reduce mining costs and maintain their competitiveness in the world, many Wyoming soda ash companies implemented continuous belt and mobile track conveyor systems to transport trona

underground more efficiently. This new haulage system has replaced ore-carrying shuttle cars, reduced the mine work force, and increased the quantity of ore mined per shift. Companies have also been considering eliminating conventional mining but retaining other mining methods sometime in the foreseeable future in order to further reduce labor, safety, and other operating costs.

Subterranean brines between 15 and 107 meters (50 and 350 feet) below the surface at Searles Lake in California are extracted using an array of injection and recovery well drilled down to specific depths where mineral concentrations favor maximum extraction. The Argus plant of North American Chemical Co. uses sodium carbonate-rich brines found in the Mixed Layer zone 67 meters to 95 meters (220 feet to 310 feet) below the surface. Solar concentration ponds are used to aerate and concentrate the brine to improve processing efficiency.

Processing.—Crushed trona is calcined in a rotary kiln at 163° to 204° C (325° to 400° F) to dissociate the ore by the monohydrate process, which produces only dense soda ash with carbon dioxide and water as byproducts. The calcined material is combined with water to dissolve the soda ash and to allow separating and discarding of the insoluble material such as shale and shortite by settling and/or filtration. The waste material is piped in a slurry to containment basins, also known as tailing ponds. The resulting clear liquid is concentrated as necessary by triple-effect evaporators or mechanical vapor recompression crystallizers, and the dissolved soda ash precipitates as crystals of sodium carbonate monohydrate, $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$. The crystallization temperature is about 100° C (212° F), which is below the transition temperature of monohydrate to anhydrous soda ash. Other dissolved impurities, such as sodium chloride or sodium sulfate, remain in solution. The crystals and liquor are separated by centrifugation. The sodium carbonate monohydrate crystals are calcined a second time at 300° F to remove water of crystallization.

The resultant finished product is cooled, screened, and shipped by rail or truck in bags or bulk.

An alternate method of soda ash production from trona is the sesquicarbonate process. Crushed trona is first dissolved and filtered to remove insoluble impurities. The liquor is evaporated in vacuum crystallizers, and the sodium sesquicarbonate precipitate is cooled to 38° C (100° F) and centrifuged to produce a pure product, which has uses as such. The sesquicarbonate can be further calcined at 204° C (400° F) to produce anhydrous soda ash of light to intermediate density.

The complex brines of the lower level of Searles Lake are first treated with carbon dioxide gas in carbonation towers to convert the sodium carbonate in solution to sodium bicarbonate, which will precipitate under these conditions. The sodium bicarbonate is separated from the remainder of the brine by settling and filtration and is then calcined to convert the product back to soda ash. The decarbonated brine is cooled to recover borax and Glauber's salt. A second dissolving, precipitating with carbon dioxide, filtering, and calcining the light soda ash to dense, refines the product to better than 99% sodium carbonate.

At Owens Lake in California, crude soda ash has been mined and processed by Lake Minerals Corp. by simply digging perimeter channels allowing the interstitial fluids to drain. The surface was tilled to promote evaporation to reduce moisture content, followed by harvesting with front-end loaders.

At Lake Magadi, Kenya, crude trona is dredged from surface crusts, crushed, washed, and calcined to convert the sodium sesquicarbonate to soda ash. At Lake Texcoco in Mexico, underground brines are recovered and sent to a surface spiral concentrator to promote the solar concentration of the sodium carbonate in solution. On the Kola Peninsula in the U.S.S.R., soda ash is recovered from processing nepheline-bearing rocks. Nepheline, a sodium-potassium-aluminum silicate, is calcined in rotary kilns to yield alumina, potash, and soda ash. The alumina content of the rocks is about one-

half of bauxite but the mining and processing produces byproduct soda ash. The Petukhi and Tanatar (Mikhaylovskiy) natural soda ash lakes in Altay Kray of West Siberia provide some source of natural product.

Synthetic soda ash using the Solvay process uses salt and limestone as raw materials. A purified sodium chloride brine is saturated with ammonia and carbon dioxide gas to produce ammonium bicarbonate, which reacts with the salt to form sodium bicarbonate and ammonium chloride. The sodium bicarbonate is calcined at 177° to 218° C (350° to 425° F) to light soda ash, and the gases produced are recycled back to the liquid phase. The liquid containing ammonium chloride is reacted with milk of lime to recover the ammonia and to produce byproduct calcium chloride. Limestone and coke are required to make the milk of lime. Dense soda ash is produced by hydrating light ash to produce larger sodium carbonate monohydrate crystals. The crystals are dehydrated in dryers to change the bulk density. To produce 1.0 ton of synthetic soda ash requires about 2.8 tons of steam, 1.7 tons of salt, 1.4 tons of limestone, 0.6 ton of coal for the boilers, and about 0.2 ton of coal for the dryers. Disposition of effluent streams containing high concentrations of calcium chloride and sodium chloride is a major problem for all Solvay soda ash plants. The Solvay process discharges about 1.7 tons of waste products that include sodium chloride and calcium chloride.

Other chemical processes can produce synthetic soda ash. The Japanese use an ammonium chloride coproduction process, a variation of the Solvay process, that converts all the sodium content of the salt into soda ash, whereas the Solvay process converts only about 70% of the sodium. The Japanese process also produces byproduct ammonium chloride that can be used as a fertilizer for growing rice in wetlands. The New Asahi process was also developed in Japan and uses less energy than the traditional Solvay process. An electrolysis-free process to produce vinyl chloride monomer with coproduct soda ash was developed in the Netherlands but

has not been in commercial operation. The method yields soda ash instead of caustic soda and uses steam and carbon dioxide instead of electricity. The energy consumption is reported to be one-half that of the Solvay process.

Recycling.—There is no recycling of soda ash by producers; however, many glass container manufacturers are using cullet glass, thereby reducing soda ash consumption.

Byproducts and Coproducts

Borax, potassium chloride, sodium chloride, and sodium sulfate are produced as coproducts with soda ash by North American Chemical in California. In Wyoming, only value-added products, such as sodium bicarbonate, sodium hydroxide (caustic soda), sodium sesquicarbonate, and sodium tripolyphosphate, are produced from trona ore. Soda ash-bearing purge liquors and waste streams, normally considered waste byproducts, have been sold to powerplants for flue gas desulfurization because of their sodium carbonate content.

Substitutes

Sodium hydroxide can be substituted for soda ash in some applications, but usually only at a higher cost and when available. About 1.3 tons of soda ash must be used to have the same chemical effect as 1.0 ton of caustic soda. Soda ash is usually shipped in dry, bulk form whereas caustic soda is transported as a liquid in various-sized closed containers.

An alternate source of soda ash is nahcolite, natural-occurring sodium bicarbonate found in a vast deposit in Colorado. The nahcolite could be converted to soda ash by calcination.

Economic Factors

Prices.—The list prices of natural and synthetic soda ash historically were identical until the mid-1970's when higher energy costs and costs to implement the controls imposed by

antipollution legislation caused the synthetic soda ash price to increase compared to that of the natural material. New natural soda ash producers came on-stream in 1976 and 1982 and contributed to slight changes in price-value trends. Changes in the domestic demand pattern also affected average annual values, especially after 1980, when domestic demand declined.

The list prices quoted in trade journals or by producers differ from the annual average values reported to and by the U.S. Bureau of Mines. The values are the combined total revenue of California and Wyoming natural bulk, dense soda ash sold on an f.o.b. plant basis at list-prices, spot-prices, discount, long-term contracts, and for export, divided by the quantity of soda ash sold. This value may or may not correspond to the posted list prices. (*See table 5.*)

Tariffs.—The United States imposes a 1.2% ad valorem tariff on imports of soda ash from countries having most-favored-nation (MFN) status. There is a 8.5% ad valorem tariff on imports from non-MFN sources.

Many nations levy import tariffs or antidumping duties of varying percentages on U.S. soda ash. In western Europe, an antidumping duty of 67.5 European Currency Units (about \$67.13 per ton) had been imposed on U.S. soda ash sold on the continent; however, the duty was rescinded in late 1990. Import tariffs in some other countries in 1991 were as follows: Republic of South Korea, 15%; Taiwan, 12.5%; Thailand, 10%; Indonesia, 5%; Japan, 3.9%; and Malaysia, 2%. Some of these duties will decline over time.

Taxes.—The total effective tax rate on the Wyoming trona industry is about 12.64% and comes from two major taxes. The trona severance tax of 5.5% is a State excise tax on minerals as they are removed from the ground and are applied as a percentage of assessed valuation. The collected taxes are disbursed to the Permanent Wyoming Mineral Trust Fund (2.0%), the General Fund (2.0%), and

the Capital Facilities Revenue Account (1.5%). The property, or ad valorem, tax is about 7.14% of the assessed value of trona produced from the mines. The ad valorem taxes on trona are higher than any other Wyoming minerals, including oil, gas, and coal. Other ad valorem taxes are placed on the assessed value of real property (buildings and equipment) and State sales and use taxes on equipment and facilities.

Royalties.—Soda ash mined on Federal lands is subject to the Mineral Leasing Act of 1920, which provides royalty payments to the United States Government. The Federal royalty is 5% of the quantity or gross value of the output of the product at the point of shipment to market. Each Federal lease also has other costs, such as bonds, acreage rental fees, sodium prospecting permit application fees, and permit bonds. In Wyoming, the soda ash deposit within the Known Sodium Leasing Area is under the jurisdiction of the U.S. Government (administered by the Bureau of Land Management), the State, and the Union Pacific Railroad, which was given alternate 1-square-mile sections north and south of the railway it constructed in the 1860's. Of the almost 915,000 total acres of sodium mineral estate, the Federal ownership is 55.7%, Union Pacific, 38.1%; and the State, 6.2%. Sixteen lessees hold 53 active and inactive Federal leases having a total of 75,783 acres. In order to prevent a possible land monopoly, no lessee may hold more than 15,360 acres of Federal land, but may lease more private or State land. The State royalty rate is tied to the Federal rate of 5%; however, the private royalty rate varies. One-half of all Federal royalties collected by the Minerals Management Service is disbursed back to Wyoming for various State and local programs.

In California, the Federal Government maintains 33 sodium mineral leases having 26,799 acres. The major lessee is North American Chemical Co., which produces soda ash, sodium sulfate, and salt on its sodium leases on Searles Lake.

Depletion Provisions.—The mineral depletion allowance granted to the mining industry through legislation passed by the U.S. Government has been an important inducement for companies willing to accept the risk and high cost of mining development. The concept of depletion allowances for minerals is similar to the depreciation of other assets. Although cost depletion and percentage depletion are two methods used to compute depletion deductions, most companies prefer to use the latter. About 100 mineral categories are entitled to percentage depletion. The rates range between 5% and 22% of the gross income from the mineral property, depending on the mineral and location (foreign or domestic), and are subject to a limitation of 50% of the net income from the property. The significance of percentage depletion is that the deduction is based on the quantity of the first marketable product (soda ash and not trona) and not necessarily on the amount invested. The mineral depletion allowance for soda ash is 14% for U.S. companies mining from domestic or foreign sources.

Operating Factors

Operating factors are different for mining companies than for manufacturing facilities engaged in producing natural soda ash and synthetic soda ash, respectively. The shift in U.S. soda ash production from synthetic to natural has been caused by higher costs attributed to the greater energy and labor requirements of the Solvay process and to environmental regulations. Within the natural soda ash industry, the operating factors vary for producing the commodity from brines and from trona ore.

Environmental Requirements.—U.S. natural soda ash facilities do not have difficult problems disposing of effluents. Residual insoluble material is piped to surface tailing ponds and allowed to settle. Some soda ash in solution that is not economically recoverable from processing is discharged and is converted to sodium decahydrate in the ponds and precipitates on the bottom of ponds to

become an additional source of soda ash if needed. For example, FMC has been dredging some of its sodium decahydrate that has been accumulating since 1950. Some pond water is recirculated into the mines and used as drilling and cutting coolant. Because of changes in environmental legislation in Wyoming, Tenneco Minerals has begun discharging its waste material into abandoned sections of its underground mine, thereby using less surface area on the surface for tailing ponds. The expense of underground discharge is partially offset with the reduction in costs of constructing and maintaining surface tailing ponds.

The alkaline surface ponds, with a pH up to 10.5, have posed some problems for migratory fowl that land on the ponds. The alkaline solutions strip the insulative natural oils from the feathers, thereby increasing the vulnerability of the birds to death from hypothermia. Also, birds have drowned because of the weight of sodium decahydrate that crystallizes on them when the temperature falls below 4° C (40° F). All trona producers have established a rehabilitation program to recover and release contaminated birds and to minimize the mortality and morbidity rate.

Land surrounding trona operations in Wyoming is relatively undeveloped, and the influx of large numbers of workers has caused great strain on the local facilities for housing, schools, shopping, and entertainment. Soda ash companies have provided financial assistance to aid local government in handling any overloads caused by the migration of their employees and families into the community. The companies have given financial aid to employees purchasing homes in the surrounding communities and other fringe benefits such as low-cost transportation to and from work.

Toxicity.—Although soda ash is not considered a highly toxic substance, contact with the eyes may be injurious and prolonged contact with the skin may cause irritation, especially to those who have allergic reactions to alkaline materials. It has also been found to be corrosive to the stomach lining if

ingested. It has an acute oral lethal dose (LD50) of 2.8 grams per kilogram (when tested on a rat) and a primary skin irritation index (PSII) of 2.54 (when tested on a rabbit). Simultaneous exposure to soda ash and lime dusts should be minimized because in the presence of moisture, as from perspiration, the two materials combine to form caustic soda, which is very harmful. Soda ash is not flammable, and the dust is not explosive.

Employment.—According to the Wyoming Office of the State Inspector of Mines, the Wyoming soda ash industry in 1980 employed 3,931 people, of which 1,817 were underground workers, to produce 11.7 million tons (12.9 million short tons) of trona. In 1991, 3,020 people were employed, of which 1,237 underground workers produced 14.6 million tons (16.1 million short tons) of ore. From 1980 through 1991, the underground work force was reduced about 32% while the quantity of trona increased 25%. This represented an 84% increase in the amount of ore mined per worker per year; 6,439 tons in 1980 and 11,803 tons in 1991.

Energy Requirements.—Natural soda ash plants consume considerably less energy per unit of product produced than do synthetic soda ash facilities. As the cost of energy has increased since the 1973 energy crisis, the differential in production costs between natural and synthetic soda ash has become greater. This is one of the major reasons why U.S. natural soda ash has maintained its competitiveness in the world market.

An early U.S. Bureau of Mines energy study using 1973 data indicated that 15.8 million British thermal units (Btu's) was required to produce 1 ton of synthetic soda ash, whereas the energy requirement to produce the same quantity from trona was 7.2 million Btu's. The domestic soda ash industry has reduced its energy requirements significantly since 1973 by replacing gas-fired dryers with steam-tube units and installing mechanical vapor recompression units to replace triple-effect evaporators. The industry has also

converted to coal exclusively or combined with other fuel sources. Plants operated by Tg and Tenneco and the Argus plant operated by North American Chemical Co. use coal only. As a result of these energy saving measures, the Wyoming soda ash industry lowered its energy requirement to a range of 4.5 to 6 million Btu, depending on the individual producer. An estimated one-half of the energy consumed in natural soda ash refining using triple-effect evaporators is for evaporating, one-third is for calcining, and the remainder, for drying.

These energy requirements exclude the amount of energy needed to ship soda ash to foreign markets. Although it has been estimated that it would take about 2.9 million Btu's of additional energy to transport soda ash by rail and by ship to western Europe, nevertheless natural soda ash production requires less energy than the Solvay process or any other synthetic technique.

Transportation.—The western geographic locations of the domestic natural soda ash industry often pose problems because of the great shipping distance to most foreign customers. Even within the United States, the majority of domestic consumption is in the Midwest and east of the Mississippi River. Overland and ocean transportation rates become important factors in the delivered price of soda ash and must be considered seriously in negotiations with foreign consumers who often have alternate supply sources. Bulk freight rates can usually be reduced by shipping in larger volumes, such as in 7,500 ton units.

The railroad is the dominant mode of transportation for the shipment of soda ash. In Wyoming, the Union Pacific Railroad provides the main service to the industry. All bulk soda ash that is railed is carried in covered hopper cars, each handling about 98 tons. Although the railroad companies make their cars available, most soda ash companies have their own sizable fleet.

Beginning in 1985, soda ash was shipped in large quantities by truck. Bonneville Transloaders, Inc. trucked soda ash from Green River to the

Burlington Northern Railroad's line at Shoshoni, WY. Of the almost 8.4 million tons (9.2 million short tons) of soda ash produced in Wyoming, Bonneville trucks about 770,000 tons (850,000 short tons) out of Green River. Other trucking companies have started similar operations with the Southern Pacific (shipping more than 227,000 tons or 250,000 short tons per year) and Denver Rio Grande railroads to compete with Union Pacific.

The railroads have been involved in establishing soda ash bulk loading terminals at ports to handle large volumes of material for export. Kansas City Southern Railroad's terminal at Port Arthur, TX, has a railcar unloading capacity of about 1,000 tons per hour. Material is conveyed to a ship loader spout for transfer to bulk cargo ocean vessels. Port Arthur was the third largest port of the 23 ports that shipped soda ash in 1991, most of which was shipped to South America. The Columbia-Snake customs district in the Pacific Northwest has a bulk loading terminal that transferred the most soda ash, 57%, in 1991.

ANNUAL REVIEW

Issues

Although world soda ash production declined by 2.9% in 1991, domestic production decreased only 1.6%. These declines were a result of the adverse economic conditions in the world that affected virtually every industry sector that consumed soda ash. Despite the decrease in U.S. production, U.S. exports rose 14%, which indicates the preference for the less expensive U.S. product by foreign consumers.

The major issues and events in 1991 that affected the U.S. soda ash industry were some changes in the international activities of some of the world soda ash producers. Botswana brought on-stream its new natural soda ash facility, Solvay et Cie of Belgium reclaimed its old synthetic soda ash plant in Bernburg in eastern Germany, and Imperial Chemical Industries of England sold its synthetic soda ash plants in England and its natural

soda ash operation in Kenya. In addition, plans were announced to close one synthetic soda ash plant in Czechoslovakia and in France and construct one in Saudi Arabia.

The elimination of the antidumping duties in 1990 on U.S. soda ash entering Europe permitted U.S. soda ash exports to that region to rise from 6% of total exports in 1990 to 13% in 1991. Other important issues confronting the growth of U.S. soda ash have been reactions to the political events in Eastern Europe and the reunification of Germany, both areas that have tremendous potential for increased soda ash consumption. The export opportunities are encouraging, pending a favorable resolution to the political and economic turmoil in that area of the world.

Production

Domestic production of natural soda ash from California and Wyoming decreased slightly to 9.005 million tons. About 117,000 tons of soda ash equivalent from soda liquors and mine waters was included in the total and used primarily for neutralizing powerplant process water. The liquors represent a growing market for soda ash producers and provide additional revenue.

At Green River, WY, Tenneco Minerals Co. commissioned its 75,000-ton-per-year liquid caustic soda plant and its 50,000-ton-per-year sodium sulfite facility, both of which use crude trona ore as feedstock. These two commodities take advantage of the same inexpensive mineral feedstock that is used to make refined soda ash. Producing additional value-added products from trona helps provide more revenue for the producing companies.

On May 28, 1991, Tg Soda Ash, Inc., and ATOCHEM North America Inc., both members of Societe Nationale Elf Aquitaine of France, awarded an engineering contract to Ahlstrom Recovery Inc., a global leader in designing and constructing causticizing and lime kiln equipment.² The project to make chemical caustic soda was announced in August 1990. The plant will

have an annual production capacity of 136,000 tons (150,000 short tons), which was higher than originally reported, with startup scheduled for 1992. By yearend, the design capacity of the facility reported was downrated to about 91,000 tons (100,000 short tons). The company will use available sodium carbonate-rich mine water to produce the caustic soda. ATOCHEM has a chloralkali facility in Tacoma, WA, that produces electrolytic caustic soda and coproduct chlorine. Once completed, there will be three Wyoming soda ash plants that have the capacity to produce chemical caustic soda.

In August, Rhone Poulenc of Wyoming awarded a \$10.5 million contract to Jacobs Engineering Group to provide engineering, procurement, and construction services to increase production capacity at its Wyoming soda ash facility. Upgrading improvements will include ore size reduction and screening, material transport, calcining, recrystallization, evaporation, air pollution control, and product bagging and loading. Once implemented, the nameplate capacity of the plant will increase from 1.78 million tons (1.96 million short tons) to 2.0 million tons (2.2 million short tons).³

On December 31, 1991, Rhone Poulenc of Wyoming transferred all of its assets into a new limited partnership in which it became a limited partner. The name of the new Delaware-based limited partnership is Rhone Poulenc of Wyoming, L.P. No changes in personnel or operational procedures occurred in the transaction.

Consumption and Uses

U.S. apparent consumption in 1991 decreased 6% compared with that of the previous year, whereas reported consumption declined 4%. The discrepancy between the two was attributed to disagreement between the sources of export data used to derive consumption statistics. The two sources were the Bureau of the Census, which reports exports upon departure from the U.S. port, and the soda ash producers,

which consider a shipment as exported when their export association (ANSAC) takes charge at California or Wyoming plant sites. Transit times between the plant and port and carryover export inventories contribute to the discrepancy between reported and apparent consumption.

The economic recession in 1991 had a negative effect on the domestic glass industry. Based on reported industry sales, the manufacture of glass products decreased 6%. Glass manufacture represented about 48% of domestic soda ash consumption, with the container sector comprising 61% of this end use; flat, 26%; fiber, 7%; and specialty, 6%. The other end uses include chemicals (primarily sodium bicarbonate, sodium chromates, sodium phosphates, and sodium silicates), 24%; soap and detergents, 13%; distributors, 6%; flue gas desulfurization, 3%; and pulp and paper, water treatment, and miscellaneous, 2% each.

U.S. reported consumption of soda ash decreased in the chemical, soap and detergent, and flue gas desulfurization sectors in 1991. The change in demand was because of the general economic conditions of the major soda ash-consuming markets.

Less soda ash was used in glass containers because of the increased use of recycled cullet. Sales to the flat glass sector declined mainly due to the downturn in the national economy that adversely affected the building construction and automobile industries. The industrial building construction industry consumes about 57% of all flat glass made, whereas the automotive glass sector used 25%. The remainder went to specialty flat glass products. (See table 6.)

The third largest use of soda ash is in detergents. It is used as a builder to emulsify oil stains, reduce the redeposition of dirt during washing and rinsing, provide alkalinity for cleaning, and soften laundry water. In addition, soda ash is a component of sodium tripolyphosphate (STPP), another major builder in detergent formulations, but soda ash consumption has been

decreasing because phosphatic detergents can contribute to the environmental problems of eutrophication. Many regions of the nation have adopted phosphate limitations or bans. These areas represent about 33% of the U.S. population. In response to the environmental issue, detergent manufacturers began reformulating their detergents to make compact and superconcentrated products. These reformulations require sodium silicates and synthetic zeolites, which are made from soda ash. Liquid detergents, which do not contain any soda ash, compete with powdered detergents and command 40% of the household laundry detergent market, up from only 15% in 1978.

Stocks

Yearend stocks of dense soda ash in plant silos, warehouses, terminals, and on teamtracks amounted to 233,941 tons. Producers indicate that a potential supply problem could exist when inventories fall below 180,000 tons. Most consumers of soda ash do not have storage facilities to accommodate large quantities of soda ash and must rely on suppliers to provide the material on a timely basis.

Markets and Prices

Domestic and export sales are essentially the two markets for soda ash. In the domestic market, the large volume buyers of soda ash are primarily the major glass container manufacturers, whose purchases are seasonal (more beverage containers made in second and third quarters for summertime beverage consumption). Soda ash sales to the flat glass sector are usually dependent on the state of the economy because the largest use of flat glass is in automobile manufacture and residential housing and commercial building construction. These two major industrial sectors are especially sensitive to changing economic conditions. If construction starts and automobile sales are up, soda ash sales will proportionally follow.

On August 12, Rhone Poulenc Basic Chemicals raised its off-list price by \$6

per short ton for dense soda ash with a limit of \$98 per ton for its list price. FMC Corp. announced that effective September 1, its off-list price would increase by \$6 per short ton with the list price not to exceed \$98 per ton. Both companies raised their bulk light ash list prices by \$5 per short ton to \$103 per ton. In late August, General Chemical and Tenneco made similar announcements. General's \$6 per short ton price hike would be effective August 26 while Tenneco's would be effective immediately. North American Chemical Co. of California followed the Wyoming producers and raised its off-list price by \$6 effective September 9. The f.o.b. Wyoming prices per short ton are: bulk dense, \$98; bulk "Lite," \$103; 100 pound bags of dense, \$146; 100-pound bags of "Lite," \$151; 50-pound bags of dense, \$156; and 50-pound bags of "Lite," \$161.⁴

Despite the downturn in domestic soda ash consumption, the average annual value for dense natural soda ash, f.o.b. Green River, WY, and Searles Valley, CA, was \$92.79 per ton (\$84.18 per short ton), which was an increase of 1.6% over that of the previous year. The value is not a "price"; it is the value of the combined revenue of California and Wyoming bulk dense soda ash sold on an f.o.b. plant basis at list prices, spot prices, discount, long-term contracts, and for export, divided by the quantity of soda ash sold. (See table 7 and figure 2.)

Foreign Trade

U.S. soda ash exports rebounded in 1991 to reach a record high of 2.7 million tons. U.S. exports to 49 countries, on a regional basis, were as follows: Asia, 40%; South America, 22%; North America, 14%; Europe, 13%; Africa, 5%; Oceania, 3%; and Central America, the Middle East, and the Caribbean, 1% each. (See tables 8, 9, 10, and 11 and figures 3 and 4.)

World Review

Solvay et Cie of Belgium and Imperial Chemical Industries of England (ICI), Europe's two largest synthetic soda ash producers, were fined a total of \$64 million by the European Community Commission for operating as a cartel in the European Currency Unit (ECU) 1 billion European soda ash market. The fine is the largest ever imposed by the Commission. In addition to Solvay and ICI, which were fined ECU 30 million and ECU 17 million, respectively, Chemische Fabrik Kalk of Germany was also fined ECU 1 million. The three companies violated Articles 85 and 86 of the Treaty of Rome that pertain to restrictive practices of competition. According to the Commission, Solvay kept out of United Kingdom and Irish markets while ICI kept out of selling to the European continent. In addition, the two companies operated an illegal rebate scheme that made it unattractive for customers to obtain alternate supply sources.⁵

The European Community Commission eliminated the antidumping duties and price commitments on imported soda ash entering the region from the former East Germany. Products exported to eastern Germany by the U.S.S.R., Bulgaria, Czechoslovakia, Hungary, Poland, Romania, and Yugoslavia on the basis of former bilateral agreements will continue to be exempt from antidumping or customs duties until yearend 1992, provided the goods are consumed in eastern Germany or undergo a transformation that makes them "of EC origin."⁶

Industry Structure.—The developed nations are generally the largest consumers of soda ash. Although the production and consumption quantities vary among the countries, the end-use patterns are basically the same (e.g., glass, chemicals, and detergents are the major sectors). Although the United States is the largest soda ash-producing country in the world, foreign ownership in the U.S. soda ash industry is presently 30% of nameplate capacity.

Eleven countries have the capability to produce more than 1 million tons annually. The major ones include, in descending order, the United States, U.S.S.R., China, the Federal Republic of Germany, India, Japan, France, and Bulgaria. Most of these countries have large populations that require consumer products made with soda ash. The lesser developed nations tend to have greater soda ash demand and higher rates of growth as soda ash-consuming industries are developed. (See table 12.)

Capacity.—World soda ash production capacity is about 35 million tons divided among 36 countries. Approximately 70% of world capacity is synthetic soda ash, 30% natural. The United States represents 28% of world capacity, and 94% of the total natural capacity.

The largest soda ash company in the world, excluding State-owned facilities, is Solvay et Cie of Belgium. It operates nine plants in seven countries and has a combined annual capacity of more than 4.3 million tons. FMC Wyoming Corp. of the United States is the second largest, with 2.59 million tons (2.85 million short tons) of capacity.

Botswana.—The \$504 million natural soda ash project of Soda Ash Botswana (SAB), the venture formed by the Botswana Government and African Explosives and Chemical Industries with its partners, the Anglo American Corp. and De Beers Holdings, commenced production in April 1991. A wellfield containing 40 wells covering 200 square kilometers was developed to supply the newly constructed soda ash refinery. The wells were sunk to depths of about 35 meters. Most of the output from the 300,000-ton-per-year facility was dedicated to markets in the Republic of South Africa. To assist the export market, SAB built a storage facility at Natsalspruit, Republic of South Africa, that will accommodate 40,000 tons of soda ash. Sales to South Africa will be handled by Suachem, a Botswana subsidiary of Chemical Services Ltd. Soda ash sales to Zambia and Zimbabwe will be

administered by SAB's main office at Sua Pan.⁷

Czechoslovakia.—Tonaso, the state agency that owns a synthetic soda ash plant at Nestemice, North Bohemia, announced that it will shut down the 100,000-ton-per-year plant, which was built in 1906. Solvay et Cie was invited to inspect the plant with the idea of purchasing it; however, the cost to retrofit the facility with more modern equipment was not cost effective. The site will continue to serve as a distribution center for Solvay's soda ash entering Czechoslovakia from its Bernburg, Germany, soda ash plant, which is located nearby, and was recently returned to Solvay in 1991. Once Tonaso is privatized in mid-1992, it will set up joint projects with Solvay.⁸

Germany, Federal Republic of.—On September 1, Solvay et Cie of Belgium regained control of its 540,000-ton-per-year synthetic soda ash plant at Bernburg, eastern Germany, which it lost in 1939 when the Nazis took control. About \$114 million will be invested in the next 5 years to modernize the light soda ash plant, and one-half of this investment will be spent to adjacently construct a 300,000-ton-per-year dense soda ash plant. Dense soda ash, which is scarce in central Europe, is preferred by the glass industry. The new plant is expected to be on-stream by 1993 and will serve some of the markets in Czechoslovakia that were disrupted when Solvay announced the closure of the Nestemice facility in 1991. In addition, the Bernburg complex is in the Sachsen-Anhalt region, which is geographically suited to serve markets in eastern Germany and Central Europe. The Bernburg soda ash plant began operation in July 15, 1883.⁹

Saudi Arabia.—Plans were approved for International Chemical Industries and Trading Co. Ltd. to construct a 250,000-ton-per-year synthetic soda ash plant at Al Jubail, near the Persian Gulf coast. One-half of the plant's production was slated for domestic consumption and the

remainder for export to other Middle Eastern countries. The \$240 million facility is scheduled to begin construction by mid-1993 and to be on-stream by 1996 using Akzo Salt and Basic Chemicals International BV ammonia-soda technology.¹⁰

Turkey.—Etibank, the state mining agency, awarded a mining engineering contract to CDF International to investigate the best method to mine the Beypazari trona deposit. Eight companies remain prospective partners with Etibank. They are BHP—Utah, FMC Corp., Rhone Poulenc, Solvay et Cie, and the four Turkish companies Demirexport, Orkimsen, Stfa, and Sise CAM.¹¹

United Kingdom.—Imperial Chemical Industries (ICI) sold the bulk of its world soda ash operations in June to Penrice Ltd. of Australia for \$150 million. Penrice previously bought ICI's 400,000-ton-per-year synthetic soda ash plant in Australia in 1989. The purchase includes all of ICI's soda ash plants in England, which have a combined capacity of 1 million tons, and its natural soda ash plant at Lake Magadi, Kenya, which has an annual production capacity of 300,000 tons. ICI retains its 61% share in the soda ash operation in Pakistan. That plant has a capacity of about 100,000 tons per year. Penrice's acquisitions were renamed Brunner Mond Holdings Ltd., which was the original name of the company before ICI was formed in 1926. Under this parent corporation, the English operation will be known as Brunner Mond and Co., the Kenyan operation as Magadi Soda, and the Australian operated as Penrice Soda Products.¹²

OUTLOOK

The world soda ash industry is restructuring itself to become more competitive in response to the growing international environmental movement. Older, less profitable synthetic soda ash plants will be evaluated for their effectiveness and closed if necessary. The closure of the soda ash plants in Czechoslovakia and France in 1991

emphasizes this. Foreign companies will continue to consider investing in natural soda ash ventures in Wyoming and California in order to guarantee long-term and inexpensive supplies of soda ash.

Exports

The outlook for U.S. soda ash is excellent. The two largest exporting organizations in the world are Solvay and the American Natural Soda Ash Corp. (ANSAC). Although ANSAC is prohibited from exporting to the European Community nations, the six individual U.S. soda ash producers will strive to increase exports to that region. Export opportunities to the Middle East and South America are very favorable. The changes in the political situation in the U.S.S.R. and eastern Europe may also lead to more U.S. exports to meet the growing demand for consumer products in those areas. The limiting factor, however, may be the lack of available hard currency and the internal manufacturing capabilities of the industries that use soda ash.

Glass

Domestic consumption of soda ash in the glass container sector is declining because of (1) the increasing use of cullet; (2) the national interest in recycling; and (3) the continuing competition with polyethylene terephthalate (PET) plastic containers.

Glass container shipments were less in 1991 than those in previous years. The public's perception that glass is completely recyclable compared to plastics will raise the quantity of cullet now being consumed. Aside from the problems with plastics' recyclability, the public also is concerned about the dioxin emissions from incineration of polyvinyl chloride (PVC) bottles. Flat glass consumption was also down because of adverse economic conditions affecting housing starts and automobile sales.

Municipal landfills are a growing national problem. Glass reportedly accounts for 8.4% of disposable household waste. The U.S.

Environmental Protection Agency has a goal of reducing the Nation's waste by 25% by 1992. It is probable that new taxes will be placed on items manufactured at the source of production to encourage greater use of recycled products. Rebates would be given for every ton of recycled material utilized.

Chemicals

The global chloralkali supply and demand situation in 1991 was not a major problem as was forecast previously. Although a few chloralkali plants shut down during the year, they were basically the unprofitable ones. Chemical caustic soda produced by the lime-soda process will satisfy part of the projected caustic soda shortages. A potential 545,000 tons (600,000 short tons) of caustic soda could be made available from Dow Chemical, pending its decision to produce propylene oxide by a different alternative method. By yearend 1991, the domestic chlorine market rebounded and caustic soda became available at less expensive prices.

Soap and Detergents

About 10 million tons of laundry detergents is consumed annually in the world. Most detergents are composed of many active and inert chemical ingredients. Household liquid detergents and phosphate-free detergents are considered environmentally safe products. More soda ash has been added as a phosphate-replacement builder in various detergent formulations in order to meet regional phosphate discharge requirements.

The environmental movement in Europe has also prompted foreign detergent manufacturers to consider changing formulations to reduce phosphate content. In West Germany, consumption of phosphates in detergents dropped from 276,000 tons in 1975 to 80,000 tons in 1987. The quantity of packaging waste discarded to landfills prompted detergent manufacturers to test-market compact and superconcentrated products in different regions. Whatever amount of soda ash lost due to

reformulation could be partially offset from the use of soda ash in synthetic zeolites and sodium silicates in the new formulations.

Consumer preferences also may determine the preferred detergent and format (i.e., liquid versus powdered, unit dose packets versus bulk). Depending on the choice, the growth of future soda ash sales is optimistic.

Pulp and Paper

Although the U.S. pulp industry is growing at about 2.75% per year, changes are taking place to alter the pulpmaking and papermaking processes. Pulp mills are striving to address the environmental issues regarding dioxins and furans, improve productivity, reduce costs, and improve paper quality. One solution is alkaline paper-sizing, which produces alkaline-based paper rather than acid-based. The conversion is not being implemented as fast as the environmental issue is mounting. Other alternatives include substituting certain pulping chemicals.

Dioxins, created from chlorine molecules introduced in the paper bleaching process, have been detected in bleached paper products as reported in a study of the 104 kraft-pulp mills in the United States. To avert the public's reaction to the issue, the industry began investigating substituting chlorine-base chemicals for nonchlorine pulping and bleaching agents, such as oxygen and hydrogen peroxide. About 1.8 million tons of chlorine is used in pulp bleaching annually. Industry sources estimate a 25% to 30% reduction in chlorine consumption by 1995. If this forecast is accurate, coproduct caustic soda, which is used to delignify wood pulp, could be in short supply. This situation could result in additional quantities of soda ash being used instead of caustic soda, although it would take 1.3 tons of soda ash to have the same chemical effect of 1.0 ton of caustic soda. FMC Wyoming Corp., Tenneco Minerals Co., and Tg Soda Ash, Inc. have made announcements to produce caustic soda from their Wyoming soda ash operations. Although the

majority of the output is for captive needs, the opportunity will demonstrate the economic feasibility of producing caustic soda from nonsalt feedstocks. Soda ash consumption in the pulp and paper sector could increase during the next few years depending on the strength of chlorine demand, which is influenced by the strength of polyvinyl chloride sales.

Flue Gas Desulfurization

The Clean Air Act, as amended by Public Law 101-549, will require the Nation's powerplants to reduce emissions of sulfur and nitrogen compounds produced from burning fossil fuels. Although most high-sulfur coal is used in eastern powerplants where inexpensive calcium-base compounds are located, sodium-base sulfur dioxide removal agents, such as trona and nahcolite, have opportunities for commercial development in the west.

In 1991, about 171,000 tons of soda ash was used for reducing stackgas emissions in the West and Midwest. Transportation costs will reduce the competitiveness of sodium minerals in the East in the future; however, the concern regarding water quality and quantity will be major issues in the Western United States in the 1990's. Several wet-scrubbing utility plants, which use tremendous amounts of water, are evaluating the economics of replacing traditional wet-scrubbing systems using lime with dry-injection technologies using calcium- and sodium-base agents. The addition of some sodium minerals removes additional sulfur and a substantial amount of the nitrogen materials. Eastern powerplants will probably use low-sulfur coal rather than use trona or nahcolite resources found in the West. As Western powerplants retrofit older facilities with dry-injection scrubbing equipment to conserve water, demand for soda ash will increase.

Although the outlook for the U.S. soda ash industry is very good, the structure of the industry continues to change as foreign participation increases. The United States will remain an

important supply source of inexpensive natural soda ash for international consumption. However, a growing percentage will be shipped by the foreign partners of the U.S. resource—primarily Australia, France, Japan, and the Republic of Korea. More shares of the U.S. soda ash industry are available for joint venture at the present time.

Average annual value:											
Dollars per short ton	\$91.19	\$88.35	\$76.95	\$67.00	\$67.82	\$65.29	\$66.78	\$66.96	\$77.07	\$82.85	\$84.18
Dollars per metric ton	\$100.52	\$97.39	\$84.82	\$73.85	\$74.76	\$71.97	\$73.61	\$73.81	\$84.96	\$91.33	\$92.79

¹Estimated. ²Revised. NA Not available; included in "Other."

³Natural and synthetic except where noted.

⁴Natural soda ash only for 1980, and 1987 and thereafter; natural and synthetic from yearend 1981-86.

⁵Also known as apparent consumption (production plus imports minus exports plus or minus stock changes) and is equal to "Total U.S. primary demand."

⁶Estimated consumption for 1980-86 was based on industry sources; reported consumption 1987 and thereafter were from quantitative and qualitative quarterly surveys of producers' sales. Other end-use categories were incorporated in the survey.

⁷Includes soda ash used in petroleum and metal refining, leather tanning, enamels, etc. Also includes data in categories indicated by "NA."

⁸Because end-use data prior to 1987 were estimated, industrial demand and U.S. primary demand calculations (both based on production, trade, and inventory data) were assumed to be equal to total U.S. consumption. Beginning with 1987, reported consumption data by end use often disagreed with derived apparent consumption calculations that necessitated, including an "Undistributed" category to account for the discrepancies. These discrepancies are because of the fluctuating balance of inventory in transit from plants to domestic or export destinations.

⁹Values are the combined total revenue of California and Wyoming natural, bulk, dense soda ash sold on an f.o.b. plant basis, at list prices, spot prices, discount, long-term contracts, and for export, divided by the quantity of soda ash sold. This value may or not be synonymous with the posted list prices of the commodity.

NA Not available.

¹The reserve base includes demonstrated resources that are currently economic (reserves), marginally economic (marginal reserves), and some of those that are currently subeconomic (subeconomic resources).

²Represents only the quantity recoverable based on an average rate of 60% extraction efficiency from room-and-pillar, longwall, and shortwall methods of underground mining. This extraction rate does not apply to brines or surface evaporite lake beds. Solution mining of trona and nahcolite is estimated to have a 30% extraction efficiency rate.

³The sodium carbonate content of nahcolite reserves and reserve base are 0.8 billion short tons and 1.26 billion short tons, respectively. The sodium carbonate content of dawsonite reserves and reserve base are 1.82 billion short tons, and 3.0 billion short tons, respectively.

⁴Data may not add to totals shown because of independent rounding.

⁵Annual leaching of volcanic rocks replenishes the resources at Lake Magadi.

NOTE.—There are at least 62 identified natural sodium carbonate deposits in the world, some of which have been quantified. The countries and number of deposits include Australia (1), Bolivia (2), Botswana (1), Brazil (1), Canada (3), Chad (9), China (9), Egypt (1), Ethiopia (1), India (2), Kenya (3), Mexico (1), Namibia (1), Niger (1), Pakistan (1), the Republic of South Africa (1), Tanzania (5), Turkey (1), Uganda (1), the U.S.S.R. (4), the United States (20), and Venezuela (1).

1987	66.78	73.61	78.13	86.12
1988	66.96	73.81	75.40	83.11
1989	77.07	84.96	83.18	91.69
1990	82.85	91.33	85.86	94.64
1991	84.18	92.79	84.18	92.79

¹Values are the combined total revenue of California and Wyoming natural soda ash sold at list prices, spot prices, discount, long-term contracts, and for export, divided by the quantity of soda ash sold on a bulk, f.o.b. basis. The average annual value may not necessarily correspond to posted list prices for soda ash.

²From final 1991 implicit price deflators for gross domestic product and not gross national product, which was used previously. In addition, the base year is 1987 and not 1982.

TABLE 6
REPORTED CONSUMPTION OF SODA ASH IN THE UNITED STATES,
BY END USE

(Metric tons)

	Imports ²	136,171	120,609	128,790	145,533	134,312
	Total domestic reported consumption ³	6,100,358	6,494,427	6,468,688	6,526,694	6,277,502
	Export ⁴	2,124,240	2,662,472	⁵ 2,644,61	2,588,477	2,797,145
	Total industry sales ⁶	⁷ 8,224,598	9,156,899	⁸ 9,113,306	9,115,171	9,074,650
	Total production	8,065,559	8,738,042	8,994,717	9,156,036	9,004,790

¹Includes soda ash equivalent from soda liquors, purge liquors, and mine water sold to powerplants for water treatment: 63,469 tons in 1987, 73,365 tons in 1988, 95,027 tons in 1989, and 111,894 tons in 1990.

²Data are from the Bureau of the Census and may vary from the quantity reported by the producer and or importer. Actual imports are proprietary data but have been distributed into appropriate end-use categories and included in "Total domestic reported consumption."

³Reported consumption data do not agree with apparent consumption data shown in tables 1 and 3 because of dissimilar sources of export data. The data vary because of different reporting periods, overland transit times between plant and port, and carryover export inventory.

⁴As reported by producers. Includes Canada. Data may not necessarily agree with that reported by the Bureau of the Census for the same periods.

⁵Revised from monthly Mineral Industry Surveys data because of 181 metric tons (200 short tons) of misreported export data in first quarter 1989.

⁶Represents soda ash from domestic origin (production and inventory changes) and imports, and for exports.

⁷In monthly Minerals Industry Surveys reports, "Total Industry Sales" for 1987 were erroneously reported as 8,088,423 metric tons (8,915,951 short tons). The misreported figure deducted imports, which already had been included in specific end uses under "Total domestic reported consumption."

⁸An extra 23,548 metric tons (25,957 short tons) of coproducer sales is included in total, but specific end-use breakout is unknown.

SODIUM SULFATE

By Dennis S. Kostick

Mr. Kostick, a physical scientist with 13 years of U.S. Bureau of Mines experience, has been the commodity specialist for sodium sulfate since 1979. Domestic survey data were prepared by Carleen Militello, statistical assistant; and international data tables were prepared by William Zajac, Chief, Section of International Minerals.

There are two types of sodium sulfate—natural and byproduct, also known as synthetic. Natural sodium sulfate is produced from naturally occurring brines and crystalline deposits found in California and Texas. It is also found as a constituent of saline lakes, such as the Great Salt Lake in Utah. Synthetic sodium sulfate is recovered as a byproduct from various manufacturing processes. Both types of sodium sulfate have several important and useful applications in various consumer products. In a survey of the top 50 basic organic and inorganic chemicals made in the United States, sodium sulfate ranked 47th in terms of quantity produced.¹

Continuing with this report, all data will be reported in metric units to comply with Public Law 100-418 of August 23, 1988. This Federal law required all Federal agencies to use the metric system of measurement by the end of fiscal year 1992. Although the use of the metric measurement standards was authorized by law since 1866 (Act of July 28, 1866; 14 Statue 339) and the United States was an original signatory party to the 1875 Treaty of the Meter (20 Statue 709), the United States has been the only industrially developed nation that has not universally converted to the metric system from the English system of measurements. As foreign trade of soda ash increases and foreign participation in U.S. joint mining ventures continues, communicating information with an international standard of measurement becomes more important. Two of the three natural sodium sulfate producers have foreign partners and some of the byproduct producers do also.

DOMESTIC DATA COVERAGE

Domestic production and inventory data for natural sodium sulfate are developed by the U.S. Bureau of Mines from monthly and annual surveys of U.S. operations. Of the three natural sodium sulfate operations to which a survey request was sent, all responded, representing 100% of the natural sodium sulfate data used in this report.

Synthetic sodium sulfate data were collected by the U.S. Department of Commerce, Bureau of the Census, from monthly and annual surveys (aggregate data published in Current Industrial Reports, Inorganic Chemicals, M28A and MA28A) of companies engaged in recovering and selling byproduct sodium sulfate. Any revised Census Bureau data have been included using most recent Census Bureau statistics. These data are aggregated with U.S. Bureau of Mines natural sodium sulfate data and included in several tables. (See table 1.)

BACKGROUND

Natural sodium sulfate was known to have been used as a medicine as early as the 16th century. It was first accurately described in 1658 by Johann Rudolph Glauber, a German chemist whose name is still associated with the hydrated crystal, Glauber's salt ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$), and the anhydrous mixed sulfate, Glauberite ($\text{Na}_2\text{SO}_4 \cdot \text{CaSO}_4$).

Glauber and other researchers prepared sodium sulfate by reacting common salt with sulfuric acid. The invention of the Kraft process for making pulp and paper

in 1880 provided the first major industrial market for sodium sulfate.

Definitions, Grades, and Specifications

The following terms are used in the sodium sulfate industry:

Anhydrous Sodium Sulfate.—Refined sodium sulfate or the mineral thenardite (Na_2SO_4). Named for the French chemist, Louis Jacques Thenard, thenardite is a colorless to white mineral with a specific gravity of 2.67 and a hardness of 2.5 to 3. Because of its whiteness and purity, it is used in detergents, pharmaceuticals, dyestuffs, glass, and ceramic glazes. Commercial-grade material has a bulk density of about 1.23 grams per cubic centimeter (77 pounds per cubic foot).

Byproduct Sodium Sulfate.—Synonymous with synthetic sodium sulfate. It is recovered as a byproduct from various chemical and textile manufacturing processes.

Glauber's Salt.—Same as the mineral mirabilite (Latin "sal mirabile" or "wonderful salt"), sodium sulfate decahydrate ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$). The mineral contains 55.9% water of crystallization and forms opaque to colorless needlelike crystals.

High Purity.—Refers to anhydrous sodium sulfate with a purity of 99% or greater. Usually sold to detergent, glass, and textile industries.

Low Purity.—Some processes occasionally produce sodium sulfate that does not meet certain physical or color specifications required by certain consumers despite being a chemically pure product. This grade of sodium sulfate is generally sold to sectors that are not as concerned about whiteness or particle size, such as the pulp and paper industry, at reduced prices.

Natural Sodium Sulfate.—Sodium sulfate obtained from mining crystalline sodium sulfate-bearing minerals or from sodium sulfate-bearing brines.

Salt Cake.—Normally refers to impure sodium sulfate containing 90% to 99% Na_2SO_4 . Because of its impurity or possible discoloration, it usually is sold only to the pulp and paper industry.

Synthetic Sodium Sulfate.—Same as byproduct sodium sulfate.

Sodium sulfate made from natural brine usually contains less than 0.5% total impurities, but that produced as a byproduct of other manufacturing may contain much larger quantities. The material meeting U.S. Pharmacopeia (U.S.P.) specifications and that intended for glassmaking must contain at least 99% sodium sulfate. In addition, glassmakers' grade must be low in iron and heavy metals. Technical grades of sodium sulfate may have from 2% to 6% impurities. Purchases of detergent or rayon-grade sodium sulfate are based primarily on whiteness. Its sodium chloride content may be between 1.5% and 2.0%, and its iron content between 60 and 100 parts per million.

Industry Structure

Three companies produced natural sodium sulfate from a total of three plants in California, Texas, and Utah. The domestic natural sodium sulfate industry supplied about one-half of the total output of U.S. sodium sulfate. Because of the location of these plants, most natural sodium sulfate is marketed in the West and southern gulf areas. Byproduct

material was supplied by 14 companies operating 15 plants primarily in the Midwest and Mid-Atlantic regions. Total rated production capacity in 1991 was 822,000 tons, and the industry operated at 85% of this capacity. (See table 2.)

Geology—Resources

Sodium is the sixth most abundant element in the Earth's crust. Sodium sulfate-bearing mineral deposits are geologically young, mainly of post-glacial age. Sodium sulfate is widespread in occurrence and is a common component of seawater and many saline or alkaline lakes. Economic reserves of natural sodium sulfate are estimated at 3.3 billion tons worldwide. With world production of natural sodium sulfate averaging about 2.6 million tons per year, supplies are sufficient to meet anticipated demand for several centuries. The quantity of synthetic sodium sulfate is dependent on the longevity of the manufacturing firms recovering byproduct sulfate.

Surface depressions or lakes that have no outlets and are fed by spring waters flowing over volcanic rocks containing sulfide minerals often yield soluble sulfide salts that are oxidized by contact with the air to produce sulfates. Some minerals over which the spring water may flow contain the sulfates directly, such as bentonite or gypsum. When an inland lake of this type evaporates and becomes highly concentrated in salts, one of the first salts to precipitate would be mirabilite, also known as Glauber's salt, which has very poor solubility at low temperatures. During seasonal temperature variations, the sulfate will precipitate preferentially to the lake bottom.

Thenardite and mirabilite are the only sodium sulfate minerals that are commercially important. Many economic deposits of sodium sulfate are in the form of crystalline beds of mirabilite such as those found in Canada and the U.S.S.R., which has the world's largest sodium sulfate resource in the Kara-Bogaz-Gol Gulf. Because mirabilite converts to thenardite when exposed to air, its outer surface may develop a thenardite crust.

Some buried sedimentary formations contain very large deposits of thenardite and glauberite, such as the deposit in Villarrubia de Santiago in Spain.

Sodium sulfate is also found dissolved in underground brines in California, Texas, and other parts of the world. The sulfate is usually converted to mirabilite when extracted from the brine by mechanical refrigeration techniques. (See table 3.)

Technology

The technology to mine and process natural sodium sulfate involves mechanical refrigeration or natural chilling to induce crystallization followed by dissolution, filtration, evaporation, and drying. Recovery of byproduct sodium sulfate from chemical processes involves various techniques.

Mining.—Sodium sulfate is extracted from the upper level of the Searles Lake brine in California and is treated separately from the carbonate-rich lower level and mixed layer brines. The subterranean sodium sulfate-bearing brines in western Texas are the simplest of the domestic brine deposits. Mechanical refrigeration is used to extract Glauber's salt crystals from the brine. The Great Salt Lake in Utah also contains valuable quantities of sodium sulfate. Brine from the most concentrated northwest segment of the lake is pumped into solar evaporation ponds on the eastern shore of the lake where sodium chloride first precipitates as the water evaporates. Sodium sulfate crystals precipitate in a fairly pure state when winter weather cools the brine to -1° to 4° C (30° to 40° F). The crystals are picked up by large earth-moving machinery and stored outdoors until further processing to anhydrous sodium sulfate can take place.

Processing.—At Searles Lake, the brine is first cooled at about 16° C (60° F) to precipitate borax crystals, which are removed from the system for subsequent further processing and sale. A second cooling to about 4° C (40° F) precipitates

the sodium sulfate in the form of Glauber's salt. These crystals are separated from the brine on a rotating drum filter. They are then redissolved in fresh water in a vacuum crystallizer. After the second separation and drying, the crystals are about 98.2% sodium sulfate. Additional treatment can obtain a 99.3% purity. Major impurities remaining are sodium chloride, sodium carbonate, and boron.

In Texas, after the crystals are processed in rotary drum vacuum filters and washed, they are melted and dehydrated using mechanical vapor recompression evaporators, which are more energy efficient than triple effect evaporators or submerged gas burners. Final classifying, centrifuging, drying in rotary kilns, and screening converts the Glauber's salt to marketable anhydrous sodium sulfate of 99.7% purity.

Purification and dehydration procedures at the facility on the Great Salt Lake are similar to those of other sodium sulfate plants. The final product results in a purity between 99.5% to 99.7%.

Sodium sulfate is also produced as a byproduct of the production of ascorbic acid, boric acid, cellulose, chromium chemicals, lithium carbonate, rayon, resorcinol, and silica pigments. It is also recovered from certain flue gas desulfurization operations. The Mannheim and Hargreaves furnace processes also produce byproduct sodium sulfate. In the Mannheim furnace, salt and sulfuric acid are reacted to form hydrogen chloride (HCl) and sodium sulfate. The Hargreaves furnace produces HCl and sodium sulfate by the reaction of sulfur dioxide, sodium chloride, air, and water. The Mannheim process is the major method used in Europe, but its use in the United States has decreased considerably since less expensive methods to produce HCl became available.

Recycling.—Because of environmental concerns regarding sulfur emissions from pulp and paper mills, many Kraft pulpers were installing pollution abatement equipment to reduce sulfur losses in the pulping process. This will result in more

sodium sulfate being recycled and less used in batch makeup solutions.

Byproducts and Coproducts

The brines of Searles Lake in California contain sodium sulfate as well as coproduct borax, potassium chloride, sodium chloride, and soda ash. The Great Salt Lake in Utah is a source of magnesium compounds, potassium sulfate, sodium chloride, as well as sodium sulfate.

Some manufacturers of ascorbic acid, boric acid, cellulose, chromium chemicals, lithium carbonate, rayon, resorcinol, and silica pigments produce sodium sulfate as a byproduct of the process. The sodium sulfate is considered a waste product but has marketability.

Economic Factors

Prices.—Producers of natural sodium sulfate tend to market and sell most of their own product, but most synthetic producers use major chemical distributors or chemical supply companies as sales agents. The principal product made and sold by the synthetic sodium sulfate producer is the primary economic factor. Because sodium sulfate is considered a waste product, it will be sold at a price that ensures prompt sales. This practice tends to set the rates at which the natural product can be sold.

The list prices quoted in trade journals or by producers of all grades of sodium sulfate differ from the annual average values reported by the U.S. Bureau of Mines. The value represents the combined amount of total revenue of domestic natural sodium sulfate sold at list prices, spot prices, long-term contracts, discounts, and export divided by the aggregated quantity of sodium sulfate sold. The published value does not necessarily correspond to the posted list price. (See table 4.)

Tariffs.—Import tariffs serve to protect the interests of domestic producers for particular products. For sodium sulfate, a 32.5-cents-per-ton tariff is imposed on

imported anhydrous sodium sulfate from countries having most favored nation (MFN) status and \$2.95 per ton from those with non-MFN status. There are no import tariffs on imported salt cake, regardless of the country of origin.

Royalties.—Sodium sulfate mined on Federal lands is subject to the Mineral Leasing Act of 1920, which provides for royalty payments to the U.S. Government. The royalty is 5% of the quantity or gross value of the output of the product at the point of shipment to market. Each Federal lease also has other costs, such as bonds, acreage rental fees, sodium prospecting permit application fees, and permit bonds. The Searles Lake sodium sulfate deposit is the only resource with active operations that has any Federal leases. Because of the variety of the brine constituents, the operator has a commingling agreement with the U.S. Government to compute royalties.

Depletion Provisions.—Legislation passed by the U.S. Government provides an allowance for the depletion of natural resources, notably timber and minerals. The depletion allowance is an important inducement for companies willing to accept the risk and high cost of mining development. The concept of depletion allowances for minerals is similar to the depreciation of other assets. Although cost depletion and percentage depletion are two methods used to compute depletion deductions, most companies prefer to use the latter. About 100 mineral categories are entitled to percentage depletion. The rates range between 5% and 22% of the gross income from the mineral property, depending on the mineral and location (foreign or domestic), and are subject to a limitation of 50% of the net income of the property. The mineral depletion allowance for natural sodium sulfate is 14% for U.S. companies mining from domestic or foreign sources.

Operating Factors

Operating factors are different for mining companies producing natural

sodium sulfate compared with manufacturing facilities recovering byproduct sodium sulfate. The quantity of synthetic sodium sulfate recovered is directly associated with the production capabilities of the primary industry (e.g., rayon, lithium carbonate, etc.) and the sulfate recovery rates.

Environmental Requirements.—Land usage may become a problem when sodium sulfate is obtained by solar evaporation, as in the case of the Great Salt Lake brines. Large areas of relatively flat land are required to allow for adequate concentration and evaporation. When land values are high, the capital required for land acquisition may increase operating costs. Disposal of the waste liquors from which sodium sulfate was extracted may develop into a major ground water discharge problem in some areas. ReInjection of spent solutions into underground source strata is expensive but often is the only acceptable method of disposal.

Because sodium sulfate is water-soluble, most releases of sodium sulfate to the environment affect water quality rather than air or land quality. These releases are mainly from Kraft pulp mills, which typically discharge between 5 to 15 million kilograms (11 to 33 million pounds) of sodium sulfate per year per site. The resulting drinking water concentrations have been estimated as high as 38.8 milligrams per liter, which is significantly below the maximum concentration level of 250 milligrams per liter set by the National Secondary Drinking Water Standard.

Problems associated with chemical effluents discharged from manufacturing plants that recover sodium sulfate have also caused environmental concerns not attributed to sodium sulfate. The second largest byproduct sodium sulfate facility in the United States at Front Royal, VA, owned by Avtex Fibers Inc., was closed in late 1989 by Federal and State regulatory agencies because of contaminated water discharges containing carbon disulfide and polychlorinated biphenyls (PCB's). These toxic chemicals

were produced from rayon manufacture, not sodium sulfate recovery.

Toxicity.—Sodium sulfate was deleted in early 1989 from the list of toxic chemicals under section 313 of title III of the Superfund Amendments and Reauthorization Act of 1986. The U.S. Environmental Protection Agency determined that there was no evidence that sodium sulfate caused, or could reasonably be anticipated to cause, adverse human health or environmental effects as specified in the act.

Employment.—According to the Bureau of Labor Statistics and industry sources, approximately 300 persons are employed in mining and processing natural sodium sulfate in the United States. Data are not available on the number of personnel employed in recovering byproduct sodium sulfate.

Energy Requirements.—The energy requirements to mine natural sodium sulfate are minimal compared to the amount of energy required to process it. An early U.S. Bureau of Mines energy survey reported that 4.5 million British thermal units (Btu's) was required to produce 1 ton of natural sodium sulfate. With the interest in conserving energy, some technical improvements, such as the installation of mechanical vapor recompression crystallizers, have reduced the overall energy requirement to slightly less than 2 million Btu's per ton of sulfate produced.

Transportation.—All natural sodium sulfate is shipped in bulk or in bags by either rail or truck. The mode of transportation depends on the location of the customer, quantity purchased, and difference in freight rates. Because of the location of the natural producers in the West and Southwest, very little natural sodium sulfate is shipped to the East because transportation rates reduce its competitiveness with synthetic sodium sulfate. Consumers in the Midwest and East tend to rely on synthetic sodium

sulfate produced in various Midwest and Southern locations.

ANNUAL REVIEW

Domestic sodium sulfate production decreased about 2% in 1991 while overall U.S. apparent consumption declined 6%. The slight downturn in production was attributed to the national economic recession that affected some of the industries that recover byproduct sodium sulfate. Although the United States is one of the largest producers in the world of natural and synthetic sodium sulfate, its share has decreased from 23% of world production total in 1980 to 14% in 1991. Figure 1 graphically shows the trend of U.S. production since 1970. Total production has declined 44% since 1970. (See figure 1.)

Issues

The environmental movement in North America continued to adversely affect the North American sodium sulfate industry. Changes toward oxygen-base bleaching chemicals by the pulp and paper industry have reduced the sales by several sodium sulfate suppliers. Some of the chemicals can be produced on-site at various pulp mills. One of the chosen bleaching chemicals, chlorine dioxide, produces sodium sulfate as a byproduct that can be used and partially recycled by the pulp mills. By producing their own sodium sulfate, certain pulp mills would not have to purchase any sodium sulfate.²

Sodium sulfate consumption by the soap and detergent industry, which has been the largest consumer of sodium sulfate, remained stagnant because of product reformulations. In addition, the growing national environmental awareness regarding the volume of packaging material discarded to landfills prompted certain detergent manufacturers to begin making superconcentrated or compact products that are packaged in smaller containers. This reduction in package size minimizes the amount of landfill waste but also reduces the quantity of sodium sulfate used in powdered detergents. Sodium sulfate is

used as a filler in powdered home laundry detergents. (See figure 2.)

Production

U.S. production of sodium sulfate decreased about 2% in 1991 primarily because of stagnant market conditions. Problems in byproduct production in the Southeast cause some tightness in the market. Production was temporarily down at the Bessemer City, NC, plant of Lithium Corp. of America, and a late startup at Cortauld's Le Moyne, AL, plant also caused supply disruptions.³ Reportedly, the Hoffman-LaRoche pharmaceutical plant at Belvidere, NJ, ceased recovering sodium sulfate. Green Bay Packaging Inc., of Green Bay, WI, converted to using recycled paper that eliminated the sodium sulfate recovery operation. W. R. Grace and Co. changed its chelate agent process technology that reduced the quantity of sodium sulfate recovered. The plant is at Nashua, NH.

The United States and Mexico were the largest producers of total sodium sulfate, each representing about 13% of the world total. Spain produced 12%, followed by the U.S.S.R., 11%, and Canada and Germany, 7% each. These six countries accounted for approximately 65% of the world's output of total sodium sulfate, based on obtainable production data. (See tables 5 and 6.)

Consumption and Uses

U.S. sodium sulfate apparent consumption decreased 6% from that of the previous year. Most of the same conditions that affected demand in 1990 remained in 1991. Concern for the environment was the paramount reason behind the stagnant supply and demand situation. Imports for consumption of sodium sulfate, primarily from Canada and Mexico, also declined because of the depressed U.S. markets in which sodium sulfate is consumed.

An estimated 53% of the total sodium sulfate consumed in the United States is for use as a filler in powdered laundry detergents. Many areas in the country have adopted phosphate bans or

limitations because phosphatic detergents contribute to the environmental problems of eutrophication. The affected areas represent about 33% of the U.S. population. In response to this environmental issue, detergent manufacturers have reformulated many of their detergents by switching from sodium tripolyphosphate (STPP) to tetrasodium pyrophosphate, which has the same building power as STPP but requires less to be used, thereby reducing the amount of phosphate released into the environment. These reformulations used more sodium sulfate as filler, which was beneficial to the sodium sulfate industry.

Sodium sulfate consumption decreased in the Kraft pulping industry because of the economic recession affecting the paper industry and recycling of paper products. Kraft pulping represented about 83% of the domestic pulp market in 1991. Public awareness about the environmental issue of nondegradable plastic packaging made many people prefer brown paper grocery bags (produced by the Kraft process), which degrade in landfills much more readily than plastic bags. Kraft pulping represents about 27% of the total demand for sodium sulfate. (See figure 3.)

Stocks

Yearend inventories of natural sodium sulfate stored by the three producers were 35,436 tons, which was a 9% decrease over that of the previous year. The material stockpiled was anhydrous sodium sulfate. Synthetic sodium sulfate was marketed mainly through major chemical distributors, which have separate storage facilities from the producers.

Atochem North America Inc. installed a new bagging system to handle its natural sodium sulfate supplies. The operation is at Charlotte, NC, and has a capacity to package more than 40,000 tons of product annually. Sodium sulfate can be packaged and stockpiled at the facility, which is closer to several of Atochem's customers.

Markets and Prices

The average value declined from \$96.63 per metric ton (\$87.66 per short ton) to \$87.34 per metric ton (\$79.23 per short ton) for bulk sodium sulfate, f.o.b. mine or plant.

As of December 1, Atochem North America increased its prices for natural sodium sulfate by \$5 per ton. The new prices, per short ton, are: bulk detergent grade, \$110; bulk glass grade, \$110; bulk paper grade, \$105; 100-pound bags detergent grade, \$137; 50-pound bags detergent grade, \$144; SS 2,000 pounds, \$137.50; and SS 1,350 pounds, \$144.45.⁴ (See table 7.)

Foreign Trade

U.S. exports of 103,000 tons were 66% higher in 1991 when compared with those of the previous year. The Republic of South Korea received almost 3 times the quantity of sodium sulfate in 1991 than it imported in 1990. This increase was because of Oriental Chemical Industries (OCI), which became a joint-venture partner with North American Chemical Co. at Searles Lake, CA. OCI was taking its share of product back to Korea for consumption.

Canada and Mexico supplied about 98% and about 2%, respectively, of total U.S. sodium sulfate imports. Small shipments were sent to the United States from Brazil, Finland, Germany, and Japan. Although the United States had a net import reliance of about 8%, most imports were less expensive to consumers than products from domestic sources, especially when overland shipping costs are considered.

Approximately 33% of the total quantity was shipped to Australia; Chile, 15%; Colombia, 14%; and New Zealand, 8%. Most was in the form of low-purity salt cake. (See tables 8, 9, 10, 11, and figure 4.)

World Review

Industry Structure.—About 52% of the world sodium sulfate production in 1991 was from natural sources; the balance

was represented by synthetic sodium sulfate recovered from various chemical and manufacturing processes. Although the U.S. Bureau of Mines collects or estimates data from 28 sodium sulfate-producing countries, other countries are known or assumed to have produced synthetic sodium sulfate, but production statistics are not reported, and available information is inadequate to make reliable estimates of output. (See table 12.)

Capacity.—The data in table 2 are rated capacities for domestic natural operations and byproduct recovering facilities in 1991. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Mine capacity for natural sodium sulfate is derived from available company data on ore throughput to the refinery. The ore refers to mined crystalline sodium sulfate, harvested precipitate, or sodium sulfate-bearing brines. Refinery capacity for natural sodium sulfate pertains to the total amount of anhydrous sodium sulfate that the plant is capable of processing from the ore. Synthetic sodium sulfate refining capacity is dependent on the production capabilities of the primary industry and the sodium sulfate recovery rates.

Canada.—Agassiz Resources Ltd., which is the second largest natural sodium sulfate producer in Canada, closed its Hardene, Saskatchewan, facility in April. By July, Agassiz's plants at Cabri, Saskatchewan, and Metiskow, Alberta, had suspended operations because of economic conditions.⁵

Iran.—A 20,000-ton-per-year synthetic sodium sulfate plant is under construction

near Ghazvin, 250 kilometers west of Teheran. Alborz Chemical Complex Co., a subsidiary of Alborz Investment Corp., the owner, planned to sell the sodium sulfate primarily to the local detergent industry. Startup of the facility was planned for 1992 or 1993.⁶

United Kingdom.—Imperial Chemical Industries licensed a new electrolytic process that recycles sulfuric acid and caustic soda from liquid wastes containing sodium sulfate. The sodium sulfate had been discharged as effluent to streams and rivers, which were becoming environmentally contaminated. Instead of purifying and selling the sodium sulfate byproduct, which had declining markets, the material could now be converted to salable acids.⁷

OUTLOOK

U.S. natural and synthetic sodium sulfate production and consumption decreased 44% and 48%, respectively, from those of 1980 to 1991. The decreases were because of changes in the recovery operations of consuming industries mandated by environmental legislation requiring reductions in sulfate emissions and declining use of sodium sulfate in powdered laundry detergents. Although production has been relatively flat since about 1982, domestic consumption of sodium sulfate has fluctuated primarily due to detergent reformulations that contain reduced quantities of sodium sulfate. U.S. consumption is expected to decline further, or less pessimistically remain flat, in the next few years.

The United States is a very important market for Canadian sodium sulfate. In 1991, 45% of Canadian output was exported to the United States. If domestic markets continue to decline, Canadian producers would encounter financial hardships and would be forced to look for more distant export opportunities. Sodium sulfate imports from Mexico are relatively minor compared to its total production capability; therefore, any erosion of U.S. domestic consumption

would not affect Mexican producers significantly.

Production

The changes in the domestic demand situation has prompted several byproduct sodium sulfate producers to consider changing their process technology that would alter the composition of byproduct wastes. For example, hydrochloric acid plants could use potash, rather than salt, to recover potassium sulfate instead of sodium sulfate. Potassium sulfate is a fertilizer used for tobacco, fruits, nuts, and other crops.

A new method to produce byproduct sodium sulfate began in mid-1991. Tonolli Canada Ltd. started to produce about 7,000 tons per year of sodium sulfate from its battery recycling operation in Mississauga, Ontario, Canada. Its technology will be used by Doe Run Co., at Boss, MO. This facility will recover about 12,000 tons of sodium sulfate annually.⁸ Reportedly, other battery recycling plants are planned that will also recover sodium sulfate. They include GNB Batteries Inc. of Fort Valley, GA, and Asarco. BASF Corp. is reportedly evaluating recovering sodium sulfate from one of its chemical operations. Formosa Plastics Corp. planned to construct a rayon plant near Wallace, LA, that would produce about 75,000 tons of synthetic sodium sulfate annually. These new byproduct operations will have an effect on the other byproduct plants and natural sodium sulfate producers that market sodium sulfate into those regions.

Detergents

The use of sodium sulfate as a filler appears to have peaked in 1989. In 1991, major detergent manufacturers continued making more superconcentrated detergent products rather than the traditional large boxes filled with bulk detergents containing up to 20% sodium sulfate as filler. This change, initiated by environmental considerations, will further reduce sales of sodium sulfate in the near future unless consumers do not purchase

the more expensive superconcentrate detergents because of the higher cost. If the economic recession continues, which affects consumer spending, less expensive powdered detergents containing sodium sulfate may be reintroduced at the expense of the more expensive concentrated and liquid products. In addition, liquid laundry detergents that do not contain any sodium sulfate continued to make up about 40% of the home laundry market.

Pulp and Paper

The economic recession that began in late 1990 and lasted throughout 1991 affected sodium sulfate sales to the pulp and paper sector, resulting in reduced sodium sulfate consumption. Environmental concerns regarding sulfur emissions prompted many Kraft pulpers to install pollution control equipment to reduce sulfur losses in the pulping process. Furthermore, many Kraft pulpers are changing their bleaching chemicals to abide by the new environmental regulations. Production of sodium chlorate, which is used to make chloride dioxide, will increase as the demand for oxygen-base bleaching chemicals rises. The process will produce sodium sulfate as a byproduct, thereby reducing the demand for saltcake. Recycling of brown paper bags made by the Kraft process will also reduce sodium sulfate consumption in the future.

CRUSHED STONE

By Valentin V. Tepordei

Mr. Tepordei, a geological engineer with more than 20 years of industry experience, has been the crushed stone commodity specialist with the U.S. Bureau of Mines since 1981. Domestic survey data were prepared by the crushed and broken stone survey staff of the Branch of Data Collection and Coordination.

Crushed stone is one of the most accessible natural resources and a major basic raw material used by a wide range of industries from construction to agriculture, chemicals, and complex industrial processes. Despite the relative low value of its basic products, the crushed stone industry is a major contributor to and an indicator of the economic well-being of the Nation.

A total of 1.1 billion short tons of crushed stone was produced for consumption in the United States in 1991, a 9.7% decrease compared with that of 1990. Despite this decrease, the 1991 tonnage represents the fifth consecutive year of crushed stone production of more than 1.1 billion tons. (See table 1.)

About three-quarters of the crushed stone production continued to be limestone and dolomite, followed by granite, traprock, sandstone and quartzite, miscellaneous stone, calcareous marl, shell, marble, volcanic cinder and scoria, and slate, in order of volume. (See table 3.)

Foreign trade of crushed stone remained relatively minor again in 1991. Exports decreased 47.3% to 2.4 million tons, while value decreased 20.3% to \$33 million compared with that of 1990. Imports of crushed stone, including calcium carbonate, increased 15.2% to 5.7 million tons, while the value increased 9.5% to \$38.6 million. Domestic apparent consumption of crushed stone was 1.1 billion tons. (See tables 25 and 26.)

The removal of nonasbestiform Anthophyllite, Tremolite, and Actinolite (AT&A) from the scope of the present Occupational Safety and Health

Administration (OSHA) standards for regulating occupational exposure to asbestos eliminates a major area of concern of the construction aggregates industries. The implementation of the provisions of the amended Federal Water Pollution Control Act of 1977, the Clean Water Act, Section 404, dealing with "wetlands" and the establishment of a "no net loss of wetlands" policy continues to constitute one of the major areas of concern to the construction aggregates industry. The other area of concern is related to the final promulgation of the permissible exposure limit for crystalline silica measured as respirable silica.

DOMESTIC DATA COVERAGE

Domestic production data for crushed stone are developed by the U.S. Bureau of Mines from voluntary surveys of U.S. producers. Full surveys of crushed stone producers are conducted for odd-numbered years only. For even-numbered years, only annual estimates for each State are generated based on information provided by the quarterly sample survey of crushed stone and sand and gravel producers. This survey, implemented by the U.S. Bureau of Mines in 1989, provides production estimates by quarters for each State and the nine geographic regions. The sample surveys canvass most of the large companies in each State, accounting for most of each State's production. The results of this survey are published each quarter in the Quarterly Mineral Industry Survey of Crushed Stone and Sand and Gravel Producers.

Of the 5,039 crushed stone operations surveyed, 3,287 operations with 4,011 quarries were active. Of these, 2,814 operations with 3,456 quarries representing 85.6% of the total number of operations reported to the U.S. Bureau of Mines survey, and their total production represented 92.6% of the total U.S. crushed stone output. The nonrespondent's production was estimated using employment data and/or adjusted prior years' production reports. Of the 2,814 reporting operations, 694 operations with 757 quarries did not report a breakdown by end use. Their production represented 23.2% of the U.S. total and is included in table 14 under "Unspecified uses, actual." The estimated production of 473 operations with 555 quarries represented 7.4% of the U.S. total and is included in table 14 under "Unspecified uses, estimated." A total of 1,290 quarries were either idle or presumed to have been idle in 1991 because no information was available to estimate their production. A total of 462 operations were closed down since 1989, the last year when a full survey of crushed stone producers was conducted.

BACKGROUND

Crushed stone is a term applied to rock that has been broken and/or crushed after quarrying. It is a low-value product characterized by its "place value," a term that describes the importance of the location of the geologic deposit in reference to the market. Stone in its multitude of forms represents a very significant part of the Earth's crust. As one of the most accessible natural

resources, it has been used since the earliest days of our civilization. First used as a tool or weapon, it was then used as a construction material, and later, in its crushed form, as one of the basic raw materials for a wide variety of uses, ranging from agriculture and chemicals to complex industrial processes.

The beginnings of the crushed stone industry are difficult to trace, but it is known that the Greeks, and later the Romans, the first great road builders, used limestone and lime extensively.¹ In the 19th century, the mining of crushed stone was labor intensive. Men with sledge hammers and shovels used their muscles to work the quarries and produce crushed stone that was used mostly for road and railroad construction.² The modern crushed stone industry began in England in about 1815 and expanded rapidly after the invention of the mechanical rock crusher in 1858.³ Today's crushed stone industry is vastly different. It evolved from a labor-intensive to a capital-intensive industry where the work force mostly directs and controls sophisticated and powerful equipment operating in the quarries.

In the United States, railroad ballast was the principal market for the crushed stone industry during the last half of the 19th century. Passage of the Federal Aid Highway Act in 1916 acknowledged the national importance of highways, and subsequent highway construction created a new and significantly larger market. The crushed stone industry grew tremendously, especially in the second half of this century. Production increased from 130 million tons in 1928 to a high of 1.25 billion tons in 1988, mainly owing to rapidly increasing demand for highway, railroad, and other construction work. Today the volume of crushed and broken stone produced is greater than that of any other mineral mined in the United States. The United States is, in general, self-sufficient in crushed stone, producing enough to meet most of the domestic needs. Small quantities of crushed stone, used mostly as construction aggregates, are being imported by water from the Bahamas, Canada, Mexico, and to a

smaller extent Scotland and the United Kingdom.

Most of crushed stone is used for construction purposes, mainly as aggregate with or without a binder. Road base or road surfacing material, macadam, riprap, and railroad ballast are the major uses without a binder. Aggregate for cement and bituminous concrete in highway and road construction and repair and in residential and nonresidential construction are the major uses for aggregates with a binder. Other uses include cement and lime manufacture, agriculture, metallurgical flux, and fillers and extenders.

Although crushed stone resources are widespread and in adequate supply in most parts of the United States, local shortages exist. Land use conflicts and environmental problems associated with rapid urban expansion are major factors contributing to these shortages. Demand pressures, land use regulations, and the cost of meeting environmental and reclamation requirements are factors that will cause a rising price trend. Larger operations with more efficient equipment, more automation, and better planning and design will be the trend of the industry in the future.

Definitions, Grades, and Specifications

Crushed and broken stone is a term applied to rock that has been broken and/or crushed into smaller, irregular fragments or ground to specified particle sizes. Crushed stone is also classified by kind of stone, including limestone, dolomite, marble, shell, granite, traprock, sandstone, quartzite, slate, volcanic cinder and scoria, and miscellaneous stone. The terminology used by the crushed stone industry is not always consistent with mineralogical definitions. Limestone and dolomite are rocks composed, respectively, of the minerals calcite, CaCO_3 , and dolomite, $\text{CaMg}(\text{CO}_3)_2$; however, they are usually called limestone by the industry, and intermediate varieties are seldom distinguished. Some deposits of limestone consist chiefly of the mineral aragonite, which has the same

composition as calcite, but has a different crystal structure. Marble may include any calcareous rock that will accept a polish. Marl is calcitic and contains varying amounts of shale or clay. Granite includes the coarser grained igneous rocks such as true granite and syenite. Gneisses, although metamorphic rocks, are usually included with granite. Quartzite is a well cemented sandstone that is indurated to the extent that, when fractured, it breaks across the grain. Traprock includes all dense, dark, and fine-grained igneous rocks such as basalt, diabase, and gabbro.

Crushed stone in its different rock types and particle sizes is used in a wide variety of applications in many industries, including construction, chemical, metallurgical, and agriculture. For the purpose of collecting and disseminating production information, the U.S. Bureau of Mines generally accepts the rock type classification and the principal end uses and their definitions as reported by the crushed stone producers.

Specifications for crushed stone are numerous because of the large number and the variety of uses, the diversity of stone types, and the variations in physical and chemical requirements for different uses. Various national specifications and tests exist for crushed stone products, but the most active organizations in preparing and reviewing them are the American Society for Testing and Materials (ASTM)⁴ and American Association of State Highway and Transportation Officials (AASHTO). For construction aggregates, these are regarded by industry as guide or reference specifications. State specifications are often much more stringent and vary from State to State. The most common specifications and tests relate primarily to gradation, but soundness, shape, abrasion resistance, porosity, chemical compatibility, and content of soft particles are also important.⁵ Specifications for construction aggregates are written by commercial users; government agencies, including Federal, State, county, and city construction and highway departments; and the ASTM. Problems arise for the producers of construction aggregates

when their product is sold or used in several different cities, counties, or States, many of which may have different specifications. Some progress is being made toward the standardization of aggregate sizes for similar requirements. A need exists for a more active interchange of data and experience among aggregate consumers and producers.

Specifications for limestone used in portland cement manufacture require a content of more than 75% calcium carbonate (CaCO_3) and less than 3% magnesium carbonate (MgCO_3). For white portland cement, the iron content of the raw materials should be very low, less than 0.01%. Because raw materials are finely ground for processing, chert nodules or coarse quartz grains are undesirable. Limestone for lime manufacture should contain more than 90% calcium carbonate, often more than 97% or 98%, less than 5% magnesium carbonate, and less than 3% of other impurities. For lime produced in vertical kilns, 5- to 8-inch stone is recommended, while in rotary kilns 3/8- to 2 1/2-inch stone may be used. Limestone and dolomite should be sufficiently hard so as not to decrepitate when heated. High-magnesium lime made from dolomite should contain more than 40% magnesium carbonate.

Specifications for the use of limestone or dolomite as fluxstone vary with the pyrometallurgical process, the kind of ore processed, and the final use of the slag; silica content should not exceed 2% to 5%, magnesia content should be less than 4% to 15%, and sulfur less than 0.1%. Size specifications also vary and include ranges from 1 to 4 inches, 2 to 4 inches, and 3 to 6 inches. The limestone or dolomite used for glassmaking should contain at least 98% CaCO_3 or MgCO_3 , respectively, and less than 0.05% to 0.02% iron oxide. Size specifications vary with the manufacturer and the kind of glass being produced, but uniformity is a major requirement; usually 100% of the material should pass a No. 10 sieve (2 millimeters) and 96% to 100% should be retained on a No. 100 sieve (0.15 millimeters).

Requirements for agricultural limestone are not very rigid and depend on the specific use: as direct application to soil, as filler and conditioner for fertilizers, in animal mineral feeds, or as poultry grit. In all of these applications, CaCO_3 or MgCO_3 equivalent or content is of major significance. Many individualized specifications exist for a wide variety of industrial applications, mostly pulverized limestone for rock dusting, or as asphalt, plastic, rubber, paper, or paint fillers or extenders.⁶

Products for Trade and Industry

The ultimate use of crushed stone determines the specification for particle size and gradation, shape, rock type, and chemical composition. Crushed stone can be used without any binder, for a variety of construction or industrial applications, or it may be mixed with a matrix binding material such as bituminous or portland cement. The most common use of crushed stone for construction purposes is as aggregate without a binder, including road base or road surfacing material, macadam, riprap, railroad ballast, filter stone, etc. The second largest use of crushed stone is as aggregate for cement and bituminous concrete in a variety of forms and applications in residential and nonresidential construction, highway and road construction and repair, airports, dams, sewers, and foundations. Sized crushed stone is used to make asphaltic concrete aggregate and road bases. Broken surfaces adhere to the hot asphaltic mixture better than rounded surfaces do and provide interlocking surfaces that tend to strengthen the asphaltic concrete. Broken particles pack better and tend to move less under load than rounded particles do and, therefore, make better road bases for highway and road construction. This is essential because bases and asphaltic concrete tend to flow when placed under great or long duration stresses. Other uses include limestone for cement and lime manufacturing and as agricultural limestone used as direct application to soil, as filler and conditioner for fertilizers, in animal mineral feeds, or as

poultry grit. Smaller amounts of crushed stone are used for a wide variety of applications ranging from metallurgical fluxing of antimony, copper, iron, lead, and zinc to the manufacture of glass, ceramic pottery, paper, and as fillers and extenders in asphalt, paint, rubber, and plastics.

A growing amount of limestone is being used in the removal of sulfur oxides from stack gases, primarily from coal burning electric generating stations, and for mine dusting to enhance mine safety by reducing the explosion risk of highly combustible coal dust.

Industry Structure

Because of the low unit value, crushed stone is usually produced near the point of use; therefore, the industry is concentrated mostly in or nearby large, rapidly expanding urban areas. Crushed stone is produced in every State except Delaware, with more than 75% of the national total coming from two major geographic regions, the South and Midwest. The largest quarries tend to be concentrated in the States with the largest populations and largest productions of crushed stone.⁷

Although limestone is produced in all States except Alaska, Delaware, Louisiana, New Hampshire, and North Dakota, the major producing States are east of the Rockies. Crushed marble is produced mostly in the eastern part of the United States in Alabama, Georgia, and Pennsylvania. Crushed granite is produced primarily in Appalachia, with Georgia, North Carolina, South Carolina, and Virginia being the largest producing States. Crushed traprock is produced mainly in the northeast and the Pacific Coast States, with California, Connecticut, Massachusetts, New Jersey, Oregon, and Washington the largest producing States. Crushed sandstone and quartzite are produced in 27 States led by Arkansas, California, and Pennsylvania. Most crushed slate is produced in the Eastern part of the United States, mainly in Arkansas, Georgia, and Virginia. Shell, primarily oyster residue, is produced by dredging along the Gulf

Coast. Volcanic cinder is produced in the West, mainly in Arizona, California, and New Mexico.

On the basis of tonnage, the crushed stone industry is the largest nonfuel mineral industry in the United States. The industry is widespread and has a large variation in operation size, kind of stone, and size of material produced. The individual companies range in size from small, independent producers with one quarry to large, diversified corporations with 50 or more crushed stone operations.

In 1991, 1,597 companies produced crushed stone from 3,287 operations with 4,011 active quarries. Individual crushed stone quarries range in size from those producing between 1 and 11 million tons annually to those reporting less than 50,000 tons per year. However, most of the tonnage comes from large operations. In 1991, for example, 53 operations each reporting production of more than 2 million tons per year represented only 1.7% of the total number of operations, but accounted for 17.4% of total crushed stone production. (See table 8.) The large operations are owned or operated by a small number of companies. In 1991, the combined production of the top 10 producers operating 507 quarries accounted for 30% of the total output of crushed stone in the United States.

The 10 leading producers were Vulcan Materials Co., Beazer USA Inc./Hanson PLC, Martin Marietta Aggregates, Lafarge Construction Materials, Dravo Basic Materials Co., CSR America, Inc., Material Services Corp., Florida Rock Industries Inc., Rogers Group Inc., and Lone Star Industries Inc.

In the past several years, significant changes in the structure of the crushed stone industry have occurred, caused primarily by mergers and acquisitions. An established and well managed company with significant reserves in the ground becomes a potential target of larger companies trying to lock up sufficient reserves or expand into the aggregate business. Some of the recent acquisitions were made by foreign companies or were associated with the influx of foreign capital. Two of the top

five crushed stone-producing companies in 1989 are subsidiaries of foreign companies.

The United States is the largest producer of crushed and broken stone among the market economy countries. Other major producing countries are Australia, Canada, the Federal Republic of Germany, France, Japan, and the United Kingdom. Some information about the production of crushed stone in foreign countries may be found in the U.S. Bureau of Mines Minerals Yearbook Volume III, Area Reports: International. For nonreporting countries, estimates of crushed stone outputs can be based on indirect sources such as the level of cement consumption.

Geology-Resources

Bedrock deposits are classified on the basis of their origin into sedimentary, igneous, and metamorphic rocks. Sedimentary rocks were produced from the consolidation of loose sediments through chemical or mechanical sedimentation. Limestone, which is primarily calcium carbonate (CaCO_3), and dolomite, which is calcium-magnesium carbonate ($\text{CaMg}(\text{CO}_3)_2$), are the most common sedimentary rocks produced through chemical or biochemical sedimentation. Limestone and dolomite formations are widespread in the United States, with most of the deposits being of Paleozoic age, with a few of Mesozoic and Tertiary age. Most States have adequate reserves for use in construction and other applications that do not require chemically pure stone.⁸ High-calcium limestone and high-purity dolomite make up only a small fraction of all limestone and dolomite formations, and they occur in restricted areas, mostly in the eastern part of the United States, with some formations in the Western States as well.⁹ High-purity dolomite deposits are more limited in occurrence than the high-calcium limestone. Of the clastic sedimentary rocks that are produced through mechanical sedimentation, only sandstones, rocks consisting predominantly of cemented sand-size

particles, are, to a limited extent, used as crushed stone.

Igneous rocks, rocks that solidify from molten volcanic magma, are classified as intrusive and extrusive rocks. Intrusive or plutonic rocks are those that were formed deep beneath the ground surface, are coarse grained, and include granite, diorite, and gabbro as rock types. Extrusive or volcanic rocks are igneous rocks that were formed from molten volcanic magma at the Earth's surface, are fine grained, and include andesite, rhyolite, and basalt. Plutonic and volcanic rocks are further subdivided on the basis of mineralogy in light-colored igneous rocks with high-silica content that include granite, diorite, rhyolite, and andesite, and dark-colored igneous rocks low in silica content that include gabbro, diabase, and basalt, commonly called traprock. Granite and traprock are the most common igneous rock types used as crushed stone. Granite occurs primarily in the eastern part of the United States from Maine to Georgia, along the Appalachian Range where major producing States are located. It also occurs in Arkansas, Minnesota, Missouri, Oklahoma, Texas, and Wisconsin and in all Western States except Utah. Most of the traprock occurs in California, Hawaii, Idaho, Oregon, and Washington in the West; in Connecticut, Maryland, Massachusetts, New Jersey, New York, North Carolina, Pennsylvania, and Virginia in the East; and to a smaller extent in Minnesota and Texas.

Metamorphic rocks are formed from preexisting rocks through mineralogical, chemical, and structural changes produced by high heat and pressure. The metamorphic rocks include gneisses, marbles, quartzite, slates, and schists. Marble, quartzite, and slate are the major types of metamorphic rocks used to some extent as crushed stone. Marble occurs primarily in Alabama, Georgia, New York, Vermont, and Virginia in the East and in California and Texas in the West.

A comprehensive report showing geologic occurrences of potential sources of crushed stone and sand and gravel of the conterminous United States for use as

natural aggregates was published by the U.S. Geological Survey.¹⁰

On the basis of geologic evidence, stone resources of the United States and the world are sufficient to meet demands, although not always precisely at the locations where needed. Reserves, which are measurable amounts of crushed stone that can be produced profitably with current technology under existing economic and political conditions, are controlled mostly by land use and/or environmental constraints. The actual volume of stone available is so vast as to preclude the necessity of measurement on a large scale. The local shortages that occasionally exist are caused less by a lack of stone than by urban encroachment or zoning regulations that force closure of operating quarries or prevent the development of new ones.

Technology

Major technological developments have been instrumental in maintaining adequate production at relatively stable real costs in the crushed stone industry. Equipment manufacturers usually conduct most of the research related to improvements in the mining and processing of crushed stone operations. Larger, more efficient equipment is being developed and improved constantly. The use of computerized control systems in plant operation and quality control has increased significantly in recent years. Automatic controls, along with monitoring by closed-circuit television coordinated with automated counting and recording and radio communications systems, have been installed in many of the larger and newer operations. Automated plants have significantly improved operating efficiency and produce the optimal product mixture to fit market requirements at lower cost.

As part of the national drive to reduce air pollution, significant progress is being made toward the desulfurization of stack gases resulting from coal burning electric generating stations and some industrial installations.¹¹ Limestone and lime are used as chemically reactive agents in most of the dry or wet scrubbing

processes as well as in the treatment of acidified waters, specifically lakes and streams.

Exploration.—A large number of geologic formations that have economic potential as a source of crushed stone have been mapped and described in the literature over the years. Consequently, detailed exploration and development work for any new crushed stone operation will most probably be done on one of these formations. However, in the event that a new stone deposit is discovered, more exploration and evaluation work would be required before development. Preliminary examination can establish the extent and nature of the deposit. This is followed by a detailed exploration program aimed at obtaining reasonably accurate information about the quality of the available material, including the kind of stone, its chemical composition and degree of cementation, and the degree of uniformity throughout the deposit. Also, the nature and the amount of waste material and the economic feasibility of its removal, processing, and marketing must be studied. In most cases, an environmental impact study is required by local or State agencies.

If the raw material cost and quality are proven to be adequate and sufficient reserves are demonstrated, the development stage of the operation can be started. Economic feasibility and marketing studies include: analysis of the availability of power and water supply; mining and processing costs and requirements; the condition of nearby roads and highways and the proximity of rail haulage; the cost of compliance with local, State, and Federal regulations; and the proximity and density of local population, as well as its attitude toward such a project.

Mining.—Most crushed and broken stone is mined from open quarries; however, in many areas, factors favoring large-scale production by underground mining are becoming more frequent and more prominent.

Surface mining equipment varies with the kind of stone mined, the production capacity needed, the size and shape of the deposit, estimated life of the operation, location of the deposit with respect to urban centers, and other important factors. Ordinarily, drilling is done with tricone rotary drills, long-hole percussion drills, and churn drills. Blasting in smaller operations may still be done with dynamite, but in most medium- to large-size operations ammonium nitrate-fuel oil mixtures (AN-FO), which are much lower in cost, are used.

Underground operations are becoming more common, especially for limestone mining in the central and eastern parts of the United States, as the advantages of such operations are increasingly recognized by the producers. By operating underground, a variety of problems usually connected with surface mining such as environmental impacts and community acceptance are significantly reduced. Underground room-and-pillar mines can be operated on a year-round basis, do not require extensive removal of overburden, and produce a minimum of environmental disturbance. The need for less surface space is also an important factor in areas of high land costs. Subsidence has not been a problem in areas mined, and the conventional practice has been to leave 12% to 15% of pillar areas and 6 to 8 feet of stone in the mined roof. A specific advantage of underground quarries is the creation of valuable storage facilities. In many cases, the value of the sale or rental of the storage space may exceed the value of the stone mine. Thus, the incentives for producing stone from underground mines can be enhanced by the economic advantages of subsequent use of the excavated areas.

Loading and hauling equipment has grown larger as increased demand for stone has made higher production capacities necessary. Track-mounted equipment is still used extensively, but hydraulic, tire-mounted hauling equipment is predominant.

Processing.—Processing plants have become larger and more efficient, in part

because of an increase in the use of computerized control systems. Programmable controllers and/or computers are viewed today as valuable tools that improve operating efficiency and product quality. Primary crushing is often done at or near the pit, usually by jaw or gyratory crushers, but impact and other special types of crushers are also used for nonabrasive stone or stone that tends to clog conventional crushers. The cost effectiveness of permanent crushing installations can be limited because the raw material moves away from the primary stage. It becomes increasingly expensive to haul material from the production face to the crushing plant. Improved crusher technology and increased capacity toward greater equipment mobility are accelerating the use of in-pit movable primary crushers. There is an increased interest in the use of portable crushers ranging in size from 500 tons per hour up to 5,000 tons per hour. For secondary crushing, a variety of comminution equipment is used, depending on plant size, rock type, and kind of material being produced. Cone crushers and gyratory crushers are the most common types used, but impact crushers, including hammer mills, and roll crushers are often used. Belt conveyors are being used extensively to haul material within the quarry because they provide continuous operation, low maintenance costs, low work force requirements, and reduced noise levels. Conveying systems are often associated with in-pit crushers and consist of several portable units and a stationary field conveyor. The portable conveyors, usually in 100- to 200-foot lengths make the connection between the portable crusher and the field conveyor and provide a good range of motion. The increased use of conveyors reduces significantly the use of haul trucks in quarries.

Screening is the single most important part of the processing cycle of crushed stone particles. A wide variety of screen types exists, and their selection is a function of the material processed as well as the final product required. Inclined vibratory screens are most commonly

used in stationary installations, while horizontal screens are used extensively in portable plants. For screening large sizes of crushed stone, grizzly bars, rod decks, and heavy punched steel or plastic plates are used; for smaller sizes, woven wire, welded wire cloth, rubber, or plastic screens are used.

Processed crushed stone is usually stored in open areas except for relatively small quantities that go to the loadout bins. In the more efficient plants, the crushed stone is transported from the storage piles on belt conveyors through tunnels installed under the piles, thus facilitating the blending of any desired mixture of sizes from different piles.

Recycling.—As the Nation moves into an age of increased environmental consciousness, recycling of old concrete and asphalt, used mostly in pavements, is increasing. Local scarcity or high cost of construction aggregates in some areas as well as waste disposal problems are making recycling more attractive economically. In some States, limited recycling, especially in road construction, is either encouraged or required by law. The best utilization for recycled cement concrete is as road base material, because the matrix of concrete cannot be converted back to cement, and also because of the lower strength of concrete compared with that of natural aggregates. Sound crushed concrete can make good coarse aggregate, but the fines produced in crushing the concrete have a higher absorption, are more friable, and will require a higher amount of asphalt in asphaltic concrete and a higher amount of mixing water in portland cement.¹²

The amount of asphalt roads recycled is significantly larger than that of concrete roads, mainly because asphalt can be rejuvenated with oil additives and used in pavements, significantly reducing the cost of the finished road. Experience has shown that about 35% of crushed asphalt pavement can be recycled into new asphalt mixtures. Proper testing under engineering supervision in all construction projects using recycled materials as aggregates should be

performed to ensure that the technical specifications are met.

Byproducts and Coproducts

Clay of good quality is sometimes encountered in limestone overburden and is mined as a coproduct. Gypsum is often encountered beneath beds of limestone and is mined as a coproduct. Amphibolite rock often occurs as formations paralleling spodumene-bearing pegmatitic dikes and is mined concurrently with these, notably in North Carolina. This coproduct of lithium mining is marketed primarily as roadstone. Stone is also mined in conjunction with many metallic ores and nonmetallic minerals, but seldom does a market exist for it.

Economic Factors

Crushed stone is a high-volume, low-value commodity. The industry is highly competitive and is characterized by thousands of operations serving local or regional markets, largely because stone is an abundant mineral. Production costs are determined mainly by the cost of labor, equipment, energy, and water, in addition to the costs of compliance with environmental and safety regulations. These costs vary depending on geographic location, the nature of the deposit, and the number and type of products produced. Despite having one of the lowest average per ton values of all mineral commodities, the constant dollar price of crushed stone has changed relatively little over the past 20 years. As a result of rising costs of labor, energy, and mining and processing equipment, the average unit price of crushed stone increased from \$1.58 per ton, f.o.b. plant, in 1970 to \$4.70 in 1991. However, the unit price in constant 1987 dollars fluctuated between \$3.37 and \$3.90 per ton, while the unit price in constant 1970 dollars fluctuated between \$1.41 and \$1.63 per ton for the same period. (See table 2 and figure 2.) Increased productivity achieved through increased use of automation and more efficient equipment was mainly

responsible for maintaining the prices at this level.

The delivered price of the product, in addition to quality, is a particularly important element in any major transaction because of the low unit value of crushed stone, and therefore, producers that are closest to markets have a significant advantage. Sophisticated equipment backed by technical knowledge combined with solid sales expertise are becoming very important. For this reason, large companies are better able to compete in the crushed stone business, especially when there is a need for a wide variety of products. Smaller, less efficient operations become less economical as operating costs, as well as costs associated with meeting various Federal, State, and local regulations, continue to increase. The only alternatives these producers have are to supply local markets with a limited number of products. The gradual trend toward larger operations has continued, mostly because the stone industry is capital intensive, and it is becoming less economical to operate small quarries. The viability of small operations is dependent on the demand in the local markets, mining costs, and the degree of processing required to supply the final product.

A 5% depletion allowance based on gross income is allowed for crushed stone used in construction, including aggregates. The depletion allowance for chemical and metallurgical crushed stone is 14%.

Operating Factors

Many States, counties, and cities in the United States have zoning laws, and land within each governmental unit is usually zoned to indicate acceptable land uses. If mining is permitted in a zone and a crushed stone company owns or leases land within that zone, the company may apply for a use permit or its equivalent to begin an operation. If the parcels to be quarried are on lands under both city and county jurisdiction, permits usually must be obtained from each. An acceptable reclamation plan that meets the guidelines

or regulations of the appropriate governmental agency must also be approved. Environmental concerns such as noise, dust, beautification, and storage of wastes must be accounted for in a manner satisfactory to the governmental entity involved. Wastewater discharge requirements must be planned for and met. If the deposit to be worked is on land controlled by a State or Federal agency, that agency's requirements must also be satisfied.

In most States, permits for crushed stone operations require an Environmental Impact Report (EIR) or Environment Impact Statement (EIS). A reclamation plan and a use permit application may also be required, with considerable overlap of subject matter with the EIS. A complete EIS may cover all the problem areas at once and facilitate acceptance.

Environmental Requirements.—Many of the environmental problems facing crushed stone producers arise because a great number of stone quarries and processing plants are in suburban areas near the major crushed stone markets. Major environmental considerations that must be dealt with in mining and processing of crushed stone are emission of particulate matter into the air, discharge of processing water, noise abatement, and employee and public health and safety. Air pollution constitutes a major problem in processing plants, especially in the drying and packaging stages of fine particle products such as limestone used as fillers or extenders. Both wet and dry methods of dust control are used. The most important water pollutant is clay in suspension that results from washing and screening crushed stone. Because of the large quantities of water used to process stone and the need for compliance with often stringent regulations, the treatment of discharge water by crushed stone producers is becoming a necessity that may require sophisticated and expensive processing methods. Significant progress has been made in reducing noise pollution both inside and outside of the quarries, including noise and vibration produced by

blasting and movement of heavy trucks. Therefore, the industry must be concerned first about any practices that can affect the community environment. An effective effort must be made to reduce noise, air, and water pollution and to improve the overall appearance of the operating mine, processing plant, and transportation facilities. Second, the industry and community must recognize the time and costs required to protect the environment and the importance of agreeing on fair and realistic environmental standards. Because crushed stone is a local industry, the effect of supply deficiencies and cost of material will affect the local community first. Undue delay and unreasonably high cost can strongly affect the movement of crushed stone into the marketplace. Also, stringent controls by the local governments that prevent permits being issued to operators can have adverse economic effects on the communities around them. These conditions can make it difficult to assess the timing and even the possibility of plants going on-stream and can therefore affect the supply of crushed stone into the marketplace.

Although much progress is being made through premining planning, the crushed stone industry continues to have problems with environmental controls, land use conflicts, and reclamation practices. Many of these problems are acute because extraction areas and plants must be reasonably near to consumers who are largely in metropolitan areas.

Transportation.—Transportation is a major factor in the delivered price of crushed stone. The cost of moving crushed stone from the plant to the market often equals or exceeds the sales price of the product at the plant. Because of the high cost of transportation and the large quantities of bulk material that have to be shipped, crushed stone is usually marketed locally. The high cost of transportation is responsible for the wide dispersion of quarries around the country, usually near highly populated areas.

However, increasing land values combined with local environmental concerns are moving crushed stone

quarries farther from the end-use locations, increasing the price of delivered material. Economies of scale, which might be realized if fewer, larger operations served larger marketing areas, would probably not offset the increased transportation costs.

Truck haulage is the main form of transportation used in the crushed stone industry, despite the fact that it is the most expensive mode of transportation on a cost-per-ton/per-mile basis. Many producers have their own truck fleet and deliver their own raw materials and products. A significant and increasing amount of crushed stone, however, is being hauled by independent truckers because of the cost of maintaining a truck fleet, particularly when the market is highly variable. Rail and water transportation combined account for about 8% of total crushed stone shipments. In recent years, an increased amount of crushed stone is being shipped into the United States by water from Bermuda, Canada, Mexico, and United Kingdom, using large ocean-going vessels. Some of these are self-unloading vessels.

ANNUAL REVIEW

In 1991, a total of 1.1 billion short tons of crushed stone was produced for consumption in the United States, a 9.7% decrease compared with that of 1990. Despite this decrease, the 1991 tonnage represents the fifth consecutive year of crushed stone production more than 1.1 billion tons.

Legislation

On December 18, 1991, the Intermodal Surface Transportation and Infrastructure Act of 1991 became Public Law 102-240. The new law authorized \$151 billion to be spent in the next 6 years on transportation projects, \$119.5 billion on highway work, and \$32.5 billion on mass transit. The new law defines a new national highway system that combines interstate routes with selected State routes, creates a Surface Transportation Program that replaces categorical grants to the States, and restructures the

Federal-Aid Highway Program giving State legislatures and Metropolitan Planning Organizations more flexibility in choosing projects and transferring funds between spending categories.

On June 8, 1992, OSHA announced that it was amending its standards governing the "Occupational Exposure to Asbestos, Tremolite, Anthophyllite, and Actinolite (AT&A)"¹³ by removing nonasbestiform AT&T from the scope of the present standards affecting the general industries, including the construction industries. OSHA has determined that substantial evidence is lacking to conclude that AT&T present the same type or magnitude of health effect as asbestos or that employees would be at significant risk because nonasbestiform AT&T were not regulated in the asbestos standards. The latest administrative stay of enforcement of the revised standards was also removed by OSHA effective May 29, 1992.

Issues

The implementation of the provisions of the amended Federal Water Pollution Control Act of 1977, the Clean Water Act, Section 404, dealing with "wetlands" and the establishment of a "no net loss of wetlands" policy constitutes one of the major areas of concern to the crushed stone industry. There is a significant amount of uncertainty regarding the process of designating some lands as wetlands and whether the current exemptions to the Clean Water Act, Section 404, permit program will be maintained in the future. Several bills were introduced in the 102d U.S. Congress to replace the current Section 404 of the Federal Water Pollution Control Act. The new proposed bills plan to provide a concise and structured program for the delineation of wetlands based on their functions and values and will balance the need for effective protection of the Nation's important wetlands with the need for essential community growth and the constitutional rights of landowners.

The removal of nonasbestiform AT&T from the scope of the present OSHA

standards for regulating occupational exposure to asbestos in general industries, including the construction industries, eliminates a major area of concern for the construction aggregates industries. Based on the entire rulemaking record, OSHA has determined that substantial evidence is lacking to conclude that nonasbestiform AT&T present the same type or magnitude of health effects as asbestos. OSHA also concluded that substantial evidence does not support a finding that exposed employees would be at significant risk because nonasbestiform AT&T were not regulated in the asbestos standard.

Another issue of concern to the construction aggregates industries is the classification of crystalline silica as a probable human carcinogen by the International Agency for Research on Cancer, an agency of the World Health Organization. OSHA-regulated sites that receive and/or use products containing more than 0.1% crystalline silica must comply with OSHA's Hazard Communication Standard. Both the classification of crystalline silica as a probable human carcinogen and the requirement to quantitatively analyze for crystalline silica at the 0.1% level are controversial.

Production

A total of 1.1 billion short tons of crushed stone was produced for consumption in the United States in 1991, a 9.7% decrease compared with that of 1990. (See table 1.) Of this total, 784 million tons or 71.1% was limestone and dolomite, 164 million tons or 14.9% was granite, and 83 million tons or 7.6% was traprock. The remaining 6.4% was shared, in descending order of quantity, by sandstone and quartzite, miscellaneous stone, calcareous marl, shell, marble, volcanic cinder and scoria, and slate. (See table 3.)

A comparison of the four major geographic regions indicates that in 1991 the South continued to lead the Nation in the production of crushed stone with 498.8 million tons or 45.2% of the total, followed by the Midwest with 335.6

million tons or 30.4%, and the Northeast with 144.5 million tons or 13.1%. Approximately 75% of the total U.S. crushed stone output was produced in two major geographic regions, the South and the Midwest. (See table 4.)

Of the nine geographic regions, the South Atlantic led the Nation in the production of crushed stone with 254 millions tons or 23% of the U.S. total. Next was the East North Central region with 222 or 20.1% of the total, followed by the Middle Atlantic with 124 million tons or 11.3%.

A comparison of the estimated 1990 and reported 1991 production data by regions indicates that the output of crushed stone decreased in all regions except the East North Central, the Pacific, and the Mountain. The largest decreases were recorded in New England, -24.5%; the Middle Atlantic, -21.2%; and the South Atlantic, -17.6%; while the increases were significantly smaller and occurred in the Pacific, 10.7%, and East North Central, 1.6%. Crushed stone was produced in every State except Delaware.

The 10 leading States in the production of crushed stone, in order of volume, were Pennsylvania, Illinois, Texas, Florida, Virginia, Missouri, Ohio, North Carolina, Kentucky, and California. Their combined production represented 49.6% of the national total.

Fewer changes in ownership, acquisitions by domestic or foreign companies, and mergers occurred in the crushed stone industry in 1991 compared with those of the prior years. Martin Marietta Aggregates of Raleigh, NC, acquired in the first half of 1991 a granite quarry operated by Barrow-Gwinnett Co. of Auburn, GA.

Rogers Group, Inc. of Nashville, TN, acquired the assets of Moulton Limestone Co. of Moulton, AL, which operates a limestone quarry in Moulton Alabama. Later in the year, Rogers Group also purchased the assets of Crushed Stone Inc. of Cowan, TN, and Lynchburg Stone Inc. of Lynchburg, TN. The two companies operate quarries in Moore and Franklin Counties of Tennessee.

Vulcan Materials Co. of Birmingham, AL, and its Mexican partner in the

Yucatan Peninsula quarry operation, Grupo ICA of Mexico City, Mexico, acquired in September the construction aggregates operations of Southdown Inc., of Hernando, FL, in Hernando and Polk Counties, Florida. These operations will be supplied with crushed limestone from the Yucatan quarry.

Hanson PLC of London, United Kingdom, an industrial management company operating mostly in the United Kingdom and the United States, acquired in the second half of 1991 C. H. Beazer PLC, of Bath, United Kingdom, the parent company of Beazer USA, Inc. of Dallas, TX. The acquisition followed Beazer's announcement in July of company plans to sell most of its European operations, including real estate and construction contracting operations. Beazer USA is the largest construction sand and gravel- and the second largest crushed stone-producing company in the United States.

Limestone.—The 1991 output of crushed limestone, including some dolomite, decreased 10.4% to 723 million tons valued at \$3.1 billion, compared with the 1989 totals. (See table 3.) In addition to the quarries reporting only limestone, 18 quarries reported producing both limestone and dolomite, without making a distinction between the two kinds of stone. Their production, 10.1 million short tons, was included with the limestone, and therefore, the limestone totals shown in this chapter include an undetermined amount of dolomite, in addition to the dolomite reported separately. Limestone was produced by 950 companies at 2,050 operations with 2,201 quarries in 47 States. Leading States, in order of tonnage, were Texas, Illinois, Florida, Kentucky, and Missouri; these five States accounted for 37% of the total U.S. output. (See table 9.) Leading U.S. producers were, in order of volume, Vulcan Materials Co., Beazer USA, Lafarge Construction Materials, Martin Marietta Aggregates, and CSR Corp. These five companies accounted for about 22.6% of total U.S. output of limestone.

Dolomite.—Production of dolomite increased 23.7% to 61 million tons valued at \$308.6 million, compared with the 1989 reported totals. (See table 3.) This increase is mostly due to better reporting by the producing companies. Crushed dolomite was reportedly produced by 90 companies at 130 operations with 137 quarries in 28 States. An additional undetermined amount of dolomite is included in the total crushed limestone. Leading States in the production of dolomite, in order of tonnage, were Pennsylvania, Illinois, New York, Michigan, and Ohio; these five States accounted for 63% of the total U.S. output. (See table 9.) Leading U.S. producers were Marblehead Lime Co., Asarco Inc., Lone Star Industries, Eastern Industries Inc., and Michigan Minerals Associates; their combined production represented 36% of the total U.S. dolomite production.

Marble.—Production of crushed marble decreased significantly to 3.7 million tons valued at \$83.3 million, mostly owing to changes in reporting the kind of stone produced by some companies. (See table 3.) Crushed marble was produced by 15 companies with 26 operations and 46 quarries in 11 States. Leading States, in order of tonnage, were Alabama and California; these two States accounted for 57.7% of the total U.S. output. (See table 10.) Leading producers of crushed marble, in order of tonnage, were Georgia Marble Co., ECC America, and Calmat of Arizona; their combined production represented 64% of the total U.S. output.

Calcareous Marl.—Output of marl increased 11.4% to 5.7 million tons valued at 13.8 million. (See table 3.) Marl was produced by 14 companies at 15 quarries in 6 States. South Carolina accounted for 57.8% of total U.S. output. (See table 11.) Leading producers, in order of tonnage, were Holnam Inc., Giant Group Ltd., and Medusa Aggregates Co.; their combined production represented 58% of the total U.S. output.

Shell.—Shell is mainly derived from fossil reefs or oyster shell. The output of crushed shell decreased 21% to 5.5 million tons valued at 44.4 million. (See table 3.) The decrease is mostly due to the restrictions imposed on the industry in Louisiana as a result of concerns that shell dredging produces irreversible damage to the environment. Crushed shell was produced by 11 companies from 14 quarries in 6 States. The major producing States were Louisiana and Florida, and the leading producers, in order of tonnage, were Dravo Basic Materials Co., Quality Aggregates Inc., and Sun City Shell, Inc.; their combined production represented 91% of the U.S. output.

Granite.—Compared with that of 1989, the 1991 output of crushed granite decreased 2.5% to 164 million tons valued at \$864 million. (See table 3.) Crushed granite was produced by 157 companies at 334 operations with 492 quarries in 36 States. Leading States, in order of tonnage, were North Carolina, Georgia, Virginia, South Carolina, and California; these five States accounted for 69.5% of the U.S. output. (See table 12.) Leading U.S. producers, in order of tonnage, were Vulcan Materials Co., Martin Marietta Aggregates, Beazer USA, Florida Rock Industries, Inc., and Tarmac America, Inc; their combined production represented 51% of the U.S. total.

Traprock.—Production of crushed traprock decreased 16% to 83.3 million tons valued at 485 million. (See table 3.) Traprock was produced by 242 companies at 561 quarries in 31 States. Leading States, in order of tonnage, were Oregon, Washington, California, Virginia, and New Jersey; these five States accounted for 64.5% of U.S. output. (See table 12.) Leading U.S. producers, in order of tonnage, were Vulcan Materials Co., Syar Industries, Inc., Beazer USA, Luck Stone Corp., and Traprock Industries Inc.; their combined production accounted for 20% of the total U.S. output.

Sandstone and Quartzite.—The combined output of crushed sandstone and quartzite decreased 10.5% to 28.5 million tons valued at 137.7 million. (See table 3.) Crushed sandstone was produced by 110 companies at 132 operations with 208 quarries in 27 States, while crushed quartzite was produced by 26 companies at 26 quarries in 17 States. Leading States in the production of sandstone, in order of tonnage, were Arkansas, Pennsylvania, and South Dakota; their combined production represented 43.1% of the U.S. output. (See table 12.) Leading States in the production of quartzite were California and South Dakota. Leading producers, in order of tonnage, were Arkola Sand and Gravel Co., American Rock and Asphalt Inc., and Latrobe Construction Co. for crushed sandstone and Southdown Inc., Concrete Materials Co., and County Line Quarry Inc. for crushed quartzite. The combined production of the top three producers represented 17% of the total output of crushed sandstone and 58% of the total output of crushed quartzite, respectively.

Slate.—Compared with that of 1989, the 1991 output of crushed slate decreased 27.9% to 1.5 million tons valued at 8.8 million. (See table 3.) Crushed slate was produced by six companies at seven quarries in five States. Most of the crushed slate is produced in North Carolina. Leading producers, in order of tonnage, were Martin Marietta and Lesuer-Richmond Slate Corp.

Volcanic Cinder and Scoria.—Production of volcanic cinder and scoria decreased 43.8% to 2 million tons valued at \$11.5 million. (See table 3.) Volcanic cinder and scoria were produced by 32 companies from 46 operations in 15 States. Leading States, in order of volume, were California, Oregon, and New Mexico; their combined production accounted for 52.7% of the total U.S. output. (See table 13.) Leading producers, in order of tonnage, were Martin Marietta, the U.S.

Forest Service, and Stony Point Rock Quarry Inc; their combined production accounted for 43% of U.S. output.

Miscellaneous Stone.—Output of other kinds of crushed stone decreased 12.1% to 24.7 million tons valued at \$122.7 million. (See table 3.) Miscellaneous stone was produced by 111 companies from 130 operations with 186 quarries in 33 States. Leading States, in order of volume, were Pennsylvania, California, and Arkansas; their combined production accounted for 44.1% of the total U.S. output. (See table 13.) Leading producers, in order of tonnage, were Evered Bardon PLC, Haines & Kibblehouse, Inc., and Better Materials Corp.

Consumption and Uses

Crushed stone production reported to the U.S. Bureau of Mines is actually material that was either sold or used by producers. Stockpiled production is not reported. Therefore, the "sold or used" tonnage represents the amount of production released for domestic consumption or export in a given year. Because some of the crushed stone producers did not report a breakdown by end use, their total production is reported under "Other unspecified uses, actual." The estimated production of nonrespondents is reported under "Other unspecified uses, estimated."

In 1991, U.S. consumption of crushed stone was 1.1 billion tons valued at 5.2 billion, a 9.7% decrease from the estimated consumption of 1990 and a 9.1% decrease from the reported consumption of 1989. About 55.9% of this tonnage was used as construction aggregates, mostly for highway and road construction and maintenance; 10% for chemical and metallurgical uses, including cement and lime manufacture; 2% for agricultural purposes; 1% for special uses and products; and 31% for other unspecified uses. (See table 15.) If the above percentages are calculated without the "unspecified uses," which totaled 340 million tons in 1991, then

about 81% of the reported tonnage was used as construction aggregates, mostly for highway and road construction and maintenance; 15% for chemical and metallurgical uses, including cement and lime manufacture; 3% for agricultural purposes; and 1% for special uses and products. The second breakdown is more representative of the actual distribution of crushed stone uses and should be utilized when analyzing the industry. It is recommended that in any such analysis, the quantities and values included in "Other unspecified uses" be distributed among the reported uses being analyzed, based on the following calculation: the percentage for each reported use should be calculated as a percentage of the U.S. total minus "Other unspecified uses"; the resulting percentages then should be applied to "Other unspecified uses" and the resulting quantities and values added to the reported uses published in the table. The same procedure should be used when calculating consumption by each kind of stone.

Limestone.—Of the 723 million tons of crushed limestone consumed, 219 million tons or 30.3% was reported as "Other unspecified uses." Of the remaining 504 million tons of crushed limestone reported by uses by the producers, 74.2% was used as construction aggregates, 19.3% for cement and lime manufacturing, 3.7% for agricultural purposes, 1.4% for chemical and metallurgical uses, and 1.2% for special uses and products. (See table 17.)

Dolomite.—Of the 61 million tons of crushed dolomite consumed, 7.7 million tons or 12.7% was reported as "Other unspecified uses." Of the remaining 53.3 million tons of crushed dolomite reported by uses by the producers, 87% was used as construction aggregates, 4.9% for agricultural purposes, 2.8% for dead-burned dolomite, 2% for special uses, and 1.3% for lime manufacturing. An additional undefined amount of dolomite consumed in a variety of used, mostly construction aggregates, is reported with the limestone. (See table 17.)

Marble.—Of the 3.7 million tons of crushed marble consumed, 1.9 million tons or 50.6% was reported as "Other unspecified uses." Of the remaining 1.8 million tons of crushed marble reported by uses by the producers, 10.7% was used as construction aggregates, 31.2% for cement manufacture, and 60.7% for miscellaneous uses, including fillers and extenders. (See table 18.)

Calcareous Marl.—Of the 5.7 million tons of crushed calcareous marl consumed, 1.7 million tons or 29.2% was reported as "Other unspecified uses." Of the remaining 4 million tons of crushed marl reported by uses by the producers, 79.7% was used for cement manufacturing, 17.2% as construction aggregates, and 3.2% for agricultural purposes.

Shell.—Of the 5.5 million tons of crushed shell consumed, 4.2 million tons or 76.2% was reported as "Other unspecified uses." Of the remaining 1.3 million tons of crushed shell reported by uses by the producers, 98.9% was used as construction aggregates.

Granite.—Of the 164 million tons of crushed granite consumed, 55.4 million tons or 33.7% was reported as "Other unspecified uses." Most of the remaining 109 million tons of crushed granite reported by uses by the producers was used as construction aggregates. (See table 19.)

Traprock.—Of the 83 million tons of crushed traprock consumed, 24.2 million tons or 29.1% was reported as "Other unspecified uses." Most of the remaining 59 million tons of crushed traprock reported by uses by the producers was used as construction aggregates. (See table 19.)

Sandstone and Quartzite.—Of the 22 million tons of crushed sandstone consumed, 8.9 million tons or 40.9% was reported as "Other unspecified uses." Of the remaining 13 million tons of crushed sandstone reported by uses by the

producers, 94.3% was used as construction aggregates and 5.7% for chemical and metallurgical uses. (See table 20.)

Of the 6.6 million tons of crushed quartzite consumed, 1.6 million tons or 24.4% was reported as "Other unspecified uses." Of the remaining 5 million tons of crushed quartzite reported by uses by the producers, 50.1% was used as construction aggregates and 49.9% for chemical and metallurgical uses.

Volcanic Cinder and Scoria.—Of the 2 million tons of volcanic cinder and scoria consumed, 600,000 tons or 29.7% was reported as "Other unspecified uses." Of the remaining 1.4 million tons of crushed volcanic cinder and scoria reported by uses by the producers, 99.3% was used as construction aggregates. (See table 21.)

Miscellaneous Stone.—Of the 37 million tons of miscellaneous crushed stone consumed, 21.3 million tons or 57% was reported as "Other unspecified uses." Of the remaining 16 million tons reported by uses by the producers, 76.4% was used as construction aggregates and 20% was used for cement manufacturing. (See table 22.)

Prices

The 1991 average unit price of crushed stone increased 7.1% to \$4.70, compared with that of 1989, the last time when an annual survey of the crushed stone producers was conducted. By kind of stone, the average unit prices showed increases of 16.7% for miscellaneous stone, 15% for dolomite, 10% for traprock, 7.2% for limestone, 6.2% for calcareous marl, 3.6% for sandstone and quartzite, 2.3% for granite, and 1.6% for volcanic cinder. At the same time, the average unit price for slate decreased 5.3%. Very large increases were recorded in the average unit price for marble, 97.7%, due to some specialized products produced in 1991, and shell, 61.4%, mostly due to the restrictions

imposed on the production of shell in Louisiana.

As a result of rising costs of labor, energy, and mining and processing equipment, the average unit value of crushed stone increased over the years from \$1.58 per ton, f.o.b. plant, in 1970 to \$4.70 in 1991. However, the unit value in constant 1987 dollars fluctuated between \$3.37 and \$3.90 per ton for the same period, with a declining trend in the past 10 years. (See figure 2.)

Transportation

For 367 million tons or 33.3% of the total 1.1 billion tons of crushed stone produced in 1991, no means of transportation was reported by the producers. Of the remaining 736 million tons of crushed stone, 72.8% was reported as transported by truck from the processing plant or quarry to the first point of sale or use, 5.5% was transported by rail, and 6.3% by waterway. About 12.9% of the total production was reported as not transported and therefore used on-site. Information regarding means of transportation used by the producers to ship crushed stone in each geographic region is also provided. (See table 23.)

Foreign Trade

The widespread distribution of domestic crushed stone deposits and the high cost of transportation limits foreign trade mostly to local transactions across international boundaries. U.S. imports and exports are small, representing less than 0.5% of the domestic consumption. However, shipments of crushed stone by water from Canada and Mexico are increasing.

Exports.—Exports of crushed stone decreased 47.3% to 2.4 million tons compared with that of 1990, while value decreased 20.3% to \$33 million. About 93% of the exported crushed stone was limestone, Canada being the major destination with 99.5% of the total crushed stone. (See table 25.)

Imports.—Imports of crushed stone increased 14% to 5.7 million tons compared with that of 1990, while the value increased 9.3% to \$38.6 million. About 95.6% of the imported crushed stone was limestone, 46% of which came from Mexico, 28% from Canada, and 8% from the Bahamas. (See table 26.)

Imports of natural calcium carbonate fines decreased by 33% to 2,000 short tons. About 68% of processed calcium carbonate was imported from France. Shipments of crushed stone from Bahamas, Canada, and Mexico into the United States continued in 1991. The imported crushed stone, used mostly as construction aggregates or for cement manufacturing, was distributed in Alabama, Florida, Georgia, Louisiana, Michigan, New York, Ohio, Pennsylvania, Texas, and Washington. This trend is expected to continue, and the volume of imports, especially from Mexico, to increase.

World Review

Canada.—The 1990 production of stone in Canada was 111 million metric tons, a decrease of 6.7% from the revised final 1989 total of 119 million tons, valued at \$663 million. An additional 16 million tons of crushed stone was used in 1989 by the Canadian cement and lime industries. About 99% of the 1989 output was crushed or pulverized stone used for construction, chemical, metallurgical, and agricultural uses. The Province of Ontario continued to be the largest producer of stone, with 50.4 million tons valued at \$301 million, followed by Quebec with 40.6 million tons valued at \$244 million. The two Provinces accounted for 81.8% of the total stone production. Preliminary estimates for 1991 stone production indicate a significant decrease of 23% to 85.8 million tons valued at \$513 million. The Provinces of Ontario and Quebec continued to be the largest producers of stone with about 84% of the total output.

United Kingdom.—The 1990 production of crushed stone in Great

Britain (Northern Ireland not included) declined 4.1% compared with the record-high level of 1989, as reported by the British Aggregate Construction Materials Industries Association (BACMI). Of this total, 162 million tons was used for construction purposes. About 65% of the total output of crushed stone was limestone and dolomite. East Midlands and South West were the largest crushed stone-producing regions, followed by Wales and Scotland. Preliminary estimates made by BACMI indicate that a total of 168 million tons of crushed stone was produced in 1991, a 9% decrease compared with that of 1990.

Current Research

Recognizing the need for research into properties and adequate use of aggregates, crushed stone, and sand and gravel, as well as the need for reliable technical information in this area, the National Aggregates Association and the National Stone Association established in 1990 the Aggregates Foundation for Technology, Research, and Education (AFTRE.) The main purpose of the foundation is to establish and provide the funding for a new Aggregates Research Center. The crushed stone and sand and gravel industries representatives consider that the research plan of the Federal Strategic Highway Research Program, for example, does not adequately address the aggregate component of highway systems, while great emphasis is being placed on scientific research on the binders—*asphalt and cement and their associated admixtures and additives.* Both industries felt that they should take the lead in supporting scientific research that will address the key issues concerning aggregates and will contribute to the effective use of available resources. Therefore, the main goal of the foundation and the research center will be to support scientific research and education and develop and disseminate authoritative technical information related to construction aggregates. The comprehensive and objective information on construction aggregates developed by the research center will promote and

extend the effective and efficient use of aggregates in the construction industries. At the 1992 CON/AGG Show held in New Orleans, LA, between February 1 through February 6, 1992, the Board of Trustees of AFTRE announced the selection of the University of Texas at Austin and the Texas A&M University at College Station as the home of the new Aggregates Research Center.

Nineteen ninety-one was the fourth year of the 5-year Strategic Highway Research Program (SHRP), a program created in 1987 by the U.S. Congress. SHRP's mission is to produce usable research results targeted toward technical areas where there is potential for improvement of our highways and the materials used to build them, research that could also yield significant cost savings. SHRP's research activities account today for more than one-quarter of all highway research conducted in the United States by Federal agencies, States, and the private industry.

SHRP's four areas of research are asphalt, concrete and structures, highway operations, and long-term pavement performance. To improve the quality of pavements, better materials specifications and asphalt-concrete mixture design systems based on a scientific understanding of how asphalt properties influence performance are needed. SHRP made significant progress toward that goal in 1991.¹⁴

Based on results obtained through the use of state-of-the-art chemical and physical analysis techniques, researchers supported by SHRP have developed a chemical model of asphalt structure that, for the first time, explains how asphalt chemistry affects binder performance. Analysis of samples of asphalt using nuclear magnetic resonance (NMR) spectroscopy indicated that the molecular structures in asphalt are very small, contrary to the long-accepted "micellar" model that had pictured asphalt as relatively large lumps of materials in a sticky gel. At the same time, chemical analysis using ion-exchange chromatography indicated that the molecules that gave the asphalt most of its physical properties comprised only a

small portion of the total number of asphalt molecules. Based on these results, a model was produced that describes asphalt as a polar dispersed fluid and reconciles asphalt's chemical features with its physical behavior.

SHRP's concrete program is developing new engineering guidelines and materials tests that will help highway engineers produce more durable concrete consistently. Alkali-Silica Reactivity (ASR) of concrete is a damaging and difficult-to-detect problem in highway structures and a major area of concern for the highway and bridge inspectors. SHRP's Construction Technology Laboratories developed a new, quick chemical field test that uses uranyl acetate fluorescence to detect whether an ASR product has been formed in concrete. SHRP's Handbook for the Identification of Alkali-Silica Reactivity in Highway Structures provides guidance on proper diagnosis and assessment of ASR problems.¹⁵

SHRP's Long-Term Pavement Performance (LTPP) program addresses the issue of how best to use and protect the very large investment made every year in building and maintaining highway pavements. SHRP's LTPP program, the largest and most comprehensive pavement performance test in history, is collecting data on pavement conditions, climate, traffic, and load conditions over a 20-year period. The LTPP experiments involve testing of almost 1,000 in-service sections of the most common types of pavement design in use in the United States, as well as sections that have been specially constructed to isolate certain factors in pavement design.

The American Association of State Highway and Transportation Officials, the Federal Highway Administration, and the National Research Council have agreed on an approach to establish an oversight of continuing activities when some of SHRP's programs expire in 1992. The SHRP Monitoring and Research Transfer Committee will be created by the National Research Council that will include representatives from a broad spectrum of organizations, including

strong State highway agency representation.

Technology

The participants of the 1990 European Asphalt Study Tour sponsored by the Federal Highway Administration and the National Asphalt Pavement Associations concluded that there is "a lot to learn from Europe about asphalt pavements and about pavement philosophy in general. European pavements are better than ours. The Europeans invest more in research, development, and deployment of new pavement technology. They build their pavement foundations better. They use innovative surfaces, such as Stone Mastic Asphalt, and mix in additives to a greater extent and with better results."¹⁶ Stone Mastic Asphalt, also called Split Mastic Asphalt, is built using the stone-on-stone concept that develops internal friction and resistance to shear. The coarse aggregate is usually 100% crushed stone with a top size of 3/4 to 1/2 inches, and 70 to 80 percent by weight retained on the No. 10 sieve. The mix has a relatively high asphalt content of 6.5% to 7.5% and addition of cellulose or mineral wool fibers that improves the stability of the binder and prevents it from draining off the aggregate.¹⁷ A section of a highway near Lansing, MI, was selected by the Federal Highway Administration as a demonstration site to test the feasibility of using Stone Mastic Asphalt in the United States. Other demonstration projects are under way in Georgia and Wisconsin. According to the Michigan Department of Transportation, the Stone Mastic Asphalt mix provides high resistance to deformation (rutting), good wear resistance, improved low-temperature performance, improved aging and skid resistance properties, and increased service life. The cost of the Stone Mastic Asphalt is about 20% to 30% more than a conventional dense-graded surface course.¹⁸

Specialized computer services using high technology provide fast and accurate earthwork volume estimating to calculate production and stock inventories in aggregates operations. Computer

generated cross sections of the pit or quarry at very close intervals are generated, and very accurate calculations of volumes are performed. Valuable three-dimensional depth maps and two-dimensional cross sections of the operations can be also produced that can assist the plant operators or the designers of new pits and quarries.¹⁹

More aggregates-producing companies are automating their operations to remain competitive. Automated weighing and information processing systems in the crushed stone and sand and gravel industries are usually one of the first areas to be automated, especially in medium- to small-size operations. A properly selected and implemented computer-based data collection, storage, retrieval, and reporting system provides the operations with fewer mistakes, reduced expenses, and more timely available information. A review of present technology, software and hardware, and recommendations on how to select and implement the proper system in aggregates operations was published by Pit & Quarry.²⁰

Technologically, the aggregates industry is very complex and requires professionals with skills in a variety of areas, including geology and geophysical sciences, mining, materials, and geotechnical engineering and management. For a long time there has been a need for a comprehensive reference book covering the construction aggregates that can be used by producers, consulting and design engineers, and users. The Aggregate Handbook published by the National Stone Association in 1991 is just such a publication. The handbook covers all aspects of the sand and gravel and crushed stone industries from basic properties of aggregates, geology, exploration, extraction, and processing, to uses, standards and specifications, sampling and testing, marketing, and regulatory compliance. Numerous references are also provided for those interested for more in-depth information.²¹

OUTLOOK

The demand for crushed stone in 1992 is expected to be about 1.16 billion tons, a 5% increase compared with that of 1991. Gradual increases in demand for construction aggregates are anticipated after 1992 as well, based on increased volume of work on the infrastructure that is being financed by the Intermodal Surface Transportation and Infrastructure Act of 1991 and the recovery of the U.S. economy. It is estimated that the demand for crushed stone will reach 1.4 billion tons in 1995. The projected increases will be influenced by construction activity primarily in the public construction sector.

Crushed stone f.o.b. prices are not expected to increase significantly, even if the demand for construction aggregates will rise over the forecasts. However, the delivered prices of crushed stone are expected to increase, especially in and near metropolitan areas, mainly because more aggregates are transported from distant sources.

TABLE 1
SALIENT U.S. CRUSHED STONE STATISTICS

(Thousand short tons and thousand dollars)

		1987	1988	1989	1990	1991
Sold or used by producers:						
Quantity ¹	thousand short tons	1,200,100	*1,247,800	1,213,400	*1,222,000	1,102,900
Quantity	thousand metric tons ²	1,088,713	1,131,985	1,100,778	1,108,580	1,000,534
Value ¹	thousand dollars	\$5,248,600	*\$5,558,000	\$5,325,800	*\$5,591,300	\$5,186,800
Exports	value, thousand dollars	\$26,063	\$30,413	\$23,345	*\$41,400	\$33,003
Imports ³	do.	\$14,024	\$16,789	\$36,870	*\$35,310	\$38,649

*Estimated. Revised.

¹Does not include American Samoa, Guam, Puerto Rico, and the U.S. Virgin Islands.

²One metric ton is equal to 1,000 kilograms or 2,204.62 pounds. To convert short tons into metric tons, multiply short tons by 0.907185.

³Excludes precipitated calcium carbonate.

TABLE 2
TIME-PRICE RELATIONSHIP FOR CRUSHED STONE

Year	Actual unit price	Unit prices in 1987 constant dollars	Unit prices in 1970 constant dollars
1970	\$1.58	\$3.77	\$1.58
1971	1.72	3.90	1.63
1972	1.72	3.71	1.56

TABLE 15
CRUSHED STONE SOLD OR USED BY PRODUCERS IN THE UNITED STATES IN 1991, BY USE

(Thousand short tons and thousand dollars)

Use	Quantity	Value	Unit value
Coarse aggregate (+1 inch):			
Macadam	4,426	19,653	4.44
Riprap and jetty stone	22,612	111,081	4.91
Filter stone	7,911	35,048	4.43
Other coarse aggregate	579	2,641	4.56
Coarse aggregate, graded:			
Concrete aggregate, coarse	100,793	491,761	4.88
Bituminous aggregate, coarse	78,227	423,372	5.41
Bituminous surface-treatment aggregate	28,980	143,572	4.95
Railroad ballast	18,074	84,862	4.70
Other graded coarse aggregate	696	1,202	1.73
Fine aggregate (-3/8 inch):			
Stone sand, concrete	20,672	112,498	5.44
Stone sand, bituminous mix or seal	24,330	112,772	4.64
Screening, undesignated	26,989	115,084	4.26
Other fine aggregate	427	2,863	6.70
Coarse and fine aggregates:			
Graded road base or subbase	179,536	723,335	4.03
Unpaved road surfacing	30,546	128,099	4.19
Terrazzo and exposed aggregate	2,208	18,910	8.56
Crusher run or fill or waste	39,441	162,695	4.13
Other coarse and fine aggregates	1,348	8,223	6.10
Other construction materials ¹	23,767	119,020	5.01
Roofing granules	4,545	27,254	6.00
Agricultural:			
Agricultural limestone	18,133	94,412	5.21
Poultry grit and mineral food	3,187	31,780	9.97
Other agricultural uses	982	5,782	5.89
Chemical and metallurgical:			
Cement manufacture	85,386	266,014	3.12
Lime manufacture	18,647	103,139	5.53
Dead-burned dolomite manufacture	1,511	5,733	3.70
Flux stone	5,143	24,501	4.76
Chemical stone	337	1,891	5.61

See footnotes at end of table.

TABLE 15—Continued
CRUSHED STONE SOLD OR USED BY PRODUCERS IN THE UNITED STATES IN 1991, BY USE

(Thousand short tons and thousand dollars)

Use	Quantity	Value	Unit value
Chemical and metallurgical—Continued:			
Glass manufacture	908	9,829	10.82
Sulfur oxide removal	2,249	12,551	5.58
Special:			
Mine dusting or acid water treatment	964	13,094	13.58
Asphalt fillers or extenders	2,418	17,606	7.28
Whiting or whiting substitute	866	28,619	33.05
Other fillers or extenders	4,577	85,598	18.70
Other miscellaneous uses:			
Chemicals	601	3,281	5.46
Abrasives	16	81	5.06
Magnesia (dolomite)	18	30	1.67
Other specified uses not listed ²	346	4,224	12.21
Unspecified:³			
Actual	259,223	1,255,712	4.84
Estimated	81,253	378,997	4.66
Total⁴	1,102,900	5,186,800	4.70

¹Includes dam construction, drain fields, lightweight aggregate (slate), building products, pipe bedding, and waste material.

²Includes refractory stone (including ganister) and paper manufacture.

³Includes production reported without a breakdown by use and estimates for nonrespondents.

⁴Data may not add to totals shown because of independent rounding.

DIMENSION STONE

By Harold A. Taylor, Jr.

Mr. Taylor, a physical scientist with 26 years of industry, Federal Government, and U.S. Bureau of Mines experience, has been the commodity specialist for dimension stone since 1981. Domestic survey data were prepared by Robin Richardson, statistical assistant.

Production of dimension stone increased slightly to 1.14 million short tons valued at \$197 million. More than one-half of the dimension stone produced was granite. Limestone, marble, sandstone, and slate were also produced.

Exports of dimension stone increased 20% in value to \$65 million. The value of dimension stone imports for consumption decreased 19% to \$475 million, equivalent to 241% of the value of domestic production.

DOMESTIC DATA COVERAGE

Domestic production data for dimension stone are developed by the U.S. Bureau of Mines from voluntary surveys of U.S. producers of rough and finished dimension stone. Of the 368 dimension stone operations surveyed for 1991, including those that were idle, 328, or 89%, responded, representing 96% of the estimated value shown in table 1. Production data for nonrespondents were estimated using preliminary production reports, adjusted prior years' production levels, and employment data. (See table 1.)

BACKGROUND

Definitions, Grades, and Specifications

Dimension stone is a natural rock material that has been selected, trimmed, or cut to specified or indicated shapes or sizes, with or without one or more mechanically dressed surfaces. This includes rough stone, rubble, ashlar, blocks, panel, and curvilinear shapes. Finished surface requirements may vary from a controlled fractured surface to

ground and polished. The most prominent required qualities of dimension stone are strength, toughness, hardness, and resistance to environmental damage. Color and grain structure contribute largely to price and marketability. The principal types of dimension stone used in construction are granite, marble, limestone, sandstone, and slate.

Stone classification by type in the dimension stone industry is somewhat ambiguous and does not correspond in some respects with the same terms used in mineralogical rock descriptions. The U.S. Bureau of Mines generally accepts the classification reported by producers. Granite includes all feldspathic crystalline rocks of predominantly interlocking texture and with mineral grains visible to the naked eye; these include igneous and metamorphic rocks, including quartz diorites, syenites, quartz porphyries, gabbros, anorthosites, and gneisses. White, gray, black, pink, and red are the common colors for granite, but greens, browns, and other shades are produced in some localities.

Limestone includes dolomitic types as well as calcitic. The latter contains less than 5% magnesium carbonate ($MgCO_3$). Dolomitic limestone contains 5% to 40% $MgCO_3$. Marble is a recrystallized (metamorphosed) limestone containing grains of calcite or dolomite or both. In commercial usage, it is any calcareous crystalline rock or serpentine, a hydrous magnesium silicate, capable of taking a polish. Travertine is a type of marble similar to onyx except that it is precipitated from warm or hot water; it has a banded cellular structure and contains cavities up to one-half inch in

width that are lined with microstalactites. Dark green serpentines are classified as marble in the industry because they are often crisscrossed with marblelike veinlets of lighter materials, chiefly calcite or dolomite, and because of their ability to take a high polish.

Commercial sandstone is a sedimentary rock consisting mostly of quartz, sometimes with feldspar, or rock fragments of clastic texture bonded by silica, clay, calcite, or iron oxide. Bluestone is a dense, hard, fine-grained feldspathic sandstone that splits easily along a plane into thin, smooth slabs. It is commonly dark or slate gray in color, and its name no longer has color significance. Brownstone is a feldspathic sandstone of brown reddish-brown color caused by abundant interstitial iron oxide. Flagstone may be either a sandstone or a slate that splits into large, thin slabs.

Quartzite is a metamorphic equivalent of sandstone that has been firmly cemented by secondary silica or by recrystallization so that it is essentially homogeneous and fractures through rather than around the original sand grains.

Slate is a fine-grained metamorphic rock derived from shale, siltstone, or claystone. It has prominent cleavage that is oriented independently from the original sedimentary bedding. Mineral constituents are quartz, mica, sericite, or chlorite with assorted minor accessories. Shale is composed mostly of original clay minerals, and cleavage is parallel to the bedding.

Traprock is a commercial term for all dark, igneous rocks too fine in grain size to be called black granite. In addition to extrusive flow rocks such as basalt, andesite, or dacite, traprock includes

intrusive igneous rocks such as diabase, diorites, gabbros, pyroxenites, amphibolites, and peridotites.

Miscellaneous stones used for dimension purposes include schist, scoria, soapstone, wollastonite, argillite, and many others.

Geology-Resources

Domestic resources of most types of dimension stone used in construction are practically unlimited. There is considerable interstate transportation of certain types of stone such as Indiana limestone, Georgia marble and granite, and Vermont granite, marble, and slate. A lack of deposits of certain specific varieties of dimension stone especially noted for their aesthetic qualities in architecture and artifact manufacture is an important cause of importation of these varieties; for example, brightly colored marbles from Italy.

Technology

Mining.—Present mining methods range from antiquated and very inefficient, which is rather uncommon nowadays, to modern and technically superior. Quarrying methods include use of various combinations of diamond saws, wire saws, diamond wire saws, chain saws, channeling machines, drilling machines, wedges, and broaching tools. The choice of equipment depends on the type of dimension stone, size and shape of deposit, production capacity, labor costs, economics, and management investment attitudes.

Little blasting is done in the mining of dimension stone. Blocks cut from the face are sawed or split into smaller or thinner blocks for ease in transportation and handling and taken to processing plants, commonly at the quarry site, for final cutting and finishing operations.

Processing.—Stone-sawing equipment includes large circular saws 10 feet or more in diameter, usually with diamond inserts; diamond circular saws of smaller size; and reciprocating diamond-bladed or

loose-abrasive gang saws for multiple cuts. Various types of diamond and other equipment are used for smoothing, polishing, edging, and decorating the finished stone products. (See table 2.)

Economic Factors

The depletion allowance for dimension stone is 14%. Dimension stone quarries are generally in mountainous or hilly areas remote from areas of dense population. Because land use for other purposes is limited, the cost of land is reasonable.

Transportation costs for dimension stone are high because of its weight and because special handling methods are required to prevent damage to the finished stone. A single stone panel broken in transit not only results in the loss of the many employee-hours of skilled labor required to produce it, but also can cause construction delays that are even more costly. Nevertheless, dimension stone is routinely shipped long distances by motor and rail freight, and special domestic varieties are shipped by ocean freight to foreign countries.

Operating Factors

Environmental requirements vary from State to State and are often a cause of conflict between State or local governments and the quarry operators.

Stone primary and waste products are not toxic, nor are the supplies utilized in their production. However, sufficient exposure to silica-rich stone dust can cause silicosis.

The approximate number of employees in the dimension stone industry by stone kind are granite, 9,600; limestone, 1,100; marble, 1,500; slate, 950; and sandstone and other dimension stone, 850. Of the total 14,000, about 3,100 are employed in quarrying and approximately 10,900 in finishing operations. Major States for employment were Georgia with 2,100 employees, Vermont with 1,700, Minnesota with 1,250, North Carolina with 850, Texas with 700, and Indiana with 650.

Fuel is used to power quarrying equipment, and electricity is used for sawing and finishing. Water is used in some quarries to cool equipment such as chain saws and in sawing and finishing plants to cool the equipment; water consumption is relatively minimal in all instances.

ANNUAL REVIEW

Production

Dimension stone was produced by 185 companies at 279 quarries in 35 States, including Puerto Rico. Leading States, in order of tonnage, were Indiana, Georgia, and Vermont, together producing 40% of the Nation's total. Of the total production by tonnage, 51% was granite, 28% was limestone, 11% was sandstone, 3% was slate, 4% was marble, and the remaining 3% was miscellaneous stone. Miscellaneous stone included argillite, schist, soapstone, and traprock (basalt). Leading producing companies, in terms of tonnage, were Cold Spring Granite Co., principally in California, Minnesota, South Dakota, and Texas; Rock of Ages Corp. in New Hampshire and Vermont; and Fletcher Granite Co., Inc., in Massachusetts and New Hampshire.

Granite.—Dimension granite includes all coarse-grained igneous rocks. Production decreased 8% to 585,300 tons and decreased 16% in value to \$97.8 million. Granite was produced by 58 companies at 104 quarries in 19 States. Georgia continued to be the leading State, producing 30% of the U.S. total, followed by Vermont and Massachusetts. These three States together produced more than 54% of the U.S. total. Cold Spring Granite, Rock of Ages, and Fletcher Granite were the leading producers and accounted for 47% of U.S. production by tonnage.

Limestone.—Dimension limestone includes bituminous, dolomitic, and siliceous limestones. It was produced by 33 companies at 39 quarries in 12 states. Indiana, the leading State, was followed

by Wisconsin and Texas. Leading producers were Indiana Limestone Co. Inc., Independent Limestone Co., and Victor Oolitic Stone Co. The top three companies accounted for 31% of U.S. output.

Marble.—Dimension marble includes certain hard limestones, travertines, and any other calcareous stone that can be polished. Dimension marble was produced by 13 companies at 15 quarries in 11 States, including Puerto Rico. Colorado, Georgia, and Vermont, in order of tonnage, were the three leading States, accounting for approximately 73% of U.S. output. Leading producers were Colorado Yule Marble Co., Georgia Marble Co., and Vermont Marble Co. The top three companies accounted for 72% of U.S. output.

The major news in marble this year was the addition of a new domestic producer and the major expansion of two almost-new producers. The production of the Colorado Yule Marble Co. rapidly expanded as it came more fully on-stream. The product will be used in the new Denver Airport. Sizable amounts of rough blocks are being exported to Italy and Japan.

Dixie Marble, Inc. has opened a quarry near Sylacauga, AL, for Alabama marble. The quarry is producing a white, a gray, and two white with gray veining marbles. Diamond wire saws and diamond belt saws are being used in the quarry to cut out the rough blocks. Reserves will last 150 years at the present rate of quarrying. The firm is also producing four shades of Tennessee marble and buying rough blocks of several colors of Arkansas marble. These marbles are being made into tile by the Armstar plant in Lenoir City, TN. The firm is planning to add some gangsaws and a finishing plant for tiles and slabs later. This represents a substantial increase in the number of colors of domestic marbles currently available, particularly counting the new Puerto Rican marbles.

The Puerto Rican operations of Marmoles Vassco, Inc., of Ponce, Puerto Rico, really hit their stride this year, now

that the new equipment is almost all beyond the startup phase. The quarrying operation presently supplies a number of colors, to which will be added a black marble when a new quarry comes on-stream. The marble is quarried by diamond wire saws. The finishing plant has a capacity of 120,000 square feet per month of tile. Thin (5/8 inch) bush-hammered tile is also produced. The firm also can produce structural items such as window sills, thresholds, and risers, plus tables and countertops. It now has 80 employees, up from 7 in 1988. The firm is considering exporting rough blocks, perhaps to Italy.

Sandstone.—Dimension sandstone includes calcareous- and siliceous-cemented sandstones or conglomerates. Quartzite, which is also included, may be described as any siliceous-cemented sandstone. It was produced by 30 companies at 55 quarries in 16 States. The leading three States were, in order of volume, Ohio, Arizona, and New York. Western State Stone Co., Inc., Briar Hill Stone Co., and Waller Bros. Stone Co. were the leading producers and accounted for 44% of U.S. production. In addition to the quantities shown in table 7, dimension quartzite totaled 16,766 tons worth \$1,340,000.

Slate.—Dimension slate was produced by 20 companies at 25 quarries in 7 States. The two leading States, Vermont and Pennsylvania, in order of volume, accounted for 69% of U.S. output. The top three producers, A. Dally and Sons Inc., LeSueur-Richmond Slate Co. Inc., and Alfred McAlpine Inc., accounted for an estimated 44% of U.S. output by volume.

Miscellaneous Stone.—Miscellaneous dimension stone, including traprock, was produced by five companies from six quarries in four States and totaled 15,643 tons value at \$1,351,000. (See tables 3, 4, 5, 6, and 7.)

Consumption and Uses

Dimension stone was marketed over wide areas. Industry stockpiles were not monitored, and production during 1989 was assumed to equal consumption.

Consumption of domestic dimension stone increased slightly to 1.14 million tons valued at \$197.1 million. Ashlars and partially squared, dressed pieces were 21% of the total value of consumption, followed by rough monumental stone with 15%; slabs and blocks for building and construction with 14%; dressed monumental stone with 14%; and other uses, 24%.

Of the total consumption of domestic granite, 31% by value was rough monumental stone, 18% was dressed monumental stone, 17% was ashlar and partially squared pieces, and 17% was curbing.

Consumption of domestic limestone totaled 316,982 tons valued at \$45.4 million, of which 43% was ashlar and partially squared pieces, 25% was rough blocks for building and construction, and 19% by value was dressed slabs and blocks for building and construction. The change in ashlar from previous years reflects shifts in building practice to veneer and a shift in reporting.

Limestone tile is an important new product that is rapidly gaining popularity. For several years now, tiles made out of hard limestone have sometimes been used as substitutes for other stones, particularly granite tile. These tiles (or slabs) have sometimes been domestic, but more commonly were French or Spanish limestones. They were used in applications where granite or marble are customarily used. Now tile of softer limestones are being made and sold. Specific applications known include some flooring areas not subject to heavy traffic or grit-bearing footwear. (See tables 8, 9, 10, 11, 12, and 13.)

In a long-enduring trend before 1980, building dimension stone was replaced to a large extent by concrete, glass, brick, stainless steel, aluminum, porcelain-enameled steel, and plastics. These materials are used in the manufacture of modern mass-produced building modules

and precast building panels. The installed cost of many of these alternate materials has been lower than that of stone. Since 1980, stone has been increasingly preferred for more dignified buildings where its architectural adaptability, permanence, and prestige are of prime importance. A movement back to stone has occurred because of the greater impact of rising energy costs on these substitutes. Resin-bonded stone panels made from stone chips are becoming an important substitute for dimension stone.

Slate has to meet competition from many sources. As a roofing material, alternates such as sheet metal, wood shingles, asbestos-cement shingles, and tile are available. For blackboards, it competes with colored glass, porcelain-enameled steel, and special painted surfaces.

Prices

The average price for dimension stone increased to \$173 per ton, down slightly from \$177 in 1990.

Foreign Trade

Exports.—Exports of dimension stone, more than 50% of which was granite, increased 21% in value.

Imports.—Imports for consumption of dimension stone decreased 19% in value to \$475 million, mostly because of decreases in imports of several major categories of dimension stone, particularly marble slabs, for the second year in a row. Imports of dressed marble slabs, mostly from Italy, decreased 50% to \$74 million. On a value basis, marble accounted for 50% of imports, followed by granite at 33%. (See tables 14, 15, 16, and 17.)

World Review

Dimension stone is quarried in the great majority of nations in the world. As usual, Italy produced about one-half of the world production. The major importing countries were the United

States and Japan; and for rough stone, also Italy. Other significant producers were Brazil, China, Finland, India, Norway, Portugal, Spain, Sweden, Turkey, and the United States.

A major review of world dimension stone markets appeared this year. The statistics are of particular interest. For example, Italy accounted for 25.9% of world dimension stone exports in 1990, Spain, 8.6%; India, 7.4%; the Republic of South Africa, 7.2%; China, 5.9%; Republic of Korea, 5.5%; Portugal, 5.3%; and Brazil, 5.2%. When world dimension stone consumption is considered by application, flooring applications account for 35.2%. In addition, external building facing accounted for 22.8%, funeral products (monumental) for 14.7%, stairs and halls for 7.2%, structural works for 7.2%, internal building facing for 5.2%, and the balance in other applications. The outlook stated was positive, considering the trend toward stone and away from competing materials, changing technology leading to new uses, and supply restrictions in many countries outside North America and Western Europe caused by increased pressure to reclaim closed quarries.¹

A major review of world slate markets appeared in the same source. The increased interest in dimension stone in the 1980's has also helped the slate industry. At the same time, many firms have undertaken considerable modernization programs, often involving saws. While much more of the production is done by machinery, roofing slate and most other products are still split by hand. Spain produces about 440,000 to 500,000 tons of roofing slate per year, of which 30,000 tons is consumed domestically. France produces about 50,000 tons of roofing slate per year, the United Kingdom about 39,000 tons, and the Federal Republic of Germany about 20,000 tons. Production in all these countries expanded to a marked degree during the 1980's. The importance of Brazil, China, and India is increasing in world slate markets. Usage of waste slate is much higher in Europe

than America, such as in road aggregate, roofing granules, and fillers.²

Finland.—A thorough review of the Finnish dimension stone industry recently indicated that it was steadily expanding and doing quite well, particularly granite and soapstone. The granite is mostly quarried in the area surrounding Helsinki, particularly to the west. Most of the soapstone is quarried near Juuka, about 200 miles northeast of Helsinki. The largest granite producer is Finska Stenindustri Ab, and the largest soapstone producer is Suomen Vuolukivi Oy (Tulikivi). The great majority of the granite is exported, almost all as rough blocks. Most of the soapstone is made into stoves, fireplaces, and architectural products and used domestically. The rest of the soapstone is exported as these same finished products. The granite industry is opening new quarries that will broaden the range of colors available. The soapstone industry will continue to respond to the growing domestic demand as well as the export demand.³

Hungary.—Centurion Mining PLC of London and the Hungarian Investment Co. Ltd. have jointly and equally bought a one-half interest in state-owned Kofargo. Kofargo will now be only one-half state-owned and will be subdivided into Pannon Marble Industries and Renaissance Stone Masonry Co. Pannon Marble's Sutto Div. will own and operate three red marble quarries, five travertine quarries, and four finishing plants for slab and tile. Pannon's Siklos Div. will operate three quarries that produce pink, yellow, cream, green, and gray marbles and a limestone and operate a finishing plant for tile. Renaissance Stone Masonry will operate a finishing plant for ashlar, architectural products, and sculptural work. It will also provide masonry and renovation expertise.

India.—Exports of Indian dimension stone have grown rapidly in recent years: in 1986-87 it was 600 million Rupees and in 1989-90 it was 1,520 million Rupees (1,470 of this being granite). More than

20 different types of granite are produced and exported as rough block, polished slab, tile, and monuments. Polished marble slabs and tiles valued at 20 million Rupees are exported. Slate exports are growing but are still very small. Granite is quarried mostly in Andhra Pradesh, Karnataka, and Tamil Nadu States, and marble is quarried mostly in Rajasthan.

Mexico.—Marmoles Muguero S.A. has built a 70,000-square-foot-per-month-capacity finishing plant, mostly for tile, in Durango. The tile will be available in many sizes and several patterns and styles, such as octagon and hexagon. The plant will process volcanic tuff, called Sierra Stone, from the firm's five quarries in or near the Sierra Madre Mountains. The tuff comes in 12 colors, mostly pastels.

MTC has just completed a finishing plant in Zacatecas for onyx. It has a capacity of 190,000 square feet of tile and 70,000 square feet of slab per month. The firm has five onyx quarries, two of which are presently operating, all of which use diamond wire saws.

Some other firms have finishing plants for marble and/or granite. The Industrias Petrus Group has six operating quarries and several plants; one plant, belonging to Granitos Naturales S.A., makes granite tiles and slabs in Nuevo Laredo, and one, belonging to Industrias del Travertino S.A., makes travertine tile. This group produces 3.6 million square feet of marble tile, 1.2 million square feet of marble slab, 600,000 square feet of granite tile, and 600,000 square feet of granite slabs per year. Terramar Mosaicos SA has a marble tile and slab plant in Puebla. Fachadas y Monumentos S.A. de C. V. has three operating quarries and several plants—one plant makes marble tile and slab in Monterrey; one, belonging to J. G. Marmol S.A. de C. V., makes marble tile in Puebla; and one, belonging to Marmorey S.A. de C. V., makes marble tile in Torreon. The latter group produces 1.4 million square feet of tile, 350,000 square feet of slab, and 750,000 square feet of cut-to-size pieces per year.

Namibia.—The only dimension stone production of any importance is for marble, which totaled 13,850 tons in 1989. Some other stone was produced; for example, limestone and granite. The marble is mostly quarried in the Karibib area (white, yellow, brown, and gray mostly) and in the Swakopmund area (verde antique). Sizable amounts of white and light-colored limestone is quarried south of Aus. Granite is also quarried in the Karibib and Swakopmund areas and in the Okahandja and Spitzkoppe areas.

Spain.—The Ingemar group of dimension stone producers has formed another firm, Ingemarto S.A., to run a new plant that has 17 gangsaws and a granite tile line. The plant, near Toledo, will serve 11 company-owned granite quarries in central and western Spain. The other Ingemar firms are in northernmost Spain, at Usurbil and Guitiriz. The group produces 18 million square feet of granite slab, 0.5 million square feet of granite tile, 4.5 million square feet of marble slab, plus cut-to-size items, limestone, and other products.

Current Research

Two comprehensive articles on stone anchoring systems appeared in the same issue of a major trade journal. Selecting the correct anchoring system is important in preventing failure of the stone cladding of a building. One article covered the Cygnus Wall System, the Slotlok Fastener System, Halfen brackets, Heckmann Building ties and anchors, and Frimeda anchors. The other article covered continuous anchors, such as an aluminum anchor with bearing point, an aluminum offset anchor, an aluminum gravity anchor, an intermediate anchor in noncontinuous slot, a soffit panel with marble liner, a frame with continuous aluminum anchors, and a noncontinuous aluminum-base support. It also recommended what metal-to-metal contacts to use to avoid galvanic corrosion.⁴

OUTLOOK

Projected demand for dimension granite totaled 1.5 million tons for 1995 and 2.2 million tons for the year 2000. Demand for dimension marble totaled 400,000 tons for 1995 and 600,000 tons for the year 2000. Demand for dimension limestone totaled 350,000 tons for 1995 and 390,000 tons for the year 2000, while demand for slate ought to be 35,000 tons in 1995 and 37,000 tons in the year 2000. This slow rate reflects a major drop in the market for building stone in 1989-93 and a welcome recovery later in the 1990's. Certain segments will continue to grow rapidly, such as the uses in kitchens and bathrooms. The supply will be adequate and is likely to shift in favor of domestic producers.

STRONTIUM

By Joyce A. Ober

Mrs. Ober, a physical scientist with 14 years of industry and U.S. Bureau of Mines experience, has been the commodity specialist for strontium since 1986. Domestic survey data were prepared by Linder Roberts, statistical assistant; and the international production table was prepared by Virginia A. Woodson, international data coordinator.

The largest consumption of strontium compounds domestically and internationally was in the production of color television picture tube faceplate glass. Strontium carbonate, produced by processing the mineral celestite, was the most important strontium compound produced. Chemical Products Corp. (CPC) of Cartersville, GA, was the only U.S. producer of strontium compounds from celestite. CPC produced compounds from imported material because there were no active celestite mines in the United States.

Strontium occurs commonly in nature, averaging 0.034% of all igneous rock; however, only two minerals, celestite and strontianite, contain strontium in sufficient quantities to make its recovery practical. Of the two, only celestite has been found to occur in deposits of sufficient size to make development of mining facilities currently attractive. Celestite, the most common strontium mineral, consists primarily of strontium sulfate. Strontianite, the second most common mineral, consists primarily of strontium carbonate. Strontianite would be the more useful of the two common minerals because strontium is used most commonly in the carbonate form, but few deposits have been discovered that are suitable for development.

DOMESTIC DATA COVERAGE

The sole U.S. strontium carbonate producer voluntarily provided domestic production data to the U.S. Bureau of Mines. Production and stock data, however, were withheld from publication

to avoid disclosing company proprietary data.

The Bureau also estimated the distribution of strontium compounds by end use. Of the 10 operations to which a survey request was sent, 8 responded. The information collected from this survey represents almost 100% of the end-use data shown in table 2. Consumption for the nonrespondents was estimated using reported prior-year consumption levels. (See table 1.)

ANNUAL REVIEW

Production

Although there have been no active celestite mines in the United States since 1959, celestite deposits have been identified nationwide. During World War II, domestic mining of celestite resources was conducted in Texas and California. U.S. celestite mines had at that time been inactive since World War I, and strontium minerals were imported to satisfy domestic demand.

Strontium carbonate, the most important strontium compound by far, was produced in 1991 by one company in the United States. CPC was the only company that produced strontium chemicals from celestite. The majority of the celestite CPC used was imported from Mexico. CPC utilizes the black ash method of strontium carbonate production at its facility. The black ash method and the soda ash method are the two most common recovery techniques. The black ash method, known alternatively as the calcining method, produces chemical-grade strontium carbonate, which contains

at least 98% strontium carbonate. The soda ash or direct conversion method produces technical-grade strontium carbonate, containing at least 97% strontium carbonate.

The black ash method received its name because the first step in the procedure involves mixing the crushed and screened celestite with powdered coal, making a black mixture. The mixture is then heated to about 1,100° C, expelling oxygen in the form of carbon dioxide from the insoluble strontium sulfate to form water-soluble strontium sulfide.

Strontium sulfide is dissolved in water and the resulting solution filtered. Carbon dioxide then passes through the solution or soda ash is added. Either compound provides the necessary carbon and oxygen for strontium carbonate to form and precipitate from the solution. The precipitated strontium carbonate is then removed from the solution by filtering and is dried, ground, and packaged. The sulfur released in the process is either recovered as elemental sulfur or in other byproduct sulfur compounds.

In the soda ash method, ground celestite is washed and most of the water removed. The thickened mixture is then mixed with soda ash and treated with steam for 1 to 3 hours. During this time, celestite and soda ash react to form strontium carbonate and sodium sulfate. Sodium sulfate is water soluble, making it possible to separate the insoluble strontium carbonate by centrifuging. Although the soda ash method is a simpler process, the lower grade of the product causes it to be the less preferred

method of recovery. The black ash method is the most common method of strontium carbonate production, and new production facilities usually use black ash technology.

CPC purchased the strontium nitrate production facilities from FMC Corp. in Modesto, CA, when that company discontinued production of carbonate and nitrate in 1984. The company moved the equipment to Cartersville and now is also the sole U.S. producer of strontium nitrate.

There are several U.S. companies that produced strontium compounds from strontium carbonate. Mallinkrodt Inc. of St. Louis, MO, produced strontium chloride, and Mineral Pigments Corp. of Beltsville, MD, produced strontium chromate. A few other companies produced downstream strontium compounds, but on a very small scale.

Domestic strontium deposits were operated in 1944 near Blanket, in Brown County, TX; in Nolan County, TX; in the Fish Mountains in Imperial County, CA; and near Ludlow, CA. At that time, the major use for strontium chemicals was for pyrotechnic applications such as signal flares and tracer bullets required for military applications. Immediately following World War II, this demand decreased markedly, causing domestic production of celestite to decrease quickly and eventually disappear.

Resources in the United States have been estimated at 3.2 million metric tons, with an identified reserve base of 1.4 million tons. The reserve figure includes material containing no more than 60% strontium sulfate, which is much too low grade to meet today's rigid specifications. In addition to deposits operated in the early 1940's, celestite has been discovered in Arizona, Arkansas, Kentucky, Michigan, Missouri, New York, Ohio, Pennsylvania, Tennessee, Utah, and Washington.

Consumption and Uses

Approximately 80% of all strontium was consumed in ceramics and glass manufacture, primarily in television faceplate glass and ceramic ferrite

magnets, and in smaller amounts in other ceramic and glass applications. Over the past 20 years, color television production has become the major consumer of strontium. Because of unique properties that strontium compounds possess, technologies have developed that take advantage of those properties for specific applications. All color televisions and other devices containing color cathode-ray tubes sold in the United States were required by law to contain strontium in the faceplate glass of the picture tube. Strontium blocks X-rays better than barium, which was previously used, and although lead is a better X-ray barrier than strontium, it causes a browning of the glass, which makes its use undesirable. Major manufacturers of television picture tube glass incorporate about 8%, by weight, strontium oxide in their glass faceplate material. The strontium is added to the glass melt in the form of strontium carbonate, and during processing, it is converted to strontium oxide. In addition to blocking X-rays, the strontium improves the appearance of the glass, increasing the brilliance and improving the quality of the picture.

Trends in television production show a shift to larger, flatter tubes that require thicker glass, and therefore, more strontium. Although the television industry in the United States is considered mature, there is a continuing demand for replacement televisions as well as additional sets in large numbers of households. The trend to personal computers and sophisticated, computerized instrumentation increased the demand for strontium in color monitors for these devices.

Permanent ceramic magnets were another large end use for strontium compounds, in the form of strontium ferrite. When these magnets were first developed, they were used primarily as magnetic closures for refrigerator doors. Applications have expanded to include extensive use in small direct current (dc) motors, especially for automotive applications such as windshield-wiper motors, as well as loudspeakers, other electronic equipment, toys, and magnetically attached decorative items.

Strontium ferrites are used in permanent ceramic magnets because they have high coercive force, high thermal and electrical resistivity, and are chemically inert. They retain their magnetism well, are not adversely affected by electrical currents or high temperatures, and do not react with most chemical solvents. Other properties that make the strontium magnets more attractive for specific applications are their resistance to demagnetization and lower density, making them more desirable in applications where weight is a factor.

Barium or lead can replace the strontium in ferrite magnets, but strontium ferrites have been found to possess the best combination of properties necessary for superior magnets.

One of the most consistent and continuing applications for strontium has been in pyrotechnic devices. Strontium burns with a brilliant red flame, and no other material has been found to be better in this application.

The strontium compound used most frequently in pyrotechnic devices was strontium nitrate. Some strontium compounds are slightly hygroscopic, but strontium nitrate takes on very little water and imparts the desired brilliant red. Strontium carbonate, strontium oxalate, strontium sulfate, and strontium chlorate can be used in pyrotechnic applications, but strontium nitrate was used in significantly larger quantities than any of these.

Pyrotechnic devices were used in military and nonmilitary applications. Military pyrotechnic applications that contained strontium included tracer ammunition, military flares, and marine distress signals. Nonmilitary applications included warning devices and fireworks.

Zinc used in diecasting alloys is required to contain less than 0.003% lead. Strontium was used to remove lead impurities during the electrolytic production of zinc. Addition of strontium carbonate in sulfuric acid to the electrolyte reduced the lead content of the electrolyte and of the zinc that is deposited on the cathode.

The addition of strontium chromate to paint creates a coating that is resistant to corrosion. It is an effective coating for aluminum, most notably on aircraft fuselages and ships. These paints are used to some degree on aluminum packaging to prevent package corrosion. The nitrate and chloride contents of strontium chromate paint pigment are very strictly controlled to prevent corrosion.

Consumption of metallic strontium was still a very limited factor in total strontium consumption. Small amounts of strontium are added to molten aluminum to improve the castability of the metal, making it much more suitable for casting items that have been traditionally made from steel. The addition of strontium to the melt improves the machinability of the casting. The use of cast aluminum parts is currently gaining popularity in the automotive industry. Aluminum parts were impractical before modification techniques were developed. The reduction in the weight of the automobile by using cast aluminum parts instead of steel helps to improve energy efficiency of the cars incorporating these parts.

At the present time other end uses consume only small amounts of strontium and strontium compounds. As mentioned previously, the presence of strontium in glass applications improves the brilliance of the glass. It also improves the quality of certain ceramic glazes as well as eliminating the toxicity that may be present in glazes containing lead or barium. One high-tech strontium ceramic is strontium titanate, which is sometimes used as substrate material for semiconductors and also in some optical and piezoelectric applications.

Strontium chloride was used in toothpaste for sensitive teeth. For this application, impurities must be strictly controlled, with limits for some of them in the parts per million range.

Strontium phosphate was used in the manufacture of fluorescent lights, and the entire range of strontium chemicals was used in analytical chemistry laboratories. (See table 2.)

Prices

The average customs value for celestite imported from Mexico was about \$78 per ton (\$70 per short ton), slightly less than the average value in 1990. Mexico was the source of almost 100% of celestite imports in 1991. Values of imported strontium compounds varied according to the type of compound and the country of origin.

Foreign Trade

According to reports from the Bureau of the Census, exports of strontium compounds decreased 37% from the levels reported in 1990. Imports of celestite decreased 32% from the levels reported in 1990.

Mexico continued as the most important source for imported strontium compounds; the Federal Republic of Germany was second. Imports of strontium carbonate in 1991 were 19% lower than those in 1990, with imports from Mexico being the largest percentage of total imports but less than those in 1990. Strontium carbonate imports from Germany increased. Imports of strontium nitrate were slightly higher than those in 1990. (See tables 3, 4, and 5.)

World Review

In almost all instances, celestite deposits occur in remote, undeveloped locations far from population centers in areas where inexpensive labor is available for mining. Huge deposits of high-grade celestite have been discovered throughout the world. Strontium commonly occurs along with barium and calcium, two elements with chemical properties very similar to strontium, thus making separation difficult. Because removing many impurities from celestite is difficult and energy intensive, current strontium chemical producers require material to contain at least 90% strontium sulfate. Most of the currently operating celestite facilities can produce sufficient supplies with only minimal processing necessary to achieve acceptable specifications. Hand sorting and some washing are all

that are necessary at many strontium mines; only a few operations use froth flotation or gravity separation to beneficiate their ore.

Detailed information on most world resources is not readily available. Many of the large deposits are in remote, sparsely inhabited areas, and very little formal exploration has been done. Other deposits may be well identified but are in countries from which specific mineral information is not easily obtained.

Capacity.—The data in table 6 are annual rated capacity for chemical processing plants as of December 31, 1991. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Two types of strontium capacity exist, ore production capacity and compound production capacity. Strontium compound capacity was deemed the more important for several reasons. Essentially all strontium is consumed in compound form, primarily as the carbonate and to a lesser extent as the nitrate. Strontium carbonate is also the intermediate product in production of downstream compounds. At least 12 countries mined celestite in 1991. Virtually all of the celestite mined annually is consumed in the production of strontium carbonate and other strontium compounds. Very little strontium was consumed directly in the mineral form.

Listing both ore and compound production capacity could be misleading, possibly resulting in double-counting of strontium capacity. Because most ore is produced for market by means of very simple sorting and beneficiation techniques, capacity can easily be raised to meet increased demand. Strontium carbonate production capacity is the limiting factor in strontium production,

requiring complicated and sophisticated processing facilities. Therefore, strontium carbonate production capacity, reported in terms of contained strontium, was selected for tabulation. Construction to expand strontium carbonate capacity has increased because of the continued growth in international sales of color television sets. Capacity information was compiled from published reports. (See table 6.)

Algeria.—Celestite was mined in Algeria from a surface deposit near Beni Mansour. Estimated reserves were more than 1 million metric tons. The deposit was mined by Enterprise des Produits Non-ferreux et des Substances Utiles (ENOF) and was controlled by L'Enterprise Nationale de Developpement Minière (Edemines), a division of Société Nationale de Recherches et d'Exploitations Minières (SONAREM). No strontium has been exported in recent years, but in the past, up to 3,600 tons per year has been exported to nations in Eastern Europe and the Federal Republic of Germany. Although the celestite was relatively low grade, only about 70% strontium sulfate, it contained low concentrations of barite, silica, gypsum, and iron, making it possible to concentrate the ore to acceptable levels using only gravity separation. The deposit has not been fully exploited, but there is interest in further development.¹

Argentina.—Celestite mining was controlled by the Argentine Mining Union at the San Juan Mine in the Province of Mendoza. Celestite has been identified at several other small mines, the Maria Del Carmen and Don Luis Mines also in Mendoza Province and the Rayoso, Julio, Cerro Partido, and Llao Llao Mines in the Province of Neuquen. It is unlikely that any production was carried out on a regular basis at these mines. Most Argentine production was exported to Brazil.²

Canada.—Canada has produced celestite ore in the past from the McRae deposit, also known as the old Kaiser

Celestite Mining Ltd. mine. It is at Enon, Cape Breton County, Nova Scotia. Mineral rights were acquired by Timminco Metals, a division of Timminco Ltd. of Toronto in 1985. Exploration identified reserves of more than 1 million tons of celestite, with grades ranging from 60% to 65% strontium sulfate. Reopening the mine has been considered, but the low grade of the ore makes economic feasibility questionable. Other strontium deposits have been identified in British Columbia, Newfoundland, and Ontario,³ but none as significant as the deposit in Nova Scotia. Timminco Metals was the largest producer of strontium metal in the world and the only producer of strontium metal in North America. The company operated a processing facility in Westmeath, Ontario. The strontium production facilities in Westmeath and facilities in Haley, Ontario, produce strontium metal by the aluminothermic reduction of strontium oxide.

China.—Celestite was mined in China almost exclusively for domestic consumption. An ore-dressing facility at the Nanjing Mine in Jiang Su Province has a capacity of 10,000 tons per year. The Nanjing deposit is reported to be high grade and close enough to the surface for open pit mining.⁴ Past import data indicated that strontium chemical plants must exist, but no specific details were available. Reports indicated that Japan imports strontium carbonate from China and that strontium carbonate from China has also been reported in the United States.

Cyprus.—Celestite mining began in Cyprus in 1985 at Vassliko, near Limassol, in southern Cyprus. The mine was operated by Hellenic Mining Co. Ltd. The ore averaged about 54% strontium sulfate and, therefore, required concentration to make it marketable. The ore was beneficiated through a flotation process to reach 94% strontium sulfate. The reserves have been determined to be 200,000 tons of celestite.⁵ No mining has occurred for the past 4 years.

Germany, Federal Republic of.—Kali-Chemie AG of Hannover produced strontium carbonate from imported celestite at its plant at Bad Hoenningen. The major western European producer used the black ash method in the production facilities. Plant capacity is estimated to be 15,000 tons per year. Kali-Chemie imported most of its celestite from Spain and Turkey; it exported 80% to 90% of the production, most of which goes to the United States and the Republic of Korea. Kali-Chemie also produced strontium hydroxide and strontium nitrate. The nitrate was produced by its Italian subsidiary, Societa Bario e Derivati SpA, in Massa.⁶

Iran.—One of the world's largest celestite deposits is in the northwestern part of the Dasht-e-Kavir salt desert. The deposit was mined by Iran Strontium Co., a subsidiary of Cherkate Sahami Sanati Va Maadani Irani (Simiran). Average strontium sulfate values for the deposit were reported at more than 91%, but there were unfavorably high levels of barium sulfate and calcium sulfate. Proven reserves total 1.8 million tons of celestite, 430,000 tons of which have no overburden.⁷ Most of the celestite produced from this deposit is believed to go to the U.S.S.R.

Italy.—Mining has been done by Minera Chimica Farnesiana SpA in Tarquinia, near Rome. Most production of this 75% strontium sulfate and 5% barium sulfate product was sold domestically. Annual production capacity at the mine was 7,300 tons per year, but production ceased in 1988. Some of the processed ore has been exported to the U.S.S.R. in the past. Other deposits are known to exist in the interior of Sicily, although none have recently been mined. Societa Bario e Derivati, a subsidiary of Kali-Chemie AG of the Federal Republic of Germany, produced strontium nitrate at Massa. Production and capacity figures were not available, but it was known that most of the production is exported to the United States.⁸

Japan.—Although celestite was not mined in Japan, it was the largest consumer of strontium carbonate in the world, mostly due to its large television and electronics industry. Four companies produce strontium carbonate from imported celestite. Honjo Chemical Corp. operated a production facility for 18,000 tons per year of carbonate at Neyagawa in Osaka using celestite from Spain and China. Sakai Chemical Industries Co. also produced strontium carbonate, by the black ash method, in Osaka at a 12,000-ton-per-year plant using Chinese, Mexican, and Spanish celestite. Japan Special Chemicals (Nihon Tokushu Kasei) and Dow Chemicals also produced strontium carbonate, but on a much smaller scale. The total capacity for both companies was only about 1,100 tons per year. These two companies used celestite from Spain.⁹

Korea, Republic of.—Although celestite deposits have not been identified in Korea, its growing electronics and television industry prompted a European company to form a joint venture with a Korean firm. Kali-Chemie and Samsung Corning Ltd., Korea, formed Daehan Specialty Chemicals Co. Ltd. to build a strontium carbonate and barium carbonate plant. The plant began operation in 1990 with a production capacity of 40,000 tons per year of strontium carbonate and barium carbonate, combined. The production was marketed to the growing television industry in that country. The black ash method was used.¹⁰

Mexico.—CPC's new strontium carbonate plant in Reinos, Tamaulipas, close to the U.S. border, began production toward the end of 1991. Capacity was reported at about 22,000 tons per year. Already possessing the capability to produce more strontium carbonate than any other country in the world, with the completion of this project, Mexico's strontium carbonate production capacity is about 42% of the known world total.

Strontium carbonate production has been a recent development in Mexico. This is a very attractive location for additional production facilities because of the huge celestite resources in the country. After a major U.S. strontium carbonate and strontium nitrate producer (FMC Corp.) closed its plant in 1984, Cia. Minera La Valenciana SA (CMV) bought the strontium carbonate processing equipment from the FMC plant in California. The plant, which utilized the soda ash method of carbonate production and was converted to the black ash method, was relocated to Torreón in Coahuila State, near a company-operated mine. The plant capacity is 50,000 tons per year. Shipments from the plant, targeted for the television and electronics industry in the Far East, commenced in May 1987. Sales y Oxidos (SYOSA), 49% owned by Kali-Chemie, built a new strontium carbonate plant near Monterrey with the capacity of 15,000 tons per year. The company's old strontium carbonate operation was converted to produce barium carbonate. SYOSA, which produced carbonate by the black ash method from celestite it mines nearby, marketed its production in the United States.¹¹

Mexico was the world's largest producer of celestite in 1991. The most recent Directory of Mexican Non-Metallic Minerals Trust lists 11 companies currently mining celestite. CMV mined celestite from the San Agustín deposit near Torreón, and Compañía Minera Ocampo SA mined a deposit near Saltillo in Nuevo Leon State, as well as some small production in Hidalgo, Aguascalientes, and Chihuahua states. Reserves of the San Agustín Mine alone have been estimated at more than 725,000 tons. SYOSA mines west of Monterrey. Other small operations occur in Coahuila, Aguascalientes, Chihuahua, and Nuevo Leon. Mexican celestite is primarily high grade, and only hand sorting is required to achieve at least 92% strontium sulfate with low barium content. Abandoned mines and easily identified deposits that have not yet been developed are common throughout a large area in northern Mexico. Reserves are believed to be

vast, but these deposits have not been extensively explored.¹²

Pakistan.—All strontium mines in Pakistan are the property of Provincial governments and are operated by private companies for the governments. Recent celestite production figures have been reported for two active mines, one near Dawood Khail and one near Karachi.¹³ Tawakkal Mineral Exports Corp. recovered celestite from these mines in the Dadu District of Sind Province. No beneficiation was necessary to produce 94% strontium sulfate. Reserves of celestite have not been quantified at this location.¹⁴ Other deposits with 500,000 tons of reported reserves have been identified in the Punjab Province.¹⁵

Spain.—Spain was another of the largest celestite producers worldwide. Celestite was produced from the Monteive deposit, which was operated by Herederos de Aurelio Farjardo Vilches, with sales and marketing handled by Bruno SA. Selective mining and hand sorting was all that was necessary to produce ore grades of more than 92% strontium sulfate, although a concentration plant has been constructed. Reserves are believed to be at least 2 million tons. Most Spanish production is exported to Japan, some remains in Spain, and the rest is exported to the Federal Republic of Germany.¹⁶ Promotora de Industria del Sur (Proinsur SA) produced strontium carbonate and strontium nitrate at a combined facility near Granada. The plant has a theoretical design capacity of 8,000 tons per year of carbonate but has never reached this capacity. Strontium carbonate was produced by the soda ash method. The plant also has a production capacity of about 3,000 tons per year of nitrate, which has not yet been fully utilized.¹⁷

Turkey.—Turkey competes with Mexico, Spain, and Iran in claiming the world's largest strontium reserves. Barit Maden Turk AS produced celestite from a mine near Sivas. Run-of-mine ore was gravity separated to produce a concentrate

with a minimum of 95% strontium sulfate. Because of the harsh climate in the region, the mine can only be operated on a seasonal basis, from May to October. Another mine near Sivas was formerly operated by Bilfer Madencilik AS, which reestablished concessions for future celestite mining. Identified reserves have been placed at 550,000 tons, and further reserve potential is estimated to be greater than 2 million tons. Turkish celestite was primarily exported to the Federal Republic of Germany.¹⁸

U.S.S.R.—Very little is known about production of strontium minerals in this area. Deposits are known in the Karakum Desert, Zaunguz Plateau; Permian deposits near Bashkir; caprocks of the Romy and Isachkov salt domes; Pinega area, Archangel Province; Yakutsk, eastern Siberia; and in Turkestan from eastern Fergana to the shores of the Caspian Sea, and from southeastern Bucharria to the shores of the Sea of Aral. Reserves are believed to be very large, but the ore grade is probably not high.¹⁹ No details are available concerning the production of strontium carbonate in the U.S.S.R. except that there is production, probably from domestic celestite as well as from imports from Iran and Turkey.

United Kingdom.—Until World War II, virtually all celestite processed in the United States was imported from the United Kingdom. When the war interfered with transportation of the ore, other sources were developed, and the United Kingdom celestite never regained its prominence. Celestite deposits, which occur in the Bristol area, were mined by Bristol Minerals Co. Ltd. The ore was crushed, washed, and graded to achieve a product with 95% strontium sulfate. The British deposits continue to be encroached upon by large-scale housing developments, limiting possible exploitation of the minerals to the near future. This was one of the few sites where celestite deposits are not in remote locations.²⁰

These reserves nearly have been exhausted, and the mining of celestite at this site will be phased out over the next 2 years. Bristol began reprocessing mine tailings and was no longer mining primary ore.²¹ (See table 7.)

OUTLOOK

The future continues to look bright for the strontium industry for the near term. Continued growth is expected in the color television industry, and larger screens are expected to increase in popularity. Demand for strontium carbonate for television application should expand. Other markets will probably continue at their current, slower rate. Development of a technology to produce an affordable flat television display could severely reduce the demand for strontium carbonate, but this is not expected in the near future. Although a high-quality, large, flat screen is not yet available, small models are, and research continued to improve the technology. The question remains whether a new display system can be developed that will be economically attractive to the general public. Initial devices are expected to find application in military hardware and other sophisticated medical and scientific instrumentation. Flat screen display systems may eventually replace cathode-ray tubes, and, at that point, strontium producers may experience a serious setback.

⁴In addition to the countries listed, China, Poland, and the U.S.S.R. produce strontium minerals, but output is not reported quantitatively, and available information is inadequate to make reliable estimates of output levels.

⁵Data are for year beginning Mar. 21 of that stated.

⁶Reported figure.

SULFUR

By Joyce A. Ober

Mrs. Ober, a physical scientist with 14 years of industry and U.S. Bureau of Mines experience, has been a commodity specialist since 1986. Domestic survey data were prepared by Pamela G. Shorter, statistical assistant; and the international production table was prepared by staff, International Data Section.

Sulfur, through its major derivative sulfuric acid, ranks as one of the more important elements utilized by humanity as an industrial raw material. It is of prime importance to every sector of the world's industrial and fertilizer complexes. Sulfuric acid consumption has been regarded as one of the best indexes of a nation's industrial development.

The United States retained its position as the world's foremost producer and consumer of sulfur and sulfuric acid in 1991. Production of recovered elemental sulfur, a nondiscretionary byproduct of petroleum refining and natural gas processing, continued to increase and set a record-high production standard. Production from U.S. Frasch mines decreased to about 2.9 million metric tons, a 23% drop due primarily to the closing of two mines during the year.

Construction neared completion on the structures necessary to recover sulfur from a major salt dome on Federal lease block Main Pass 299 in the Gulf of Mexico. Rights to develop this deposit were acquired from the U.S. Department of the Interior in 1988. Main Pass 299 was the first new domestic Frasch mine to be built in more than 20 years.

Recovered elemental sulfur shipments to domestic consumers were greater than Frasch shipments. Recovered sulfur exports, primarily from California where sulfur supplies exceeded local demands, were higher than Frasch sulfur exports.

Byproduct sulfuric acid from the Nation's nonferrous smelters and roasters, essentially mandated by laws concerning sulfur dioxide (SO₂)

emissions, supplied a significant quantity of sulfuric acid to the domestic merchant acid market. Marketing sulfuric acid continued to be difficult for some producers because smelters were near western copper mines and far from major sulfuric acid markets.

Total world production of sulfur in all forms decreased about 4% compared with that of 1990; worldwide Frasch sulfur output decreased significantly because of the Gulf War, reduced output in the United States, production problems in Poland, and political turmoil in the former U.S.S.R. Recovered elemental production increased in Asia, Eastern Europe, and North America, decreased slightly in Western Europe because of declining production from gas plants, and remained about the same in the rest of the world. Almost five-eighths of the world's elemental sulfur production came from recovered sources; the quantity of sulfur supplied from these sources was dependent on the world demand for fuels and petroleum products, not on the demand for sulfur.

World sulfur consumption decreased slightly, with little change in the amount used for fertilizer production. Consumption for a myriad of industrial uses continued to be pressured by environmental constraints placed on the products produced or effluents from the chemical processes utilizing sulfur or its major derivative, sulfuric acid.

World trade of elemental sulfur decreased by an estimated 1.6 million metric tons, about 10% below levels recorded in 1990. Although individual country sulfur inventories showed

important variations from yearend 1990, total world producers' stocks of elemental sulfur remained about the same. (See table 1 and figure 1.)

DOMESTIC DATA COVERAGE

Domestic production data for sulfur are developed by the U.S. Bureau of Mines from four separate, voluntary surveys of U.S. operations. Typical of these surveys is the "Elemental Sulfur" survey. Of the 175 operations to which a survey request was sent, all responded, representing 100% of the total production shown in tables 1 and 2.

BACKGROUND

Sulfur, also known as brimstone, "the stone that burns," was used in small quantities for thousands of years. Ancient people were probably first drawn to native sulfur by its bright yellow color and pungent odor. Early humanity used sulfur as a colorant for cave drawings, as a fumigant, for medicinal purposes, and as incense. As early as 2000 B.C., the Egyptians used sulfur in the bleaching of linen textiles. In the *Odyssey*, Homer refers to its use as a fumigant. During the Peloponnesian War, fifth century B.C., the Greeks burned a sulfur-pitch mixture to generate suffocating gases. The Romans combined brimstone with tar, pitch, and other combustible materials to produce the first incendiary weapons. Muslims during the "Golden Age of Arabic Science," from about A.D. 700, developed alchemy and were probably the first producers of sulfuric

acid. Sulfur is a necessary ingredient in gunpowder, which was developed as a pyrotechnic in China by the 10th century. Gunpowder's introduction into Europe led to its use in warfare in the 14th century and made sulfur an important mineral commodity for the first time.

However, it was not until the birth of the science of chemistry in the 1700's and the growth of chemical industries in the 1800's that sulfur became of major importance to the world outside of its use in warfare. Early chemists soon recognized the importance of sulfuric acid as the cheapest and most versatile of the mineral acids, and it rapidly became and remains the most common acid in the chemical industry.

Sulfur is one of the few elements that occurs in the native, or elemental, state. It also occurs combined with iron and base metals as sulfide minerals, and with the alkali metals and alkali earths as sulfate minerals. In petroleum, sulfur is found in a variety of complex organic compounds, and in natural gas as hydrogen sulfide (H_2S) gas. In coal, sulfur occurs in complex organic compounds and as "coal brasses" (pyrites-marcasite). Commercial production of sulfur in the United States is accomplished by a variety of methods dictated by the source of sulfur.

Definitions, Grades, and Specifications

Bright Sulfur.—Crude sulfur free of discoloring impurities and bright yellow in color.

Brimstone.—Synonymous with crude sulfur.

Broken Sulfur.—Solid crude sulfur crushed to minus 8-inch size.

Crude Sulfur.—Commercial nomenclature for elemental sulfur.

Dark Sulfur.—Crude sulfur discolored by minor quantities of hydrocarbons ranging up to 0.3% carbon content.

Elemental Sulfur.—Processed sulfur in the elemental form produced from native sulfur or combined sulfur sources, generally with a minimum sulfur content of 99.5%.

Frasch Sulfur.—Elemental sulfur produced from native sulfur sources by the Frasch mining process.

Native Sulfur.—Sulfur occurring in nature in the elemental form.

Prilled Sulfur.—Solid crude sulfur in the form of pellets produced by cooling molten sulfur with air or water.

Pyrites.—Iron sulfide minerals that include pyrite, marcasite, and pyrrhotite.

Recovered Sulfur.—Elemental sulfur produced from combined sulfur sources by whatever method.

Slated Sulfur.—Solid crude sulfur in the form of slatelike lumps produced by allowing molten sulfur to solidify on water-cooled, moving belt.

Sulfur Ore.—Unprocessed ore containing native sulfur.

Sulfuric Acid.—Sulfuric acid of commerce produced from all sources of sulfur, generally reported in terms of 100% H_2SO_4 with a 32.69% sulfur content.

Products for Trade and Industry

Elemental sulfur of commerce, sometimes called crude sulfur or brimstone, may be marketed in either the liquid or the solid phase, generally with a minimum sulfur content of 99.5%. Most elemental sulfur marketed in North America is sold as liquid sulfur. In worldwide commerce, sulfur is shipped either as broken sulfur or formed sulfur. Formed sulfur—prills, slates, and pastilles—is generally preferred to broken sulfur because it is less prone to dusting and the release of fugitive dust at terminals where sulfur is stored and

transferred from one transportation mode to another. Sulfuric acid may be sold at various strengths, usually depending on the requirements of the consumer. The acid is generally marketed on a 100% basis, but is normally shipped at 66° Baume (93% H_2SO_4), as 98% acid, or as 20% to 22% fuming oleum, which is sulfur trioxide dissolved in sulfuric acid.

Industry Structure

Over the centuries, many fundamental changes have occurred in the sources of sulfur supply. Early civilizations obtained their meager requirements from native sulfur deposits in or around volcanoes. The increase in demand for sulfur in the late 1700's and early 1800's was largely satisfied from extensive native sulfur deposits in Sicily. Monopolistic practices by the owners of sulfur-mining facilities in Sicily led to exorbitant sulfur prices, causing consumers to adopt iron pyrites as the second major sulfur source during the mid- to late-19th century. The development in 1895 of the Frasch process for mining the large native deposits associated with salt domes in Louisiana and Texas brought a new and important source of sulfur to the United States and world markets. Frasch sulfur and pyrites maintained their joint predominance as world sulfur sources through the mid-1970's.

With small beginnings in the 1930's and increasing significantly from the 1950's onward, environmentally mandated or involuntary sulfur recovered during natural gas processing and petroleum refining grew to surpass Frasch sulfur and pyrites as the world's major source of sulfur. In addition, increasing quantities of byproduct sulfuric acid from smelting operations have been produced to comply with pollution control laws and environmental regulations worldwide.

Sulfur in its various forms is produced worldwide, with no single nation predominating as a producer or supplier to world markets. In 1991, world sulfur production and consumption amounted to 55.6 and 57.6 million tons, respectively. The United States and the U.S.S.R. were

the world's largest producers and consumers; both nations, however, were net importers of sulfur. Canada and Poland, respectively, the third and fifth largest world producers, ranked first and second among the world's exporting nations. China, the world's fourth largest producer and largest pyrites producer, was the third largest sulfur consumer; China, however, satisfied most of its sulfur requirements from internal sources.

Geology-Resources

Sulfur is widely distributed in nature, constituting 0.060% of the Earth's crust. Sulfur combines with most other elements, except the inert gases and nitrogen. Practically all plant and animal life on Earth contains some sulfur. Only a very small portion of the world's sulfur resources occurs in sufficiently concentrated quantities to justify commercial extraction by mining or other recovery methods. Sulfur is one of the few substances found in nature in the elemental form; it also occurs combined with other elements as sulfides, sulfates, or organic compounds in sedimentary, metamorphic, and igneous rocks, as well as in all fossil fuels. By type, sulfur deposits are classified as follows:

Native (Elemental) Sulfur Deposits.—These include deposits (1) in anhydrite-limestone cap-rock on the top and flanks of salt domes, (2) in bedded anhydrite-gypsum evaporite basin formations, and (3) in unconsolidated volcanic deposits. In salt dome cap-rock and evaporite beds, the sulfur is believed to have been formed by hydrocarbon reduction of anhydrite, assisted by bacterial action. Volcanic sulfur was produced by the reaction between escaping hydrogen sulfide and sulfur dioxide.

Large deposits over salt domes are mined in the gulf coast regions of the United States and Mexico. Extensive deposits in evaporites are mined in west Texas, Iraq, Poland, and the U.S.S.R. Together, these deposits are by far the principal source of mined elemental sulfur, generally extracted by the Frasch

hot water process. Most volcanic sulfur occurrences are in the circum-Pacific belt. Volcanic sulfur deposits are locally important, but furnish only a minor portion of the world's sulfur supply.

Sulfide Deposits.—These include deposits of (1) ferrous sulfides (pyrite, marcasite, and pyrrotite) that, while they may contain minor quantities of nonferrous metals, are generally mined and processed for their sulfur content and (2) nonferrous metal sulfides, which are mined for their metal content and in the processing produce sulfur in the form of sulfuric acid. In order of importance from the quantity of acid produced, sulfide minerals of copper, lead, zinc, molybdenum, nickel, mercury, arsenic, antimony, and silver are the most noted in the nonferrous sulfide group.

Sulfate Deposits.—These included bedded deposits of anhydrite and gypsum. Although they are mined on a large scale worldwide for their mineral content, they represent one of the world's largest, yet virtually untapped sulfur resources. Existing technology can recover elemental sulfur from these sources, but the economics are presently unfavorable.

Natural Gas.—Hydrogen sulfide occurs as a component of natural gas in many parts of the world. To market this "sour" natural gas, the hydrogen sulfide must be removed and, consequently, as additional sour natural gas fields have been brought into production, elemental sulfur recovered from these fields has become a major source of the world sulfur supply. Major deposits of sour natural gas occur in western Canada, the Near East, and the U.S.S.R.; substantial deposits occur in the mountain and gulf coast regions of the United States, France, the Federal Republic of Germany, Mexico, and Venezuela.

Petroleum and Tar Sands.—Complex organic sulfur compounds occur as a component of petroleum and tar sands in a wide range of concentrations. In the refining of petroleum or bitumen from tar

sands, a portion of the sulfur is removed and recovered in the elemental form. Changing environmental regulations have required larger proportions of contained sulfur to be removed annually. The vast petroleum reserves of the Near East contain high percentages of sulfur, as do many of the recent discoveries in Mexico and off the U.S. west coast. Additionally, Canadian tar sands constitute a major sulfur resource.

Coal and Oil Shale.—Sulfur occurs as pyrites or complex organosulfur compounds in varying concentrations in both coal and oil shales. Although little sulfur is produced from these vast resources at present, the potential for large-scale output exists in the United States and in the rest of the world.

Economic Factors

During the past 20 years, world sulfur price leadership has shifted from dominance by the U.S. Frasch producers to the Canadian exporters. The transfer was aided in the 1980's by Canada's ability to export most of its production from the Port of Vancouver and by its willingness to ship large volumes of sulfur from vatted stocks. The maturation of Sultran Ltd., dealing almost exclusively with sulfur destined for the offshore market, into a well-organized and skilled transportation arm of the Canadian sulfur industry aided immeasurably in Canada's ascension to world price leadership.

In the United States, the quoted liquid Frasch sulfur price, f.o.b. terminal Tampa, FL, is the benchmark price. Recovered sulfur producers, in many cases, consider the economic desirability of producing sulfur subordinate to the necessity of producing it. As a result, domestic recovered elemental sulfur producers normally offer sulfur at a price \$5 to \$15 per ton below the Tampa quote to ensure prompt sale and reduce storage costs. This marketing strategy has resulted in restricting Frasch sulfur sales from many market areas that they formerly served.

During the 1980's, the sulfur price showed a significant degree of volatility compared with its prior history and the early years of the 1990's continued the trend. The worldwide recession of 1982 and the U.S. Department of Agriculture Payment In Kind program in 1983 reduced world sulfur production and demand. (See table 2.)

ANNUAL REVIEW

Production

Frasch.—Native sulfur associated with the cap-rock of salt domes and in sedimentary deposits is mined by the Frasch hot water method, in which the native sulfur is melted underground and brought to the surface by compressed air. In January 1991, the United States had five Frasch mines operating in Louisiana and Texas; two of the Louisiana mines ceased operation during the year. Freeport Sulphur Co. owned and operated three mines in Louisiana. The Caminada Pass mine 9 miles offshore in the Gulf of Mexico operated throughout the year. Garden Island Bay on the Mississippi River Delta and Grand Isle, 7 miles offshore, were closed during the year due to depletion of resources. Mines in Texas were Pennzoil Sulphur Co., at Culberson, and Texasgulf Inc. (TG), at Boling Dome in Wharton County.

In December 1988, Freeport McMoRan Resource Partners, operator for a consortium that included the IMC Fertilizer Group Inc. and Felmont Oil Co., reported a geologic reserve of 50 million long tons of sulfur on its Federal lease block, Main Pass 299, which is offshore in the Gulf of Mexico, 17 miles from the mouth of the Mississippi River. The announcement was based on the results of five exploratory holes. Additional drilling in 1989 delineated the size of the salt dome deposit and established the total reserve at 67 million long tons, which made Main Pass 299 the second largest domestic sulfur deposit yet discovered. Freeport McMoRan began construction on the offshore platform for the mine in 1990. The company expected to begin production at Main Pass 299 in

early 1992, reaching full capacity of about 2 million tons per year sometime in 1993. The project required an investment of more than \$550 million.

The shutdown of the two Freeport mines severely curtailed Frasch production. Frasch sulfur output decreased 860,000 tons from the quantity produced in 1990. Total shipments to domestic and overseas consumers decreased by more than 550,000 tons. Frasch sulfur accounted for 27% of domestic production in 1991. Approximately 86% of Frasch sulfur shipments was for domestic consumption; the remainder, for export. The total value of Frasch sulfur shipments decreased by more than \$63 million.

Recovered.—Recovered elemental sulfur, a nondiscretionary byproduct from petroleum refining, natural gas processing, and coking plants, was produced primarily to comply with environmental regulations that were applicable directly to emissions from the processing facility or indirectly by restricting the sulfur content of the fuels sold or used by the facility. Fuel processing plants accounted for 61% of the total domestic output of sulfur in all forms compared with 56% in 1990. Production and shipments of recovered sulfur reached alltime high levels owing to record production from the Nation's petroleum refineries. Production and shipments from natural gas processing plants remained at about the same level as that in 1991. Recovered elemental sulfur was produced by 58 companies at 151 plants in 26 States, 1 plant in Puerto Rico, and 1 plant in the U.S. Virgin Islands. Most of these plants were of relatively small size, with only 16 reporting an annual production exceeding 100,000 tons. By source, 64% was produced at 84 refineries or satellite plants treating refinery gases and 3 coking plants. The remainder was produced by 27 companies at 64 natural gas treatment plants. The five largest recovered-sulfur producers in 1990 were Exxon Co. U.S.A., Standard Oil Co. (California), Standard Oil Co. (Indiana), Shell Oil Co., and Mobil Oil Corp. The

54 plants owned by these companies accounted for 58% of recovered elemental sulfur output during the year. (See tables 3, 4, 5, 6, and 7.)

Byproduct Sulfuric Acid.—Byproduct sulfuric acid at copper, lead, molybdenum, and zinc roasters and smelters amounted to 12% of the total domestic production of sulfur in all forms. Eight acid plants operated in conjunction with copper smelters, and eight were accessories to lead, molybdenum, and zinc smelting and roasting operations. The five largest acid plants (all at copper mines) accounted for 72% of the output. The five largest producers of byproduct sulfuric acid were Phelps Dodge Corp., Magma Copper Co., ASARCO Incorporated, Kennecott Corp., and Cyprus Miami Mining Corp.

Their eight plants produced 85% of the 1990 total. (See table 8.)

Pyrites, Hydrogen Sulfide, and Sulfur Dioxide.—The total sulfur contained in these products did not constitute a significant portion of total domestic sulfur production. (See table 9 and figure 2.)

Consumption and Uses

Domestic consumption of sulfur in all forms was virtually the same in 1991 as it was in 1990. In 1991, 77% of the sulfur consumed was obtained from domestic sources compared with 80% in 1990 and 82% in 1989. The sources of supply were domestic recovered elemental sulfur, 46%; domestic Frasch sulfur, 21%; and combined domestic byproduct sulfuric acid, pyrites, hydrogen sulfide, and sulfur dioxide, 10%. The remaining 23% was supplied by imports of Frasch and recovered elemental sulfur.

The U.S. Bureau of Mines collected end-use data on sulfur and sulfuric acid according to the Standard Industrial Classification of industrial activities. Shipments by end use of elemental sulfur were reported by 60 companies, and shipments of sulfuric acid were reported by 52 companies. Shipments of both

elemental sulfur and sulfuric acid were reported by seven companies.

Sulfur differs from most other major mineral commodities in that its primary use is as a chemical reagent rather than a component of a finished product. Its predominant use as a chemical reagent generally required that it first be converted to an intermediate chemical product prior to its initial use by industry. The largest sulfur end use, sulfuric acid, represented 85% of shipments for domestic consumption. Some identified sulfur end uses were tabulated in the "Unidentified" category because these data were proprietary. Data collected from companies that did not identify shipment by end use were also tabulated as "Unidentified." Although there are no supporting data, it could be reasonably assumed that a significant portion of the sulfur in the "unidentified" category was shipped to sulfuric acid producers or was exported. The difference between exports reported in the canvass and exports of 1.12 million tons reported by the Bureau of the Census may have been caused by differences in accounting between company records and compilations by the Census Bureau, or by sales to other parties that exported sulfur and were not included in the U.S. Bureau of Mines canvass.

Sulfuric acid, because of its desirable properties, retained its position, both domestically and worldwide, as the most universally used mineral acid and the largest volume inorganic chemical in terms of the quantity produced and consumed. U.S. shipments of sulfuric acid (100% basis) decreased by about 700,000 tons in 1991 owing primarily to decreases in demand for the production of phosphoric acid, the largest single end use. Sulfuric acid demand for copper ore leaching, the second largest end use, increased about 150,000 tons to 2.1 million tons as reported by sulfuric acid producers because solvent extraction-electrowinning (SX-EW) operations could produce high-purity copper at a significantly lower cost than by conventional smelting methods. Reported shipments of sulfuric acid for petroleum refining and other petroleum and coal

products were not significantly different from those of 1990.

According to the 1991 canvass reports, company receipt of spent or contaminated sulfuric acid for reclaiming totaled 3.2 million tons. The largest source of this spent acid continued to be the petroleum refining industry, which accounted for 51% of the total returned. About 0.9 million tons of spent acid was reclaimed from plastic and synthetic materials producers. The remaining reclaimed acid was from manufacturers of inorganic pigments, copper ores, other chemical products, industrial organic chemicals, phosphatic fertilizers, explosives, and some unidentified sources.

The largest use of sulfur in all forms, for agricultural purposes, decreased from 9.2 million tons in 1990 to about 9.0 million tons. The estimated quantity of sulfur needed to manufacture exported agricultural chemicals increased by more than about 70,000 tons to 4.6 million tons, indicating that consumption for domestic purposes, especially for phosphatic fertilizers, decreased by more than 150,000 tons. (See tables 10, 11, 12, 13, and 14 and figures 3 and 4.)

Stocks

Yearend inventories held by Frasch and recovered elemental sulfur producers decreased 16% from those of 1990, indicating a tightness of supply. Combined yearend stocks amounted to approximately a 44-day supply compared with a 51-day supply in 1990, a 46-day supply in 1989, a 38-day supply in 1988, and an 86-day supply in 1987 based on domestic and export demands for Frasch and recovered sulfur. (See table 15.)

Markets and Prices

The posted price for liquid sulfur exterminal Tampa, FL, began the year at \$140 per long ton and remained at that level until the middle of June when it dropped to \$125, the \$15 drop being the largest single price change in Frasch history. The Tampa price dropped another \$15 to \$110 at the beginning of August and to \$98 at the beginning of

November. Such dramatic changes in the price situation were unexpected. A shortage of sulfur supply was expected because of the closing of two U.S. mines as well as the damage sustained to the Kuwaiti and Iraqi sulfur operations as a result of the war in the Persian Gulf. The oil refineries in Kuwait were nearly destroyed by the Iraqi army, and although Iraqi Frasch operations were not believed to be significantly damaged, the trade sanctions against Iraq imposed by the United Nations Security Council remained in effect, which essentially removed the annual 1.5- to 1.7-million-ton Iraq-Kuwait sulfur exports from international commerce.

However, Canadian sulfur exporters, hard hit by low natural gas prices, slashed their sulfur prices to establish markets in areas traditionally supplied by Frasch producers. The posted Frasch Tampa price decreases of 30% were a direct attempt by the domestic Frasch producers to maintain market share and to reduce the Canadian influence in the U.S. market.

On the basis of total shipments and value reported to the U.S. Bureau of Mines, the average value of shipments of Frasch sulfur, f.o.b. mine, for domestic consumption and exports combined decreased from \$91.17 to \$87.05 per ton. The average value, f.o.b. plant, for shipments of recovered elemental sulfur varied widely by geographic region, with reported values by State averaging anywhere from a low of about \$38 per ton to about \$88 per ton. The national average value for the year was about \$64 per ton, almost \$10 per ton less than the average for 1990. (See table 16.)

Foreign Trade

Exports of elemental sulfur from the United States, including the U.S. Virgin Islands, increased 23% in quantity and increased 9% in value. According to the Bureau of the Census, exports from the west coast were 641,000 tons or 54% of total U.S. exports.

The United States continued to be a net importer of sulfur; imports exceeded exports by more than 1.8 million tons in

1991. Frasch sulfur from Mexico and recovered elemental sulfur from Canada, both delivered to U.S. terminals and consumers in the liquid phase, furnished 97% of all U.S. sulfur import requirements. Total elemental sulfur imports increased 17% in quantity; imports by rail from Canada increased 17%, while waterborne shipments from Mexico were 12% higher than those in 1990. Imports from other sources, while still very small compared to those from Canada and Mexico, increased 400%.

The United States also had significant trade in sulfuric acid. Sulfuric acid exports decreased about 8% from those of 1990. Imports, which were significantly greater than exports, were mostly by rail from Canada. The tonnage increased 9% from the quantity reported in 1990; the value of imported sulfuric acid, however, decreased 8%. Approximately 554,000 tons of acid was imported into the Tampa, FL, area, about 6% more than the Tampa acid imports of the previous year. Two sulfuric acid terminals had been established there in 1989. (See tables 17, 18, 19, and 20.)

World Review

The volatility of the world political and economic situation was reflected in events in the sulfur industry in 1991. Early in the year, the tenuous situation in the Middle East raised concerns over the possible shortage of sulfur for the world market and possibly large price increases. Price increases never occurred; in fact, prices fell precipitously through the second half of the year. The eventual military action did cause significant damage to the petroleum industry in Kuwait and Iraq, but the shortages from those countries were compensated for by increased production in other countries and shipments from stockpiled material.

The political and economic climates in Eastern Europe remained changeable, and the situation was not expected to be resolved quickly. Industry has experienced serious setbacks, and until the economic problems ease, demand for sulfur in the region will be low. The poor economic conditions also have a

more widespread impact owing to decreased demand for imported fertilizers, which in turn lessens the need for sulfur in countries that would normally have supplied that fertilizer.

With the abolition of the Communist party in the U.S.S.R. in August, the same type of situation arises there as in Eastern Europe. The economy is extremely weak, and the political situation is unstable. Stability, both economic and political, in the region may take many years to achieve.

Industry Structure.—In 1991, the sulfur industry was divided into two sectors, discretionary and nondiscretionary. In one, the mining of sulfur or pyrites was the sole objective; this voluntary production of native sulfur or pyrites was based on the orderly mining of discrete deposits, with the objective of obtaining as nearly a complete recovery of the resource as economic conditions permit. In the other, sulfur or sulfuric acid was recovered as an involuntary byproduct, the quantity of output subject to demand for the primary product irrespective of sulfur demand. In 1991, involuntary sources represented almost 60% of the elemental sulfur produced worldwide.

Large quantities of Frasch sulfur were produced from mines in only five countries: Iraq, Mexico, Poland, the U.S.S.R., and the United States. Poland and the U.S.S.R. also produced significant quantities of native sulfur using conventional mining techniques; small quantities of native sulfur were produced in Asia, Europe, and South America. Pyrites were the prime sulfur source in China, Spain, and the Republic of South Africa and an important source in Scandinavia and the U.S.S.R.

Recovered elemental sulfur was the predominant sulfur source in Canada, France, the Federal Republic of Germany, Saudi Arabia, and the United States. Additionally, recovered elemental sulfur was an important source in Iran, Japan, and the U.S.S.R. Due to the Gulf War, sulfur production in Iraq and Kuwait was significantly less than that in previous years. Production levels in

these countries were not expected to fully recover in this century.

International sulfur trade was dominated by a limited number of exporting countries; exports from Canada, Poland, Saudi Arabia, Mexico, the United States, and the Federal Republic of Germany, in descending order of the quantity shipped, accounted for 93% of sulfur trade in 1991. Major sulfur importers in 1991 were the United States, Morocco, India, Tunisia, Brazil, the U.S.S.R., France, the Republic of Korea, and the United Kingdom, in descending order of importance.

Capacity.—The data in table 21 are rated capacity for Frasch mines, elemental sulfur mining facilities and attendant beneficiation plants, pyrites mines and plants, sulfur and/or sulfuric acid recovery units associated with petroleum refineries, natural gas processing plants, metal smelting operations, electric powerplants, and coke ovens as of December 31, 1991. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the facility, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with a minimum of capital expenditure. Rated capacity is not equivalent to engineering (design) capacity of installed equipment.

Frasch mines operate continuously, and capacity is related to the quantity of superheated water that can be injected into the associated sulfur deposit. The nature of Frasch mining makes capacity quite variable over time and depends on the number of "steaming wells," water injection rates, water losses from the formation, location of wells within the deposit, and length of time that the deposit has been worked. The rated capacity or realizable capacity of a Frasch

mine generally decreases as the deposit becomes depleted.

Petroleum refineries—large, very costly, and complex processing facilities designed to produce a spectrum of fuels and petrochemical products—operate continuously. Sulfur recovery units make up only a small segment of these facilities; because sulfur recovery is mandated by environmental considerations, the installed sulfur recovery capacity at petroleum refineries generally exceeds the expected sulfur production. To ensure that the loss of a sulfur recovery unit does not require the shutdown of the entire refinery, multiple sulfur recovery units, each capable of servicing the petroleum refinery, are installed. The quantity of sulfur recovered by domestic petroleum refineries in the United States during 1991 was equal to slightly more than 50% of the installed engineering capacity. Rated capacity for petroleum refineries is assumed to be 50% of installed engineering capacity.

Natural gas processing plants may be installed to service gasfields and/or oilfields that contain significant quantities of associated gas. Gas plants are designed to accommodate the natural gas from a specific field that may contain in addition to methane, which is sold as pipeline gas, varying amounts of nitrogen, carbon dioxide, helium, condensable hydrocarbon liquids, and poisonous hydrogen sulfide. The poisonous nature of hydrogen sulfide makes its removal from pipeline gas imperative. Sulfur removal and recovery plants in natural gas facilities vary in size from small units rated at 5 to 10 tons per day to multiple-train plants capable of recovering thousands of tons per day. In general, sulfur recovery rates from gasfields approximate installed engineering capacity, based on a 340- to 345-day-per-year operation of all units, in the first 7 years of operation. In succeeding years, sulfur recovery declines steadily because the gas apparently becomes "sweeter" over time and because gas flow rates drop as the field is depleted. Rated capacity for gas processing plants is based on the age of

the plant and its recent production history.

Rated capacity for plants operating in conjunction with metal smelters, powerplants, and coking operations is assumed to approximate engineering capacity. Where information on design capacity is unknown, rated capacity was estimated to be equal to the greatest output recorded by a plant or country in the past 5 years. World rated sulfur annual production capacity is significantly lower than the installed world engineering capacity of approximately 91 million tons. (See table 21.)

Canada.—The world's leading sulfur exporting country experienced a setback in its offshore sales, but because of increased sales to the United States, Canadian exports were about the same in 1991 as they were in 1990. Production in Canada was 6.23 million tons, 5.8% higher than that in the previous year. Sulfur recovered from natural gas processing represented 87.6% of total Canadian production, with 8.7% from oil sand and 3.7% from oil refining.

The majority of Canadian sulfur is produced in Alberta and British Columbia. With the completion of Shell Canada's Caroline natural gas recovery project in Alberta, an additional 1.5 million tons of sulfur capacity should be operational by early in 1993. An estimated 25 million tons of sulfur is contained in this deposit, which has an average H₂S content of 35.3%.

Shell was also completing a project to determine the feasibility of producing sulfur from a deposit containing more than 90% H₂S as well as elemental sulfur. The Bearberry sulfur reserves are estimated at 40 million tons, and because of the corrosiveness of the material, presented significant challenges to designing a successful recovery process. Materials were developed, and the pilot project proved successful, but the cost of construction of a full-scale plant would be prohibitive, especially with sulfur prices at current lows.

At yearend, a group of 27 Canadian sulfur producers formed a new marketing organization to sell sulfur outside North

America. Named Prism Sulphur Corp., the group should temper the fierce competition among Canadian producers and in so doing establish a more stable pricing structure.

Iraq.—Iraq's Frasch sulfur operation was not believed to have been damaged during the war in the Persian Gulf, but sulfur production and exports remained very low due to the United Nation's trade embargo that was instituted after Iraq invaded Kuwait in early August 1990. The embargo was to remain in effect until Iraq complied with all the conditions in the United Nations ceasefire agreement. U.N. inspectors were still attempting to verify compliance at yearend with little cooperation from Iraq.

Kuwait.—In the aftermath of the Gulf War, fires set by retreating Iraqi troops raged at 749 oil wells. Projections at the time estimated that years of firefighting would be required for all the fires to be extinguished. Due to a heroic international effort, the last well fire was put out on November 6, 1991, less than 7 months after the cease-fire agreement. The effects of the environmental devastation will be felt for years to come, but the immediate emergency passed, enabling the Kuwaiti Government to begin the rebuilding process. The Kuwaiti Government was in the position to get started with reconstruction, possessing cash sufficient to begin. Oil production and refining in Kuwait resumed by the end of the year, with sulfur recovery expected early in 1992.

Mexico.—Frasch sulfur production decreased 24% from 1990 to about 1.1 million tons. Exports to the United States increased to replace the Frasch sulfur shortages experienced with the closing of the Freeport mines, although total exports decreased. More than 55% of the sulfur produced in Mexico is from Frasch deposits. Serious technical problems occurred at the Coachapa/Otopan and the Jaltipan Mines, raising questions as to the future of those mines.

Morocco.—Morocco was a major world importer of elemental sulfur because of consumption at its phosphate fertilizer facilities at Safi and Jorf Lasfar. Imports were about 2.07 million tons in 1991, a 13% decrease from approximately 2.38 million tons imported in 1991.

Poland.—Economic problems in Eastern Europe and the U.S.S.R. have taken their toll on the Polish sulfur industry. In the past, the majority of Polish sulfur exports was to this region, but Polish exports in 1991 were about 2.9 million tons, 24% less than those in 1990. Although efforts were made to sell Polish sulfur in new markets, high production costs made it difficult to compete in current market conditions, and inventories grew.

Poland was the largest world producer of native sulfur, with major mines at Jeziorko, Grzybow, and Machow. The construction of the new Osiek Mine was beset by financial problems, but production was expected to begin there late in 1992. The mine should come on-stream in two phases, one in 1992 and the second in 1993.

U.S.S.R.—Production of sulfur in all forms decreased substantially for the fourth consecutive year. Political events that precipitated the dissolution of the Communist party, have pushed the region to a market economy. The majority of sulfur in the former U.S.S.R. was produced in Kazakhstan, Russia, Turkmenistan, and the Ukraine. Three Frasch mines were operated in the Ukraine and one in Turkmenistan. Technical and economic problems with the Frasch operations suggested that production will continue at reduced levels in the immediate future.

The former U.S.S.R. was believed to contain huge oil and gas reserves that had not yet been tapped. Operating refineries were in Kazakhstan (Tengiz), Russia (Astrakhan and Orenburg), and Uzbekistan (Mubarek), but not to their full potential. The Tengiz oil and gas processing plant began production at

Tengiz I, the first phase of construction, but adjustments were necessary immediately owing to higher than expected sulfur content. Tengiz II and Tengiz III were expected to begin operation in 1992 and 1993, respectively. (See table 22.)

OUTLOOK

Discussing the outlook for the sulfur industry is much like predicting the outcome of the political and economic upheaval occurring throughout the world—it is very difficult if not impossible. The future of the sulfur industry is closely tied to world economy, which in turn is very dependent on the political climate. With events in the Middle East and Eastern Europe only beginning to sort themselves out, it may be several years before predictions can be made with any degree of confidence.

However, at least one fact is certain—sulfur will continue to be produced throughout the world for all of the foreseeable future, and the volume of production will continue to increase. Demand, however, may not. Environmental concerns and legislation reflecting those concerns will mandate increasingly large proportions of sulfur to be recovered from effluent streams, as elemental sulfur, sulfuric acid, or sulfur in other forms. But similar environmental concerns will continue to play a part in determining areas for sulfur consumption. In many cases, processes dependent on sulfur and/or sulfuric acid have been changed to eliminate sulfur requirements and replace it with materials that are perceived as less damaging to the environment.

World sulfur demand, from 1992 to 1996, is forecast to increase at an annual rate of less than 1% per year. From 1996 to the year 2000, growth is expected to be higher at almost 2%. World demand is projected to attain 59.1 million tons in 1995 and increase to more than 65 million tons in the year 2000. In the short term, U.S. sulfur demand is forecast to increase from 12.9 million tons consumed in 1991 to 13.7 million

tons in 1995 and 14.2 million tons in the year 2000.

Almost two-thirds of sulfur consumption in the United States is for agricultural uses. More than 90% of U.S. agricultural sulfur demand and almost 80% of world agricultural sulfur consumption was for the manufacture of phosphoric acid in 1991. World demand for phosphate fertilizers is forecast to increase at an annual rate of about 1.5% for the next 10 years. It is assumed that 90% of the growth will be for the production of phosphoric acid to produce high-analysis fertilizers, which will directly affect world sulfur demand. Consumption of sulfur for phosphate fertilizer manufacture in the United States is divided into two main components: (1) demand for phosphate fertilizers consumed by domestic farmers and (2) demand for exported phosphate fertilizers.

In 1991, an estimated 4.6 million tons of sulfur was required to manufacture the phosphatic fertilizers exported from the United States compared with 3.7 million tons of sulfur for domestic phosphoric fertilizer use. Sulfur demand for domestically consumed phosphates is forecast to increase to almost 4.8 million tons by 1995 and remain relatively stable thereafter. However, the situation in Eastern Europe and the former U.S.S.R. raises questions about fertilizer consumption for the rest of this century. It may take until the beginning of the next century before these economies stabilize and trends in fertilizer consumption become more predictable.

The broad spectrum industrial or nonagricultural sulfur use category accounted for almost 33% of U.S. sulfur consumption and about 42% of world sulfur demand. While significant variations in demand for the diverse elements within this broad category are expected in the United States and other geographic areas, world industrial demand is expected to average less than a 1% increase annually through the remainder of the century, reaching 25 million tons in the year 2000.

The necessity for the removal of sulfur from solid, liquid, and gaseous effluents

for environmental protection has caused the production of sulfur and sulfur compounds from these sources to exceed production from primary sources of supply. The long-term prospect is that 85% or more of the world sulfur supply will come from environmentally regulated sources and that output from these sources will be produced regardless of world sulfur demand. As a result, it is probable that, after the turn of the century, no new operation that produces sulfur as its primary product will be developed, except where it may be deemed necessary for political or social reasons. In 1980, voluntary sources of production, Frasch, native sulfur, and pyrites, accounted for 50% of world output of about 55 million tons. In 1991, these same sources supplied only 40% of world production of 55.6 million tons. (See table 23.)

It is anticipated that, in the short term, world sulfur supply and demand will be closely balanced, but a number of new production facilities that will be completed soon, are under development, or in the planning stage will create tremendous new supply sources. In Canada, projects nearing completion should raise output from existing gas plants 400,000 to 500,000 tons by 1992. The development of the Caroline Gasfield should increase Canadian capacity by 1.2 million tons in 1993. The development of a new mine in Poland and new associated gas processing facilities in the former U.S.S.R. are currently behind schedule, but upon completion could add an additional 5.3 million tons of production capacity. Freeport McMoRan plans to have its new Main Pass 299 Mine on-stream by early 1992 and be producing at a rate of more than 2 million tons per year by 1993 or early 1994, increasing U.S. Frasch capability almost 1 million tons compared with that of 1990 and 2 million tons more than that in 1991. Net additions to world production from expansions and new facilities at oil refineries and gas processing plants should amount to several hundred thousand tons. A worldwide sulfur surplus will probably develop in 1993, a surplus that could

persist for much of the remainder of the century. World sulfur production may attain a level of 62 million tons in 1995 and exceed 66 million tons in the year 2000.

Unspecified sources	2,422	2,325	2,384	2,386	2,362
Gypsum	35	20	20	10	10

¹Estimated. ²Revised. ³W Withheld to avoid disclosing company proprietary data; included with "Byproduct: Unspecified sources."

⁴Table includes data available through June 8, 1992.

²In addition to the countries listed, a number of nations may produce limited quantities of either elemental sulfur or compounds (chiefly H₂S or SO₂) as a byproduct of petroleum, natural gas, and/or metallurgical operations, but output, if any, is not quantitatively reported, and no basis is available for the formulation of reliable estimates of output. Countries not listed in this table that may recover byproduct sulfur from oil refining include Albania, Bangladesh, Brunei, Burma, Costa Rica, Guatemala, Honduras, Jamaica, Malaysia, Nicaragua, Paraguay, and the Republic of Yemen. Albania and Burma may also produce byproduct sulfur from crude oil and natural gas extraction. No complete listing of other nations that may produce byproduct sulfur from metallurgical operations (including processing of coal for metallurgical use) can be compiled, but the total of such output is considered as small. Nations listed in the table that may have production from sources other than those listed are identified by individual footnotes.

³The term "source" reflects both the means of collecting sulfur and the type of raw material. Sources listed include the following: (1) Frasch recovery; (2) native, comprising all production of elemental sulfur by traditional mining methods (thereby excluding Frasch); (3) pyrites (whether or not the sulfur is recovered in the elemental form or as acid); (4) byproduct recovery, either as elemental sulfur or as sulfur compounds from coal gasification, metallurgical operations, including associated coal processing, crude oil and natural gas extraction, petroleum refining, tar sand cleaning, and processing of spent oxide from stack-gas scrubbers; and (5) recovery from the processing of mined gypsum. Recovery of sulfur in the form of sulfuric acid from artificial gypsum produced as a byproduct of phosphatic fertilizer production is excluded because to include it would result in double counting. It should be noted that production of Frasch sulfur, other native sulfur, pyrites-derived sulfur, mined gypsum-derived sulfur, byproduct sulfur from extraction of crude oil and natural gas, and recovery from tar sands are all credited to the country of origin of the extracted raw material; in contrast, byproduct recovery from metallurgical operations, petroleum refineries, and spent oxides are credited to the nation where the recovery takes place, which in some instances is not the original source country of the crude product from which the sulfur is extracted.

⁴Reported figure.

⁵Less than 1/2 unit.

⁶In addition, may produce limited quantities of byproduct sulfur from oil refining.

⁷Includes only the elemental sulfur equivalent of sulfuric acid produced as a byproduct from metallurgical furnaces; additional output may be included under "Byproduct: Unspecified sources."

⁸Official Polish sources report total Frasch and native mined elemental sulfur output annually, undifferentiated; this figure has been divided between Frasch and other native sulfur on the basis of information obtained from supplementary sources.

⁹Estimates for 1987-91 include byproduct production from synthetic fuels.

¹⁰Data may not add to totals shown because of independent rounding.

TALC AND PYROPHYLLITE

By Robert L. Virta

Mr. Virta, a physical scientist with 16 years U.S. Bureau of Mines experience, has been the commodity specialist for talc and pyrophyllite since 1986. Domestic survey data were prepared by Linder Roberts, statistical assistant; and international data tables were prepared by Brad Colquitt, international data assistant.

Domestic production of talc decreased 12% from that of 1990 to 1,040,000 metric tons and increased 3% in value to \$32 million. Sales of crude and processed talc decreased 15% in tonnage to 864,000 tons and 23% in value to \$83 million. Imports for consumption increased 3% in tonnage to 67,000 tons and 8% in value to \$12 million. Exports decreased 25% in tonnage to 178,000 tons and 9% in value to \$30 million. Over the past 10 years, talc production averaged 1,060,000 tons; sales, 957,000 tons; domestic consumption (talc and pyrophyllite), 955,000 tons; exports, 232,000 tons; and imports, 53,000 tons. The major use for talc was in ceramics, which accounted for 31% of the domestic consumption, followed by paint, 17%; paper, 16%; roofing, 11%; and plastics, 6%. Other applications accounted for 19% of consumption. Production and sales of pyrophyllite decreased from those of 1990. The major uses for pyrophyllite were in ceramics, refractories, insecticides, paint, plastics, and rubber.

DOMESTIC DATA COVERAGE

Domestic production and sales data for talc and pyrophyllite are developed by the U.S. Bureau of Mines from a voluntary survey of U.S. mines and mills. Survey forms were sent to 17 companies that operated 47 mines and mills. Sixteen companies that account for approximately 96% of the domestic production responded to the survey. Production data for the nonrespondent was estimated from reported prior-year production levels

adjusted by trends in employment and other guidelines. (See table 1.)

ANNUAL REVIEW

Legislation and Government Programs

The Occupational Safety Health Administration (OSHA) issued a final rule on June 8, 1992, removing the nonasbestiform varieties of actinolite, anthophyllite, and tremolite from the scope of its asbestos standard. The nonasbestiform varieties will be regulated according to limits set for "particulates not otherwise regulated."¹

The Mine Safety and Health Administration (MSHA) continued to review its proposed revisions to its air quality, chemical substances, and respiratory protection standards. The proposed permissible 8-hour time-weighted average exposure limit is 2.5 milligrams per cubic meter (mg/m^3) of air for talc (containing no asbestos), 3 mg/m^3 for respirable soapstone, and 6 mg/m^3 for total soapstone dust. The nonasbestiform varieties of tremolite, anthophyllite, and actinolite would be covered under the proposed respirable mine dust standard.²

MSHA continued reviewing its proposed rule that would create a hazard communication standard. Mine operators would be required to provide information to their employees through labeling, material safety data sheets, and employee training if hazardous chemicals were produced or used on the premises.

Issues

An issue that is attracting attention from some segments of the talc industry is the classification of crystalline silica as a probable human carcinogen by the International Agency for Research on Cancer, an agency of the World Health Organization. Additionally, OSHA-regulated sites that receive and/or use products containing more than 0.1% crystalline silica must comply with OSHA's Hazard Communication Standard (HCS). Both the classification of crystalline silica as a probable human carcinogen and the need to quantitatively analyze for crystalline silica at the 0.1% level to demonstrate exemption from the HCS are controversial.

Production

Talc.—Twelve companies operating 19 mines in 8 States produced talc, soapstone, and steatite. These companies generally were structured to cover all aspects of talc mining, from mining to processing. Only a few companies hired custom grinders to mill the ore. The largest of the domestic producers were Cyprus Minerals Co. Inc., Dal Minerals, Gouverneur Talc Co., Montana Talc Co., and Pfizer Inc. The major producing deposits were in Montana, New York, Texas, and Vermont.

Commercial talc production was from deposits that were formed through hydrothermal alteration of ultrabasic rocks and low-grade metamorphism of siliceous dolomites. They generally occur as lenses or pods in the country

rock. Magnesite, quartz, chlorite, magnetite, serpentine, anthophyllite, tremolite, dolomite, and actinolite may be present as accessory minerals.

Most of the domestic talc production was from open pit mining operations. Underground mining was used only when a large waste-rock-to-ore ratio made open pit mining uneconomical. Typically, overburden was removed and blasting was used to fracture the ore. The companies then used selective mining and manual or automated sorting to produce a high-grade feed for the mill. Jaw crushers were used to reduce the size of the mill feed, and ball mills or roller mills were used to produce the final product. Fluid-energy mills or pulverizing mills were used for ultrafine grinding of the talc ore. In a few instances, the ore was calcined prior to milling to increase its whiteness.

Flotation processes were used when the desired product purity was not obtained by using conventional processing. The milled ore was chemically treated, passed through rougher and cleaner cells to separate the talc from the gangue material, dried in a flash dryer, and ground in a pulverizer. Ore composition, reagent type, pulp density, pH of the flotation system, and residence time in the flotation circuits determined flotation efficiency.

Cyprus Minerals Co. signed a letter of intent to sell its talc operations to RTZ Corp. PLC, London. The sale includes talc operations in Alabama, California, Montana, Vermont, and Spain. Also included is a milling operation in Belgium and an interest in a talc operation in Japan.³

Southern Talc Co., a subsidiary of UCI, Louisville, KY, closed its mine in Georgia. The company recently built a flotation plant to improve the quality of its milled products but the ore could not be adequately upgraded for higher value markets.⁴

Pfizer Inc. completed its flotation mill at its Barretts, MT, operation. The \$8.6 million expansion will permit the company to produce a higher value talc product and extend the life of recoverable reserves.⁵

ECC Group PLC sold its U.S. subsidiary, Southern Clay Products Inc. Southern Clay Products' bentonite operations in Texas were sold to Laporte PLC.⁶ Its talc operations in Texas were sold to United Clays of Texas, a subsidiary of WBB Ltd., London.

U.S. mine production of crude talc decreased 12% in tonnage to 1,040,000 tons and increased 3% in value to \$32 million. Mines that operated in Montana, New York, Texas, and Vermont accounted for 96% of domestic talc production. Montana led all States in the tonnage and value of talc produced.

Pyrophyllite.—Pyrophyllite was mined by two companies operating three mines in North Carolina. Production was from hydrothermally altered volcanic deposits of acidic composition. The deposits consisted of pyrophyllite with sericite, andalusite, and/or quartz as accessory minerals. After removing the overburden, the ore was either stripped using dozers and scrapers or extracted using conventional open pit mining techniques. The ore was dried, and then jaw crushers and gyratory crushers were used to reduce the size of the mill feed. Ball, pebble, or roller mills were used to produce the final product.

U.S. mine production of crude pyrophyllite decreased in tonnage from that of 1990. (See table 2.)

Consumption and Uses

Talc.—Talc was used in a wide variety of products because of its softness (1 on the Mohs scale), purity, fragrance retention, whiteness, luster, moisture content, oil and grease adsorption, chemical inertness, low electrical conductivity, high dielectric strength, and high thermal conductivity. These properties were not universal to all talcose materials because of differences in their mineralogical composition and particle shape. Mineral content was extremely important because it determined the end use for the material. Generally, only two or three of these

properties were critical for any one application.

Domestic producers reported that overall sales (including exports by producers) declined 15% in tonnage to 864,000 tons and 23% in value to \$83 million in 1991. The major consumer of talc was the construction industry, with applications in ceramic tiles and sanitaryware, joint compounds, paint, and roofing. The end-use distribution was ceramics, 31%; paint, 17%; paper, 16%; roofing, 11%; plastics, 7%; cosmetics, 5%; and insecticides, refractories, rubber, and other, 14%. Reported sales to the ceramics and plastics industries increased in 1991. Sales to the paint, paper, and roofing industries declined as a result of the downturn in the building construction industry. More than 90% of the companies responded to the end-use portion of the 1991 annual survey, representing 91% of the data in table 3.

Pyrophyllite.—Pyrophyllite, being different in composition from talc, did not have the same applications as talc. Properties such as softness (1 to 2 on the Mohs scale), whiteness, chemical inertness, high melting point, low electrical conductivity, and high dielectric strength made pyrophyllitic materials useful for ceramics and refractories.

Domestic consumption of pyrophyllite decreased 3% in tonnage in 1991. The largest portion of domestically produced ground pyrophyllite was used in ceramics, followed by refractories, insecticides, paint, plastics, and rubber. (See table 3.)

Markets and Prices

Talc prices were based on the quality and on the degree and method of processing. The unit value of crude talc based on data reported by producers was \$32 per ton. The average reported unit value of processed talc was \$105 per ton. The average unit value of crude and processed pyrophyllite was unchanged from that of 1990. Unit values for imported crude and ground talc ranged from \$66 per ton to \$928 per ton for quantities greater than 100 tons. The

average unit value for all imported talc was \$178 per ton. Unit values for exported talc ranged from \$95 per ton to \$1,044 per ton for quantities greater than 100 tons and averaged \$169 per ton for all exports.

Prices, quoted by the American Paint & Coatings Journal, December 26, 1991, in U.S. dollars per metric ton for paint-grade talc in carload lots ranged from \$99 to \$226. Approximate equivalents, in dollars per metric ton, of price ranges quoted in Industrial Minerals (London), December 1991, for talc, c.i.f. main European ports, ranged from \$210 to \$385. (See table 4.)

Foreign Trade

Talc exports decreased 25% in tonnage to 178,000 tons and decreased 9% in value to \$30 million. Belgium-Luxembourg was the largest importer of talc, followed by Canada, Mexico, and Japan. Talc imports increased 3% in tonnage to 67,800 tons and 8% in value to \$12 million. Canada and China provided 86% of all talc imports. (See tables 5 and 6.)

World Review

China was the world's largest producer of talc. The United States remained the largest market economy talc producer, and Japan remained the largest pyrophyllite producer. China, Japan, and the United States accounted for 52% of the world's talc and pyrophyllite production.

Capacity.—The data in table 6 are annual rated capacity for mines and refineries as of December 31, 1991. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought

into production within a short period of time with minimum capital expenditure. (See tables 7 and 8.)

Canada.—International Larder Minerals Inc. (ILM) evaluated a proposal to permit Bakertalc Inc. to mine ILM's undeveloped high-grade talc deposit near Thetford Mines, Quebec. The proposal also requested funding to upgrade Bakertalc's operations and reduce company debt.⁷

Finland.—Finnminerals operates three facilities in Finland. The flotation mill near Sotkamo is the largest of its operations. The facility produces approximately 180,000 tons of talc per year. The flotation process increases the purity of the talc to 97%. Talc is used by the paint, paper, and polymer industries. Its second facility, in northern Karelia, has an output of approximately 120,000 tons per year. Its third facility, in Luikonlahti, was acquired from the Partek Group in 1991. This operation produces approximately 75,000 tons per year for the fertilizer, paint, paper, and plastics industries.⁸

India.—Pyrophyllite is mined in Madhya Pradesh, Orissa, Rajasthan, Udaipur, and Uttar Pradesh. Approximately 46% of India's pyrophyllite production is from Madhya Pradesh. Talc is mined in Andhra Pradesh, Bihar, Madhya Pradesh, and Rajasthan. Production in Rajasthan accounts for 83% of India's talc production.⁹

Spain.—Three companies mine talc in Spain: Iberica de Talcos SA, Sdad Espanola de Talcos SA, and Distribuidora Malayuena de Talcos SA. Iberica de Talcos and Sdad Espanola de Talcos operate mines in the Pueblo de Lillo area. Sdad Espanola de Talcos produces 30,000 to 40,000 tons per year, one-half of which is cosmetic-grade talc. Distribuidora Malayuena, a subsidiary of Cyprus Minerals Co., operates mines near Mijas and Malaga. These facilities produce approximately 25,000 tons per

year for sale to the animal feed, chewing gum, fertilizer, olive oil, paint, paper, rubber industries.¹⁰

OUTLOOK

The average annual growth in domestic demand for talc and pyrophyllite was 1.2% between 1982 and 1991. Demand averaged between 900,000 and 1,000,000 tons per year for this period. Relative increases and decreases in demand have been the result of minor market fluctuations rather than long-term trends. Demand for talc and pyrophyllite is expected to continue to fluctuate about 1 million tons per year in the near future. With a slight improvement in the domestic economy predicted, talc markets affected by the current economic recession also should improve.

Ceramics will continue to be the major domestic end use for talc, followed by consumption in paint, paper, plastics, roofing, and cosmetics, in descending order. For pyrophyllite, the major domestic end uses will continue to be in ceramics and refractories.

THALLIUM

By Thomas O. Llewellyn

Mr. Llewellyn, a physical scientist with over 30 years of industry and U.S. Bureau of Mines experience, has been the commodity specialist for thallium since 1987. Domestic survey data were prepared by Carolyn F. Crews, statistical assistant.

In 1991, domestic demand for thallium metal was met by imports. Thallium is a trace element with an estimated average abundance of 2.2 parts per million in zinc sulfide ores and is a byproduct recovered from flue dust and residues collected in the smelting of zinc as well as copper and lead. There are a number of rare thallium minerals found in nature, which have no commercial importance as sources of thallium metal.

BACKGROUND

Current Research

A thallium-copper oxide superconductor, said to have a very high superconductivity transition temperature, was reportedly developed at the Superconductivity Research Laboratory, Tokyo, Japan.¹ Researchers in California designed a practical X-ray laser using energized atoms of thallium. The X-ray laser beam can penetrate living tissue like conventional X-rays, but it can also produce three-dimensional pictures of proteins as they react inside living cells.²

Operating Factors

Thallium metal and its compounds are highly toxic; they should be handled with extreme care and require the use of rubber gloves. It can be absorbed into the human body by skin contact, ingestion, or by inhaling dust or fumes. The element is not quickly eliminated from the body; therefore, absorption of subtoxic quantities eventually may accumulate to a toxic level.

ANNUAL REVIEW

Production

Although thallium was contained in ores mined or processed in the United States, it was not recovered domestically as a marketable product in 1991.

Consumption and Uses

Based on import data and discussions with metal traders, the domestic consumption of thallium in 1991 was estimated to be 850 kilograms, about 21% higher than that in 1990.

Thallium was used in superconductivity research, gamma radiation-detection equipment, additives for changing the refractive index and density of glass, low temperature mercury-thallium alloy switches, high-density liquids, alloys, photosensitive devices, and radioactive isotopes for cardiovascular diagnostic procedures.

Markets and Prices

Thallium metal was sold at various prices during the year according to its purity. Metal traders reported that the average price of thallium metal in 100-kilogram lots was \$190 per kilogram for 99.99%-pure thallium metal. The average value per kilogram of unwrought thallium metal and waste and scrap imported into the United States was estimated to be about \$181 per kilogram.

Foreign Trade

In 1991, thallium materials were imported from Belgium, Canada, and the United Kingdom. However, Belgium remained the principal source of imported thallium materials. Since January 1, 1990, the import duty for unwrought thallium and waste and scrap (Harmonized code 8112.91.6000) has been 5.5% ad valorem for most favored nations (MFN) and 25% ad valorem for non-MFN.

Thallium producers are granted a depletion allowance of 14% on both domestic and foreign production.

World Review

World production data for thallium were not available. The U.S. reserves in zinc ores were estimated to be about 32,000 kilograms. Rest-of-the-world reserves were estimated to be 345,000 kilograms of thallium.

OUTLOOK

The United States is not expected to resume recovery of thallium within the next 5 years. The toxicity of thallium is the factor that continues to influence domestic dependence on foreign sources for its supply.

THORIUM

By James B. Hedrick

Mr. James B. Hedrick, a geologist and physical scientist with the Federal Government for 14 years, has been the commodity specialist for thorium since 1982. Domestic survey data were prepared by Kevin Bacon, statistical assistant; and the international data table was prepared by Harold Willis, international data assistant.

Domestic consumption of refined thorium products decreased, according to the U.S. Bureau of Mines, Department of the Interior. Thorium was recovered worldwide primarily from the rare-earth ore mineral monazite, a byproduct of processing heavy-mineral sands for titanium and zirconium minerals or tin minerals. Thorium compounds are produced from monazite during processing for the rare earths. Only a small portion of the thorium produced is consumed; most is discarded as waste. The major monazite-producing countries were Australia, Brazil, China, India, Malaysia, the Republic of South Africa, Sri Lanka, Thailand, and the United States. None of the domestically produced monazite was refined in the United States. Essentially all of the thorium compounds used by the domestic industry originated from either imports or U.S. Government stocks.

Limited demand for thorium, relative to the rare earths, continued to create an extensive world oversupply of thorium compounds and residues. Excess thorium, not designated for commercial use, was either disposed of as a radioactive waste or stored for potential use as a nuclear fuel or other application. Major nonenergy uses were in the traditional areas of refractories and lighting. Coleman Co. announced it had developed a suitable substitute for thorium used in incandescent lamp mantles.

Thorium's natural radioactivity represented a significant problem to those companies involved in its mining, processing, and use. Increased costs to comply with environmental regulations

and to pay for storage and waste disposal were the principal problems cited by industry, not health factors associated with its natural radioactivity.

DOMESTIC DATA COVERAGE

Domestic mine production data for thorium-bearing monazite are developed by the U.S. Bureau of Mines from a voluntary survey of U.S. operations entitled, "Rare Earths, Thorium, and Scandium." The one mine to which a survey form was sent responded, representing 100% of domestic production. Mine production data for thorium are withheld to avoid disclosing company proprietary data. Statistics on domestic thorium consumption are developed by surveying various processors and end users, evaluating import-export data, and analyzing Government stockpile shipments. (See table 1.)

ANNUAL REVIEW

Legislation and Government Programs

The calendar year 1991 included the U.S. Government fiscal years for 1991 and 1992. Public Law 101-189, the National Defense Authorization Act for Fiscal Years 1990 and 1991, covered the first 9 months of 1991 and continued the authorization for disposal of all stocks of thorium nitrate in excess of the National Defense Stockpile goal of 272,155 kilograms (600,000 pounds). Thorium nitrate classified as excess to goal at yearend 1991 was 2,946,185 kilograms (6,495,225 pounds). In the last 3 months

of 1991, Public Law 102-190, the National Defense Authorization Act for Fiscal Years 1992 and 1993, renewed the authorization to dispose of thorium nitrate at the aforementioned levels.

Legislation was proposed to revise the National Defense Stockpile goal for thorium nitrate to zero. Congressional action on the proposal was expected in 1992.

Production

RGC (USA) Minerals Inc., previously Associated Minerals (USA) Ltd. recovered thorium-bearing monazite for its rare-earth content at its dredging operation near Green Cove Springs, FL. Monazite was produced as a byproduct during processing for titanium and zirconium minerals. One rare-earth processor in Texas produced thorium as a byproduct compound. None of the monazite produced domestically was processed in the United States for its thorium content. Essentially all thorium alloys and compounds used by the domestic industry were derived from either imports, company stocks, or U.S. Government stocks. Domestic companies processed or fabricated various forms of thorium for nonenergy uses such as ceramics, incandescent lamp mantles, carbon arc lamps, magnesium-thorium alloys, refractories, magnetrons, triodes, crossfield amplifiers, and welding electrodes. The value of thorium compounds and alloys used by the domestic industry were estimated at \$1 million.

W.R. Grace and Co. announced it had switched from a thorium-bearing

monazite feed to a thorium-free rare-earth chloride feed for its rare-earth plant in Chattanooga, TN. The feed change to a thorium-free material was the result of increased disposal costs at approved radioactive waste sites. (See table 2.)

Consumption and Uses

Domestic thorium producers reported consumption of 54.3 metric tons of thorium oxide equivalent in 1991, a decrease of 11.2 metric tons from the 1990 level. Nonenergy uses accounted for all of the total consumption. The decrease in consumption was the result of decreased demand for thorium used in lamp mantles as Coleman Co. developed a proprietary thorium-free mantle coating using rare earths. The approximate distribution of thorium by end use, based on data supplied by producer, processors, and several consumers, was as follows: refractory applications, 85%; lamp mantles and lighting, 13%; metallurgical applications, 1%; and ceramics and welding electrodes, 1%.

Thorium oxide (thoria) has the highest melting point of all metal oxides, 3,300° C, a property that contributed to its use in several refractory applications. High-temperature uses were in high-temperature ceramics, investment molds, and crucibles.

Thorium nitrate was used in the manufacture of some mantles for incandescent "camping" lanterns, including natural gas lamps and oil lamps. Thorium mantles provide an intense white light that is adjusted toward the yellow region by a small addition of cerium. Its use in this application is declining due to the development of a suitable thorium-free substitute.

Thorium nitrate was also used to produce thoriated tungsten welding electrodes. Thoriated tungsten welding electrodes were used to join stainless steels, nickel alloys, and other alloys that require a continuous and stable arc to achieve precision welds.

The nitrate form was also used to produce thoriated tungsten elements used in the cathode (negative pole) of magnetron tubes. Thorium was used

because of its ability to emit electrons at relatively low temperatures when heated in a vacuum. Magnetron tubes were used to emit electrons at microwave frequencies to heat food in microwave ovens, in radio frequency (RF) induction heating, and in radar communication. Magnetrons were also used in military and commercial aircraft tracking radar and in weather radar.

Thorium was used in other types of electron emitting tubes, elements in special use light bulbs, high-refractivity glass, radiation detectors, computer memory components, catalysts, photoconductive films, target materials for X-ray tubes, and fuel cell elements.

Thorium fluoride was used in the manufacture of carbon arc lamps. Carbon arc lamps were used in searchlights, movie projectors, and cinematography lighting.

Most thorium used in metallurgical applications was alloyed with magnesium. Magnesium-thorium alloys used by the aerospace industry are lightweight, have high-strength, and have excellent creep resistance at elevated temperatures. Small quantities of thorium were used in dispersion hardened alloys for high-strength, high-temperature applications.

Thorium was used as a nuclear fuel in the thorium-232/uranium-233 fuel cycle. Only a few foreign-based nuclear reactors continued to operate with this fuel cycle.

Stocks

Government stocks of thorium nitrate in the National Defense Stockpile were 3,219,457 kilograms (7,097,687 pounds) on December 31, 1991. The stockpile's goal at yearend was 272,155 kilograms (600,000 pounds) of thorium nitrate. Stocks classified as excess to goal totaled 2,946,185 kilograms (6,495,225 pounds) and were all authorized for disposal.

The U.S. Department of Energy's inventory at yearend was 1,244,020 kilograms (2,742,595 pounds) of thorium oxide equivalent contained in ore, metal, and various compounds.

Prices

The price range of Australian monazite (minimum 55% rare-earth oxide, including thoria, f.o.b.),¹ as quoted in Australian dollars (A\$),² decreased from A\$800 to A\$900 per metric ton at yearend 1990 to A\$650 to A\$700 per metric ton at yearend 1991. Changes in the United States-Australia foreign exchange rate in 1991, resulting from a slighter weaker Australian dollar, caused the corresponding U.S. dollar to be up \$0.02 against the Australian dollar at yearend. The U.S. price range, converted from Australian dollars, decreased substantially from US\$618 to US\$695³ per metric ton in 1990 to US\$494 to US\$532⁴ per metric ton in 1991.

Thorium prices quoted by the Reed Manufacturing division of Magnesium Elektron, Flemington, NJ, at yearend 1991 were \$220.35 per kilogram (\$99.95 per pound) for thorium hardener (80%Mg-20%Th) in single drum quantities and \$41.40 per kilogram (\$18.78 per pound) for thorium-containing HZ-32 magnesium alloy ingot.

World Review

France.—Rhône-Poulenc SA was the leading producer of thorium compounds. Thorium was produced as a byproduct during processing for the rare earths at its operations in La Rochelle, France, and at Freeport, TX. It was derived almost entirely from the rare-earth ore mineral monazite.

United Kingdom.—The principal magnesium-thorium alloy producer in the United Kingdom, Magnesium Elektron has reportedly ceased production of magnesium-thorium alloys and master alloys. Sufficient stocks were produced to supply domestic needs for about 5 years. (See tables 3 and 4.)

OUTLOOK

Nonenergy uses of thorium are expected to continue to decrease. The long-term outlook for demand is for a significant decline. Industry users have

been successful in developing suitable substitutes for thorium used in incandescent lamp mantles and ceramic applications. The search for substitutes is expected to last as long as the costs of environmental compliance continues to escalate. Costs associated with handling, storing, and disposing of thorium have continued to increase. In addition, public concerns and potential liabilities arising from its natural radioactivity are expected to continue to impact thorium's use. No shortage of thorium is anticipated.

⁴In addition to the countries listed, China, Indonesia, North Korea, the Republic of Korea, Nigeria, and the U.S.S.R. may produce monazite, but output, if any, is not reported quantitatively, and available general information is inadequate for formulation of reliable estimates of output levels.

TIN

By James F. Carlin, Jr.

Mr. Carlin, a physical scientist with the Branch of Metals, has been the commodity specialist for tin for 12 years. Domestic survey data were prepared by Elsie Isaac, mineral data assistant; and international data tables were prepared by William L. Zajac, Chief, Section of International Data.

Tin was one of the earliest metals known to humankind. Tin occurs in nature mostly as the oxide mineral cassiterite. Tin metal is commonly used as a protective coating or as an alloy with other metals. It finds applications in products and processes as diverse as tin cans, solder for electronics, tin chemicals, bronze fittings, and flat-glass production. Its strategic importance is exemplified by the fact that it generally has been the largest dollar-volume holding of all metals in the National Defense Stockpile (NDS) since the establishment of the stockpile in the 1940's.

In 1991, for the 11th consecutive year, there was an excess of tin on the world market. Excess stocks were believed to be about 40,000 metric tons of tin at yearend.

The price of tin remained in a fairly narrow band throughout the year and at a level that was low by historical standards. World tin mine output declined as producers reduced output in view of continued low tin prices. In the United States, there was continued interest in the recycling of used tin cans largely due to the rising costs and limited space of landfills.

DOMESTIC DATA COVERAGE

Domestic consumption data for tin are developed by the U.S. Bureau of Mines from a voluntary survey of U.S. tin users. All of the 290 consumers to which a survey request was sent responded. (See table 1.)

BACKGROUND

Definitions, Grades, and Specifications

Primary or virgin tin metal is cast and sold as bars, ingots, pigs, and slabs in weights of 50 kilograms or less. Most of the tin metal imported into the United States is in the form of 45-kilogram pigs. During 1982-84, the American Society of Testing and Materials (ASTM) Pig Tin Task Group developed a new specification for grade-A tin, calling for 99.8% minimum tin content and 0.030% maximum bismuth content. This specification bore the code B-336-90. In 1990, the American Tin Traders Association modified the silver content of tin to be 0.01% maximum. This action was taken to limit some tin metal that was being imported into the United States with high silver content, which was thought to be detrimental to the electronic soldering industry.

Products for Trade and Industry

Tin is rarely used in its pure form, but is usually alloyed with other metals. Bronze, developed in the fourth millennium B.C., traditionally was a copper-base alloy containing about 10% to 15% tin to harden the copper. Today, the term "bronze" is seldom used without a modifier because it is applied also to some copper-base alloys containing no tin. The most important tin bronzes are the phosphor bronzes, containing up to 12% tin with small additions of phosphorus, and the gun metals, which are tin-bronze casting alloys containing

from 1% to 6% zinc. Brass, another old and important alloy, is primarily an alloy of copper and zinc, but often tin is a component.

There are numerous solder compositions, typical of which are tin-silver solder (95% tin, 5% silver), antimony-tin solder (95% tin, 5% antimony), and soft solders (ranging from 1% to 70% tin, with the remainder essentially lead).

Tin-base babbitt is an alloy containing antimony and copper, used for lining bearings. Lead-base babbitt metal contains 1% to 10% tin.

Compositions for tin foil and "white metal" vary with the producer. Most foil now is a tin-lead alloy. Some foil is made from relatively pure tin or tin containing small amounts of copper or antimony hardener. White metals, such as britannia metal, jewelers metal, and pewter, are tin alloys, normally hardened with antimony. Pewter may have a wide range of composition, but high-grade pewter contains 90% to 95% tin, with 1% to 2% copper and the remainder antimony. Copper and antimony serve as hardeners.

Tinplate is a thin-gauge steel sheet product that has a very thin tin coating on both surfaces; the steel thickness and the weight of surface tin coating vary according to end-use requirements. Terneplate is sheet steel coated on both surfaces with a tin-lead alloy.

Tinplate is commonly shipped as coil, solder as ingot, bronze as strip or plate, and brass as any of these forms. Each of these semifinished products is then used to fabricate a wide variety of end-use items. Brass and bronze are also

produced in cast forms. Tin usually becomes a very small, but essential, part of the end-use item's weight or cost.

Industry Structure

At least 35 countries mine or smelt tin. Virtually every continent has an important tin-mining country. Most operations are privately owned, but many are publicly owned. A similar situation exists in the tin-smelting industry.

In the major Southeast Asian tin-producing countries, small, labor-intensive, high-unit-cost mines, such as gravel-pump mines, produce a significant proportion of total output. In these same countries, massive, expensive dredges also are used. Large, privately owned mining enterprises operate in Southeast Asia, but many of the operations are also Government-owned. The four largest tin-mining companies in the market economy countries are Paranapanema in Brazil, the Malaysia Mining Corp., P.T. Timah in Indonesia, and Corporación Minera de Bolivia (COMIBOL).

An agreement establishing the Association of Tin Producing Countries (ATPC) came into force on August 16, 1983. The five charter members were Bolivia, Indonesia, Malaysia, Thailand, and Zaire. Australia and Nigeria joined later. The stated objectives of the ATPC were to obtain fair returns for tin producers and adequate and stable supplies at reasonable prices for tin consumers, to facilitate cooperation in the marketing of tin, and to enhance the growth of tin use. Members stated that they viewed the ATPC as complementary and supportive of the activities of the ITC. The Tin Council was an association of leading world tin producer and user countries that attempted to stabilize tin prices and supply-demand from 1956 until its demise in 1989. In recent years, the most visible activity of the ATPC has been to attempt to reduce the world oversupply of tin through a series of supply rationalization schemes. These programs have essentially featured export-control limits placed on the seven member countries. While these programs have succeeded in drastically reducing the

huge tin oversupply, they have not eliminated it largely because major producers such as Brazil and China were not bound by the guidelines of the programs.

U.S. mine production of tin has been negligible for many decades. Small quantities of tin concentrates are produced from placer deposits in Alaska, and small quantities were once produced in several Western States.

In recent decades, the only tin smelter in the United States was the Texas City, TX, facility of TexTin Corp. In recent years, this smelter treated tin concentrates imported from Bolivia and Peru, as well as some domestic tin concentrates and some accumulated secondary residues. In 1989, owing to continued low tin prices and difficulties in obtaining feedstocks, TexTin ceased tin production and converted its equipment to process secondary copper.

The tinsplate-producing industry is quite concentrated, comprising only seven major steel firms. The solder-producing industry is considerably more dispersed, but most of the tonnage is accounted for by a relatively few soldermaking firms. During the past decade, both the tinsplate and the solder industries have undergone considerable consolidation. In the tin chemical field, while there are a number of companies, one firm dominates.

The other domestic tin-using industries are diverse, such as the brass, bronze, solder, and flat-glass industries, and are represented by hundreds of firms and plants. Most are in the East and Midwest.

Geology-Resources

Tin is a relatively scarce element; its average abundance in the Earth's crust is about 2 parts per million (ppm), compared with 94 ppm for zinc, 63 ppm for copper, and 12 ppm for lead. Tin is preferentially concentrated by magmatic differentiation processes and shows a worldwide affinity for granitic rocks or their extrusive equivalents. The principal deposits are scattered irregularly along a belt surrounding the Pacific Ocean. Most of the world's tin is produced from placer

deposits; about one-half of placer tin comes from Southeast Asia.¹

The only mineral of commercial importance as a source of tin is cassiterite (SnO₂), although small quantities of tin are recovered from the complex sulfides stannite, cylindrite, franckeite, canfieldite, and teallite. Cassiterite has a high specific gravity (6.8 to 7.1), a Moh's scale hardness of 6 to 7, and is usually a dark-brown or black color with an adamantine luster.

Because cassiterite is both heavy and chemically inactive, it is concentrated in residual (eluvial) placers that form over or adjacent to bedrock source areas where weathering and erosional processes remove lighter rock materials and gravity assists in downslope movement of heavy minerals released by weathering. The richest placers are stream deposits (alluvial placers) found where flowing water has concentrated heavy minerals generally derived from residual placers. Ocean beach sands may also contain placer accumulations of tin; such placers are mined offshore in Indonesia and Thailand. No extensive tin placer deposits have been found in the conterminous United States.

Technology

Exploration.—Historically, prospecting for tin has been carried out by the time-honored methods of panning, drilling, and pitting. As rich deposits were exhausted and the costs of exploration rose, the search for tin required more sophisticated methods. Geophysical and geochemical analyses have been employed to cover large areas more rapidly, isolating areas of possible tin deposits so that drilling can be more effective and less costly.

Mining.—Principal methods for mining placer deposits are bucketline dredging and gravel-pump operations, although hydraulicking and various open pit methods are also used. The bucketline dredges used are floating dredges similar to those used to mine other placer deposits. The ore is excavated and transported by buckets to the interior of the dredges, washed on screens, and

concentrated in jigs and on shaking tables. Tailings are discharged at the rear of the dredges to fill in the mined pond, and the crude tin concentrate is sent to the dressing shed for final concentration.

Although gravel-pump and hydraulic mining both use water jets to break up the tin-bearing material, the methods of conveying the material to the launders differ. In gravel-pump mining, a pump is used, whereas hydraulicking employs the pressure developed by a natural head of water. In each method, the material is washed through a riffled launder, called a palong in Malaysia, where the cassiterite is collected by the riffles and the waste is washed away.

In open pit operations, the material is excavated by power shovels and transported on a conveyor belt to the washing plant for treatment.

Vein tin deposits are mined by methods similar to those used in the hard-rock mining of other nonferrous ores. Access to the ore bodies is by adits and shafts. The ore is broken by conventional drilling and blasting and transported from the mine to a concentrator for treatment.

Processing.—The crude tin concentrate from placer mining is further upgraded by washing, tabling, and magnetic or electrostatic separation. The final product is virtually pure cassiterite.

Tin ore from lode deposits is reduced to the necessary size by conventional crushing and grinding. The ore is concentrated by gravity methods involving screening, classification, jigging, and tabling. The gravity concentrate is usually of lower grade than placer concentrate owing to associated sulfide minerals. The sulfide minerals are removed by flotation or magnetic separation, with or without roasting, to produce a second-stage concentrate.

Cassiterite in placer deposits is fairly coarse grained, and recoveries range from 90% for gravel-pump mines to 95% for dredging operations. However, the cassiterite in vein deposits is very fine grained and is difficult to recover by gravity concentration. Cassiterite ore at mines in Australia, Bolivia, the Republic

of South Africa, and the United Kingdom are floated, but recoveries are seldom more than 70%. Recovery of the tin content in Bolivia is reportedly as low as 50%.

Cassiterite is reduced to tin by heating with carbon at 1,200° to 1,300° C. The almost pure cassiterite concentrate from placer deposits is smelted directly. Other concentrates, particularly from Bolivia, contain impurities that must be removed before smelting. This is usually done by roasting the tin concentrates with or without fluxes, followed by acid leaching. During roasting, most of the sulfur and arsenic are removed as oxides. Bismuth, copper, iron, and zinc oxides are removed by leaching the roasted concentrate with sodium carbonate or sulfate and leaching with water. Antimony, bismuth, lead, and silver may be removed by a chloridizing roast, followed by an acid leach.

In modern tin-smelting plants, reverberatory furnaces are used to smelt primary tin concentrate and to resmelt the slag for additional tin recovery. Although blast and electric furnaces are also used to smelt tin concentrate, reverberatories are often preferred because of better control, cleaner slags, and superior efficiency in smelting finely divided materials. Electric furnaces are often favored for energy-saving reasons, especially for smaller smelters.

Tin smelting is a batch operation. A typical charge consists of cassiterite concentrate, a carbon reducing agent, and limestone and silica fluxes. From 10 to 12 hours is required to smelt a charge. When smelting is complete, the molten batch is tapped into a settler, from which the slag overflows into cast-iron pots. The molten tin from the bottom of the settler is cast into slabs or pigs for refining.²

The slag, containing 10% to 25% tin, is resmelted to yield a slag containing less than 1% tin.

Heat treatment is the most widely used refining method and consists of heating the tin from smelters on a inclined hearth to a temperature slightly above the melting point of pure tin, but below the melting points of the impurities. Thus,

the comparatively pure tin melts and flows into a kettle, leaving impurities such as iron and copper in a dross residue that is retreated to recover the contained tin.

The molten tin is then stirred with green wood, which produces a strong boiling action. During the stirring, the metal impurities and part of the tin are oxidized and form an oxide dross that is skimmed off. Sometimes tossing is used instead of stirring. In this operation, hand ladles of molten tin are dipped from and poured back into the kettles, exposing the tin to the oxidizing action of the air. After refining has been completed, the tin is cast into pigs for marketing.

Recycling.—The only form of tin recycling in which free tin is produced is detinning. In recent decades most detinning has been conducted on new, flat tinplate scrap, mostly from tin mills or canmaking plants. In the detinning of flat tinplate, generally the tinplate scrap is treated with a hot solution of caustic soda in the presence of an oxidizing agent to dissolve the tin as sodium stannate. The base steel is then washed and compacted into bales for shipment. The tin may be recovered from the stannate solution as metal, sodium stannate crystals, or tin oxide. Because of advantages in processing costs and production of a high-purity metal, the common practice is electrolysis of the stannate solution to yield metallic tin. The refined tin averages as high as 99.99% purity, with antimony, iron, and lead as common impurities.

Until recent years, the detinning of used tin cans was not performed on an economic, high-volume basis because cans were often in a crushed condition and had enamel coatings and food particles attached that made effective detinning impossible. However, in the late 1980's, techniques were developed to detin these used tin cans. The most common method is to shred the cans into small popcorn-sized pieces and then proceed with the caustic soda treatment.

Most scrap tin is alloyed tin (such as solder, brass-bronze, or babbitt) that is recycled in its own alloy industry. These

producers refine out undesired elements from the scrap charge or may use additions to build up desired elements.

Byproducts and Coproducts

In some tin placer deposits, large amounts of columbium, tantalum, and rare-earth minerals are associated with the cassiterite. Some lode tin deposits contain numerous other materials such as copper, lead, silver, and zinc, usually in the form of sulfides.

Tin has been recovered as a coproduct of molybdenum mining at the Climax lode mine in Colorado. Small quantities have been produced as a coproduct of placer gold mining or tailings-cleanup operations in Alaska or South Dakota. It has been produced as a byproduct of lead-zinc mining in Ontario and British Columbia, Canada.

In some major tin-producing countries, such as Malaysia and Thailand, tantalum contained in tin smelter slags is a major source of tantalum supply.

Substitutes

Alternative materials, often less costly, have been a significant factor in the downward trend in domestic tin consumption over the past two decades. Aluminum and chromium-coated tin-free steel were two materials used to replace tinplate in beverage cans over the past two decades. Other substitutes for tinplate include enameled steel, glass, paper, and plastics. Nonmetallic materials, aluminum, copper, and galvanized steel have largely replaced terneplate for roofing and both tinplate and terneplate for other construction. In general, no satisfactory substitutes have been found for tin in solder, although lowering the tin content of the solder may be possible in some applications. Aluminum alloys, other copper-base alloys, and plastics could be substituted for some bronzes. Low-tin aluminum-, copper-, or lead-base bearing alloys and roller or ball bearings may be substituted for babbitt metal. Other chemicals may replace some tin chemical compounds for use as fungicides, biocides, marine

antifouling paints, or polyvinyl chloride stabilizers.

ANNUAL REVIEW

Legislation and Government Programs

The National Defense Stockpile (NDS) continued in its third year of being managed by the Department of Defense, with day-to-day operations guided by the Defense Logistics Agency (DLA).

The DLA sold 6,195 tons of tin from the stockpile in 1991. Through April 18, the disposals were direct sales to the marketplace; then on that date, and for the balance of the year, DLA recommenced its earlier tin swap program with the ferroalloy upgraders and also continued its cash sales to industrial users. The direct sales were held each day, with orders for lots of 5 tons or more being accepted daily between 1:30 p.m. and 3:30 p.m. at the price set by the DLA for that day. Pickup points for the stockpile tin were Point Pleasant, WV; Curtis Bay, MD; Hammond, IN; and Stockton, CA. The DLA had authority from Congress to dispose of 12,000 tons in fiscal 1991. At yearend 1991, the NDS inventory was 162,994 tons of tin and the stockpile goal was 42,674 tons.

On February 7, a bill (S. 391) was reintroduced calling for either a ban or reduction in the use of lead in certain products. On August 1, the bill was reported out to the Senate by the subcommittee on toxic substances. No further action was taken on the bill during 1991. Certain features of the bill calling for drastic lowering of lead content could be of special importance for tin because tin is often a coalloy of lead.

Strategic Considerations

Tin's strategic importance is indicated by its major position in the NDS. Tin is used in such defense-related products as solder for printed circuit boards used in aircraft and night-vision weaponry, and brass or bronze fittings and gears for naval needs. Tin in the NDS is stored in warehouses around the country, often

close to plants that would use the tin during wartime.

It is considered unlikely that domestic tin deposits will yield significant amounts of tin in the next 10 years, so the Nation's strategic needs must be met by imports, the NDS, and recycling.

Issues

Throughout the year major tin-producing countries and some tin traders voiced their displeasure with the increased pace of NDS tin disposals and the prospect of an even faster pace in future years. They argued that the disposals made in these higher annual quantities disrupted the tin market and depressed the price of tin.

In December, the U.S. Government announced that unwrought and alloyed forms of tin from China were being targeted, along with a host of other items, for possible penalty duties of up to 100% starting in 1992. The U.S. Trade Representative's office was taking the action in response to allegedly insufficient protection of U.S. intellectual property rights by the Government of China. Tin was one of only three metal categories listed as possible tariff targets; the rest of the items, numbering in the hundreds, were primarily textiles.

Production

The Cache Creek Mine, in the Toftoy District near Manley Hot Springs, AK, was the only mine in the United States to produce significant amounts of tin concentrates. The tin was recovered as a byproduct of gold mining. The mine, owned by Shoreham Resources, Inc., Houston, TX, was in its second year of production. The tin output from the mine amounted to only a small fraction of domestic tin requirements.

Early in the year, Alco-Met Corp., Boston, MA, started production of high-grade tin at its Boston plant. The firm intended to fill part of the gap left by the closure of the Capper Pass tin smelter in the United Kingdom. The plant's initial capacity is 100 tons annually of 99.9999% pure tin. Such purities are

avored for certain electronic applications.

The United States was believed to be the world's largest producer of secondary tin. Tin metal recovered from new tinplate scrap and from used tin cans was the only type of secondary tin available in the marketplace as free tin; other secondary tin was available in scrap materials as an alloying ingredient. Secondary tin from recycled fabricated parts was used in many kinds of products and was a major source of material for the solder and the brass and bronze industries. The Steel Can Recycling Institute (SCRI) in Pittsburgh, PA, funded by five domestic tinplate producers, sought to advance the collection, preparation, and transportation of can scrap. SCRI expanded its program of having representatives in various regions of the United States work with municipalities, scrap dealers, and detinners to promote the recycling of tin cans. Until 1989, generally all detinning operations treated only new (factory-generated) tinplate scrap. This usually came from steel plant tin mills or canmaking plants. Little or no old scrap, such as that from used (post consumer) tin cans, was detinned. This was partly due to the availability of relatively inexpensive and nearby landfills, which in earlier years could readily accept municipal trash; but mostly it was due to technical difficulty in processing the cans. These used cans typically have enamel coatings, outside paper wrappers, remnants of food particles, and are often crushed, making it difficult to treat them effectively with chemical detinning solutions on a high-volume basis. However, in recent years, new scrap preparation procedures were developed, especially a new shredding method, that permitted detinning of used tin cans. Also, municipalities, by the late 1980's, faced increased costs for disposing of trash in landfills and the dwindling of landfill sites. These developments began to set the stage by 1990 for large-scale detinning of used tin cans. The domestic detinning industry responded with the construction of several new plants.

In 1990, Proler International Corp. started up the world's largest detinning facility in Houston, TX. This new plant was capable of recycling 163,000 metric tons of tinplated steel cans and clippings annually, the equivalent of 2.5 billion tin cans. This operation involved the shredding of feedstock followed by continuous detinning in a series of rotating cylinders. The separated products were sold to various foundries and steelmakers. Plans were announced for the establishment of a new \$260 million steel minimill, a joint venture of Proler International Corp., Birmingham Steel Corp., and Danielli & C. Officine Meccaniche S.p.A. (Italy). An important feature of the new operation was an ensured supply of detinned can scrap generated by Proler's new Houston detinning plant. The new minimill was to be constructed on the site of the USX Corp.'s former Baytown, TX, steelworks. Plans were scuttled when Birmingham Steel withdrew from the deal. Then in 1991, Proler closed its new continuous detinning plant, reportedly because it had strong competition from steel mills buying tinplate scrap directly from tin mills, canmakers, and municipalities and charging this scrap (with the tin still on it) directly into their furnaces on a diluted basis.

During 1991, steelmakers, who depended on significant amounts of used tin cans to meet the scrap steel needs of their furnaces, moved up the learning curve and found they could accept higher levels of tin in their scrap charge than they believed several years earlier.

AMG Resources Corp. continued operating its new tin can recycling plant in St. Paul, MN. The facility had an electrolytic detinning system with a capacity to process up to 40,000 metric tons of mostly used tin cans annually. (See table 2.)

Consumption and Uses

Primary tin consumption remained about the same as that in the prior year. The major consumption categories of tinplate and solder had slight decreases in

consumption, while chemicals registered a small increase.

Early in the year, USX Corp. announced that by yearend it would permanently close the steel production section of its Fairless Works, north of Philadelphia, PA. The closure would affect about 2,000 of the plant's 3,100 employees and entail the shuttering of the plant's blast furnaces, open-hearth furnaces, a slag mill, and a hot strip mill. The plant's tin mill would continue to operate, with hot band coils being supplied from USX's Mon Valley Works near Pittsburgh, PA. By yearend, the Mon Valley Works was expected to have its new continuous slab caster in operation. The present Fairless Works had no continuous caster, and continuously cast slabs are an important ingredient for top quality, flat-rolled steel products such as tinplate.

Tinplated steel and tin-free steel accounted for 27% of the 130 billion cans shipped domestically; aluminum accounted for 73%. This compared to 1990 figures showing steel accounting for 29% of the 126 billion cans shipped domestically and aluminum accounting for 71%. Aluminum held an overwhelming advantage in the beverage can market, while steel predominated in the food can and the general-line markets.³ (See tables 3, 4, 5, and 6.)

Recycling

The Waupaca Foundry Co., Waupaca, WI, commenced a new pilot program utilizing used tin cans as a charge for its furnaces. Waupaca is the second largest cast iron foundry in the country, pouring about 2,200 metric tons of iron daily in its four plants. Previously, the foundry industry had considered that the tin levels in used tin cans were so high as to possibly have harmful metallurgical effects. However, Waupaca's experience indicated that higher amounts of tin can be tolerated than previously thought. Used tin cans make up as much as 40% of the material charged into the foundry's cupola furnace. The firm also had an electric furnace but the used tin cans had not yet been tried in it. The State of

Wisconsin had in recent years passed a strict recycling law that phases out acceptance of certain materials such as batteries, waste oil, and appliances for landfill. Many expected that in a few years, tin cans will be added to the list of material banned from landfills.

AMG Resources Corp., based in Pittsburgh, PA, announced that its new detinning and tin can recycling facility in St. Paul, MN, operated smoothly in its first full year. On the Mississippi River, the plant had an initial capacity to process 40,000 metric tons per year of used steel food, beverage, paint, and aerosol cans, and other ferrous materials. The plant was built on the basis of a 20-year guaranteed purchase contract to process about 20,000 metric tons annually of magnetically separated ferrous materials from the municipal waste stream. The balance of the plant capacity is filled mainly from curbside collection programs in Minnesota. Some material is also received from The Dakotas, Iowa, and Wisconsin.

USX Corp., a major producer of tinsplate, expanded its metal beverage container recycling operations into three more States in the South. The firm installed Coinbak reverse vending machines at 280 gasoline-convenience stores in Alabama, Florida, and Georgia. These combination service stations and food stores are operated by Marathon Oil Co., a subsidiary of USX, and the rest are Ecol and Starvin' Marvin outlets. The Coinbak reverse vending machines return one penny for each 12-ounce steel or aluminum beverage can. USX began installation of the container recycling devices at Emro stores in 1989 in Indiana and Ohio, and the program was expanded in 1990 to stations in North Carolina and South Carolina. With the newest additions, about 400 Emro stations in 7 States in the Midwest and South now are equipped with reverse vending machines. There are about 1,700 Emro-managed service station and convenience stores spanning 21 States in the Midwest and throughout the Southeast. The used cans are gathered from the machines by Nationwide Recyclers Inc., a division of Crown, Cork & Seal Co., and sold to

U.S. Steel to be remelted in the firm's steelmaking furnaces. Used cans from the newly installed machines in Alabama, Florida, and Georgia were to be shipped to USX's Fairfield Works in Birmingham, AL. Steel melt shops can charge bimetal tin cans (steel bodies and aluminum tops) into their furnaces; the aluminum is useful as a deoxidizing agent in the steelmaking process.

The Steel Can Recycling Institute (SCRI) announced that the 1991 overall recycling rate for steel cans was 34%, compared with a 1990 rate of 25%. This new rate brings the SCRI a step closer to its 1995 goal of a 66% recycling rate, which would match the steel industry's current overall recycling rate. The 1991 steel food can recycling rate was 37%, a dramatic increase over the 1990 rate of 26%. The 1991 recycling rate for steel beverage cans (often called bimetal cans) was 46%. The 1991 recycling rate for general-line cans was 12%.

In 1991, the SCRI began the development of a data base through which information on steel can recycling programs, on a national basis, may be obtained. By late 1992, SCRI expected that this data base would be used in conjunction with a toll-free number, allowing consumers to call to obtain information on programs and collection locations.

Also in 1991, SCRI, through its regional offices, began to encourage and assist communities in adding empty steel paint and aerosol cans to their recycling programs.

Markets and Prices

Marketing of tin metal in the United States was performed mostly through trading firms, which imported the tin from a variety of countries and warehoused it in this country until they sold it to customers. Some tin was also marketed directly in the United States by large foreign producers who maintained sales offices here and sold their tin metal, usually on a 1-year contract basis, only to the largest users. Among these direct-sale operations were Indo-Metal Corp. and Renison Consolidated Goldfields Corp.

Most traders and direct-sale operations were based in the New York, NY, area. The year was one of consolidation after the significant shakeout in the tin trading community. Foreign-owned trading firms seemed to dominate the field.

The price of tin metal, as published in Metals Week, remained in a narrow band all year. The LME remained the primary trading focus for tin. The Kuala Lumpur Commodities Exchange in Malaysia continued as an active tin trading forum. (See table 7.)

Foreign Trade

Bolivia remained the major source of U.S. tin metal imports. China ranked second, followed by Brazil, Indonesia, and Malaysia.

Imports of tin in all forms (ore and concentrate, metal, and waste and scrap) remained free of U.S. duty. (See tables 8, 9, and 10.)

World Review

The Executive Committee of ATPC met in Kuala Lumpur, Malaysia, March 5-8. Five of the seven member countries were represented, with Nigeria and Zaire not represented. As usual, non-ATPC member Brazil sent an observer. The Committee reviewed progress on ATPC's Fifth Supply Rationalization Scheme (SRS), which is intended to cut into surplus world stocks by limiting tin exports of member countries in 1991 as follows: Malaysia, 28,556 tons; Indonesia, 28,376 tons; Thailand, 17,116; Bolivia, 12,611 tons; Australia, 6,937 tons; Zaire, 1,351 tons; and Nigeria, 901 tons, for a total of 95,849 tons.

Capacity.—The data in table 11 represent rated annual production capacity for mines and smelters on December 31, 1991. Rated capacity was defined as the maximum quantity of product that can be produced in a specific period on a normally sustainable, long-term operating rate, based on the physical equipment of the plant and routine operating maintenance. Capacity includes both

operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period with minimum capital expenditure. Estimates of the rated capacities of mines and smelters were based on discussions with officials from private industry, on past and present production rates, and on published capacity data. (See table 11.)

Australia.—The Renison Bell Mine in Tasmania, owned by Renison Consolidated Goldfields Ltd., remained the largest tin mine, accounting for more than 90% of Australia's total mine output. It was the world's largest hard-rock underground tin mine and a relatively low-cost producer with substantial high-grade reserves.

During the year, Renison suffered a lengthy period of inactivity due to labor strife, and when it resumed production, it did so with 30% fewer employees. Most of the firm's mine output was shipped to either the DKS or Malaysia Smelting Co. tin smelters in Malaysia for refining. The Renison material was an important feedstock for both smelters, which reportedly operated at only 50% to 70% capacity during Renison's difficulties.

Greenbushes Ltd. continued to mine tin and tantalum near Perth, in Western Australia. This operation produced about 200 to 300 metric tons of tin-in-concentrate annually in recent years. A major project to develop underground access to the tin-tantalite ore body was completed. Other improvements included the construction of a 300,000-metric-ton-per-year integrated mining and processing operation. With these additions, it was expected that tin output would be increased to about 1,200 metric tons annually, with one-half of that coming from the underground mine.

Broken Hill's Port Kembla steel plant was announced to be the site of a new tin recycling facility. The plant would detain and recycle tin cans and other ferrous scrap. The facility was to be owned by Australian Metal Recovery Ltd. (AMR), a subsidiary of Edward C. Levy Co. (USA). Renison continued direct sales of refined tin to large American consumers

from an affiliate office in Green Cove Springs, FL. (See tables 11, 12, and 13.)

Bolivia.—This was a year of consolidation for the Bolivian tin industry, after several years of rapidly increasing production.

Traditionally, the Huanuni tin mine, in the Department of Oruro, has been the richest underground tin mine in Bolivia. The capacity of the mine is 3,600 metric tons of tin-in-concentrate annually, with the output being delivered to the Vinto metallurgical complex of Corporación Minera de Bolivia (COMIBOL). Huanuni experienced a 1-month strike over pay for its 1,200 workers. Lost output due to the strike was estimated to be 300 tons. Other important operations were the Catavi-Siglo tin mine in the Department of Potosí, leased by COMIBOL to four cooperatives employing 4,500 miners; and the Caracoles tin mine in the Department of Potosí, with reported reserves of 3,900 metric tons.

At midyear, Government mining ministry officials announced that the large Brazilian tin-mining company, Paranapanema, had won the bidding for the tin tailings and dumpings at the Siglo-Catavi Mine. Paranapanema offered to invest \$8 million in Siglo-Catavi, which has an estimated 21 million tons of dumpings. The only other company to bid was Tympten Ltd. (Australia). Siglo had been the world's largest underground tin mine before it was closed in 1986. Several small mining cooperatives currently work the mine.

Following the tender by Bolivia's COMIBOL for the sale of its Bolivar tin-silver-zinc-lead operation, a local concern called COMSUR (in which RTZ Ltd. has a one-third interest) offered to build a 1,000-metric-ton-per-day milling plant, to start in 1993. COMIBOL estimated Bolivar to have 856,000 metric tons of reserves (1.26% tin) and more than 350,000 tons of tailings (0.76% tin). Reportedly, other bids were made by Carnon Consolidated Ltd., Tiwanacu, Consolidated Goldfields Ltd., and the

Metall Mining Group (a Metallgesellschaft A.G. subsidiary).

During the year, reports indicated somewhat of a lessening of the active market in smuggling tin concentrates from Brazil into Bolivia. Still, some tin mined in Brazil shows up on statistical tables as being of Bolivian origin.

Bolivia was, for the second straight year, the major source of tin for the United States.

Brazil.—Brazil lost its position as the world's leading producer of mined tin; it ranked third in 1991. It remained the world's largest tin smelter. Tin mines and smelters were mostly privately owned. Tin was mined from both alluvial and lode deposits. Brazilian mines were generally considered the lowest cost to operate in the world. Brazil was not a member of ATPC, but generally agreed to cooperate with the spirit of its guidelines and restrict its tin exports.

The Paranapanema Group was the largest private tin producer in the world, owning and operating six tin mines. The mines were Capipore in the State of Amapa, Massangana (also known as C-75, Ariqueemes, and Serrinha) in the State of Rondônia, São Francisco in the State of Mato Grosso, São Raimundo in the State of Pará, and Iarape Preto and Pitinga, both in the State of Amazonas.

Pitinga, the country's largest tin mine, used four Elliot bucket wheel dredges and mined to a depth of 6 to 8 meters. The mine site employed nine floating wash plants and seven gravel-pump plants. The dredging capacity was about 13 million cubic meters annually. Management was in the process of developing mining of a soft weathered tin ore, separate from the alluvium, and reportedly was considering constructing a tin smelter. Total investment at Pitinga was about \$115 million.

Paranapanema announced the creation of a new subsidiary, Paranapanema USA Inc. The new unit was to be based in Providence, RI, and was to serve as a direct sales office in the United States for the firm's refined tin, thereby bypassing the traditional traders. This new

arrangement replaced an agreement whereby Cookson America Inc. acted as North American sales agent for Paranapanema.

The São Francisco Mine in Mato Grosso State was sold at midyear by the Paranapanema Group to the garimpeiros cooperative, Coopegro, for a reported \$1 million. Up to 4,000 garimpeiros were expected to eventually work at the mine site, producing gold and tin concentrates. In 1991, the mine produced about 200 metric tons of tin-in-concentrates.

At midyear, the Government closed tin-mining operations by independent miners at the Bom Futuro Mine near Ariquemes, in Rondônia State. The action was prompted by charges that independent tin miners were involved in the drug trade and by increased concern over environmental damage caused by uncontrolled mining in the area. The Government stated that any future operation of the mine would have to be by an organized entity (either a mining company or a garimpeiros cooperative) to ensure the needed investment of several millions of dollars to satisfy environmental requirements. At yearend, the Infrastructure Ministry was finalizing a decree that would allow Empresa Brasileira de Estanho SA (Ebesa), a consortium of seven companies headed by Paranapanema, to reopen and exploit the Bom Futuro Mine. Although mining at the site was prohibited, reportedly moderate amounts of tin-in-concentrate were being smuggled out. At its peak in 1989, about 20,000 garimpeiros worked at Bom Futuro producing 30,000 metric tons of tin-in-concentrates annually. The Bom Futuro closure was the largest factor in Brazil's large decline in tin mine production in 1991.

Reports indicated that within a year of its startup, Reynolds Metals Corp.'s aluminum can plant in Brazil captured virtually the entire beer and beverage can market there. Among the reasons cited were that an aluminum can is only one-third the weight of a tin can, even though the aluminum can is three times the cost. Brazil's tinplate producers believed they could regain market share once they adopted two-piece-can technology.

Burma.—Mining Corp. Two, based in Rangoon, was responsible for the country's entire production of tin, as well as antimony, tungsten, and other metals. The organization totaled about 1,000 persons who operated various underground, opencast, gravel-pump, and dredge tin operations, as well as a tin concentrator at Tavoy. The country's tin ore was smelted at the Syriam smelter, with a capacity of 1,000 metric tons annually.

Burundi.—Tin has been mined here since the 1930's, across the northern part of the country, where small pits are worked by local artisans. The deposits of cassiterite are alluvial although vein lodes are known to exist. Tungsten and occasionally columbium-tantalum minerals are often associated with the tin minerals. Production is typically reported as containing 60% to 70% tin oxide, which is sold to ore buyers in Bujumbura who accumulate it and ship it to smelters.

Canada.—Rio Algom Ltd. announced it would close its East Kemptville, Nova Scotia, tin mine in early 1992. Discovered as a tin property in 1979, the mine started production in 1985 and had a series of owners. The mine's shutdown had been anticipated by industry sources for the past year. Rio had provisions of \$20 million to cover closing costs. Rio is 53% owned by RTZ Ltd., and the demise of this mine represented the end of RTZ's involvement in tin mining, since in 1991 RTZ's other tin holdings (all based in the United Kingdom) ceased operations.

The Mount Pleasant tin-tungsten-molybdenum property in New Brunswick was purchased by Novagold Resources Ltd. from Billiton Metals Canada Ltd. and Lac Minerals Ltd. for \$10 million. Mount Pleasant began operations as a producer of molybdenum and tungsten in 1983 and closed in 1985 due to depressed prices. During 1991, Babcock Contractors Co. undertook a feasibility study, and by 1992, a decision on whether to restart production, this time as a tin-base mine, was to be made. Reportedly, minable underground

reserves total 5.1 million tons grading 0.70% tin; in addition, drill-inferred near-surface reserves total 5 to 10 million tons grading 0.30% tin.

China.—Yunnan Tin Corp., a subsidiary of China National Nonferrous Metals Industry Corp. (CNNC), Gejiu City, Yunnan Province, was the largest tin producer. It operated 5 underground mines, 7 open pit mines, 10 mineral dressing plants, and 1 smelter, giving it an annual mine production capacity of 7.5 million tons of tin ore, while the smelter capacity was 20,000 tons of refined tin yearly. Both surface alluvial deposits and underground lode deposits were worked. After 100 years of exploitation, the high-grade alluvial deposits were virtually depleted. In 1990, low-grade alluvial tin ores of fine particle size, tailings, and underground lodes were the main sources.

Yunnan used reverberatory smelting of tin concentrate, pyrometallurgical refining of tin metal, electrolytic separation of tin-lead alloy, and tin slag fuming. It used a continuous electrothermal crystallizer for removal of lead and bismuth, using the different melting points and specific gravities of tin and lead-tin alloy; direct recovery of tin was increased by 6% over former methods and staffing levels were reduced by 50%. Several other tin smelters around the world utilized Yunnan crystallizer technology.

The Dachang Mining Administration (a subsidiary of CNNC) in Dachang, Nandan Xian, Guangxi Zhuangzu Zizhiqu, continued its expansion program that was expected to eventually make it China's largest tin mine.

Germany, Federal Republic of.—The Government enacted tough new laws aimed at reducing the volume of waste materials. The new rules call for reduced use of materials for packaging and regulations for packaging specifications. The laws encourage private industry to implement these, but also set deadlines when the Government will determine whether its targets have been reached. By 1993, the law mandates a 60% recycling rate for glass; 40% for tinplate;

30% for aluminum, paper, cardboard, and plastics; and 20% for mixed materials. By 1995, the recovery rates must be 90% for tinplate.

In the former East Germany, high operating costs and environmental problems caused the closure of the only tin smelter, in Saxony. The firm was previously known as VEB Altenburg, before changing to Saxonea A.G. in 1990 when Germany was reunited. Depressed tin prices and low-grade feedstock also contributed to the plant's demise. Tin concentrates were sourced locally but contained just 3% to 5% tin and high amounts of sulfur. Output of sulfur dioxide during the smelting process was too high to meet German emission standards, and pollution-abatement equipment could not be afforded. The plant employed 840 workers. All tin produced was consumed domestically.

The VIAG Group announced the purchase of Continental Can Europe for more than \$1 billion from the Peter Kiewit Co. of Omaha, NE. The purchase made VIAG Europe's third largest canmaker after Pechiney and CMB Packaging.

Indonesia.—Tin mining was performed mostly offshore, usually by means of large-scale dredging. P.T. Tambang Timah (P.T. Timah), the Government-owned mining firm, ranked as one of the world's largest tin-mining organizations and accounted for about 80% of Indonesia's tin output. Formerly, P.T. Timah's three primary tin production complexes were on the islands of Bangka, Belitung, and Singkep, with the Bangka Island facilities accounting for 70% of P.T. Timah's tin production.

During the year, P.T. Timah embarked on a stringent restructuring program designed to bring its costs in line with the depressed tin price. It closed its operations on Belitung and Singkep Islands, consolidated its tin production on Bangka Island, and moved its headquarters from Jakarta to Bangka Island.

P.T. Timah sold its tin output in the United States exclusively through its

subsidiary, Indo-Metal Corp., in New York, NY.

Italy.—The city government of Genoa announced plans to move steel production at the Cornigliano Works to other locations. The steel plant is part of Italy's large Government-owned Italsider. Under the plan, known as Project Utopia, Italsider's tin mill would be relocated to the Cantieri Metallurgici Italiani Works at Naples. Italsider's tin mill at Genoa has an annual capacity of 435,000 tons of tinplate.

Japan.—The Ministry of International Trade and Industry (MITI) announced a new Action Program on recycling. The program raises the recycling rate target for both aluminum and steel cans to 60% by 1994. In 1990, the recycling rates were 43% for aluminum and 45% for steel cans. One feature of the program would be that aluminum and steel cans each bear distinctive markings for easy separation. The aluminum cans would have a triangle mark and the steel cans a circle mark. Since the program covers imported cans also, MITI is trying to obtain approval from member countries of the General Agreement on Tariffs and Trade (GATT).

Korea, Republic of.—The Korea Zinc Co. announced it would cease producing refined tin this year. Closure of its 1,800-ton-per-year smelter was attributed to the rising cost of feedstock and weak tin prices. The smelter produced 850 tons of tin in 1990. In recent years, the smelter had been modified to treat dirty, low-grade concentrates supplied from China. The other Korean tin producer, Lucky Metal Co., has a small smelter at Changhang and reportedly was planning to cut its production by 30% to 40% because of the rising cost of feedstock. Import tariffs on tin, which in 1991 amounted to 10% of the value, are scheduled to be reduced to 7% in 1992 and to 5% in 1993. This was expected to render local tin production uncompetitive.

Pohang Iron & Steel Co. (POSCO) announced the opening of a new plant to

produce 120,000 tons of tinplate annually. Pohang is one of the world's largest tinplate producers.

Malaysia.—Malaysia Mining Corp. (MMC) remained the largest tin producer in the country, but continued low tin prices depressed its operations. MMC had been mostly dependent on its tin operations until recent years, but for the second year continued the expansion of its exploration program in other base metals and gold in several countries, including Brazil, Burma, China, Laos, and Vietnam. MMC was already active in engineering and construction and announced plans to enter manufacturing. Diversification plans included one joint venture to set up a plant to make video tapes and another to build a plant to make car components. In the minerals field, MMC planned to assess the feasibility of mining sulfide and oxide ores at the Mengapur base metals project, a search for alluvial diamonds in Indonesia, and gold exploration in Brazil. In 1991, only 16 of MMC's tin dredges out of a total of 38 were operating.

MMC announced the sale of a 12% interest in Austral Amalgamated Tin to a local firm called Global Stature. Austral operated two dredges, and its production averaged 450 tons of tin-in-concentrate annually.

Construction was completed on a second tinplating line at the tin mill operated by Perstima. The new line doubled the plant's capacity to 180,000 tons annually. Perstima was partially owned by Kawasaki Steel Co. (Japan), and the technology for the line was supplied by Kawasaki. Perstima announced that the new line was designed to permit later installations that could produce tin-free steel as well as tinplate. Tinplate demand in Malaysia was about 130,000 tons annually.

The main producing State, Perak, announced cessation of renewal of leases for idled tin mines. The land would instead be redeveloped and turned over to industrial and agricultural uses. Many gravel pump mines in Perak closed down in 1991. Gravel-pump mines accounted for 40% of Malaysia's tin mine

production until closures this year. About 50 gravel pumps were active in Perak, compared with more than 20 in 1985.

Many of the Chinese gravel-pump miners in Perak have left the industry, and it is believed that even if the tin price were to climb to the \$4 per pound level, very few would reenter mining. The All-Malaya Chinese Miners' Association announced that as many as 30% of the gravel pump mines currently operating could close down by 1992 owing to continuing low tin prices. The association asked the Government for increased subsidies, particularly for energy, which accounts for 40% of production costs.

The large Derak Keramat Smelter (DKS) announced that it had started to produce 99.99% and 99.999% tin at a new electrorefining plant. DKS planned to reach its targeted production of 10 to 20 tons monthly by yearend.

The other large tin smelter, the Malaysian Smelting Corp. (MSC), also announced plans to produce a premium high-grade electrolytic tin with a minimum 99.99% purity. Production capacity was 100 tons annually. MSC operates a 60,000-ton annual capacity tin smelter at Butterworth, Penang, and the newly constructed unit to produce 99.99% tin would be an adjunct to that. A major factor in both DKS' and MCS' decision to enter this specialized field was the decision by the Capper Pass tin smelter in the United Kingdom to close this year; Capper Pass had produced about 99.99% tin for years. MSC officials stated that the high-purity tin would be marketed in 12.5 kilogram bars, rather than the normal 29.5-kilogram bars used for the Straits and MSC brands.

The Government eliminated the export duty on several commodities, including tin, on January 1, 1991. The export duty on tin had averaged 11%.

Mexico.—Tin mining was focused in the north-central region in the three adjoining States of Durango, Zacatecas, and San Luis Potosí. The country's main

tin mine, the El Perro Mine, was owned by Cia. Mineral Pizzuto.

Estañó Electro S.A. de C.V. operated a tin smelter at Tlalnepantla, near Mexico City. Fundidora de Estañó S.A. operated a tin smelter at San Luis Potosí. Metales Potosí S.A. had a smelter in San Luis Potosí as did Minera de Rio S.A. Most of the tin concentrates processed by the four smelters was imported, primarily from Canada and China.

Netherlands.—Billiton Ltd. announced plans to cease production of primary tin and secondary lead at its smelter in Arnhem. Billiton's decision to close the plant, which has a capacity of 4,000 tons of tin and 10,000 tons of secondary lead annually had been somewhat expected. Some of the factors in the firm's decision were: current low tin and lead prices, the need to make a substantial investment to modernize the lead side of the facility to meet environmental regulations, a persistent oversupply of tin ingot inventory worldwide, and a worldwide excess of tin smelter capacity relative to tin mine capacity. Another possible factor may have been recurring problems with the new Siromelt technology installed about 2 years ago on the tin side of the plant and which reportedly kept it running far below capacity. Production of tin tetrachloride, tin anodes and granules, and tin foil were to continue. The shutdown was to take place gradually during the first half of 1992.

Nigeria.—Tin was mined from alluvial deposits by two major companies: Consolidated Tin Mines Ltd. and Nigerian Tin and Allied Minerals Products Ltd. Cassiterite was mined in association with columbite, tantalite, and tungsten minerals. All tin concentrates were shipped to the sole tin smelter, the Government-owned Makeri Smelting Co., in Jos, Plateau State. Makeri continued to operate well-below capacity.

Substantial amounts of tin concentrates were reportedly smuggled out of the country. The Government officially permitted only refined tin to be exported, on which a 15% royalty per ton was charged. These exports were then

marketed by London-based Decacia International Ltd.

Portugal.—Somincor S.A. announced that the medium-grade concentrate circuit at its copper-tin mine at Neves Corvo was now in full production. Somincor signed a contract with the DKS smelter in Malaysia to smelt some of its output; it already had existing contracts with Billiton (The Netherlands), Malaysia Smelting Co., and Zamora (Spain). In 1991, Somincor expected to increase its mine output of low-grade (25% tin) and medium-grade (45% tin) concentrates. The firm looked ahead to 1992 when full-year production from its medium-grade concentrate circuit would be effective.

Singapore.—A severe shortage of high-grade tin concentrates forced the closure of the Kimetal tin smelter. The smelter had a nameplate capacity of 11,000 tons of tin annually, but this was never fully realized. Two electric arc furnaces operated in conjunction with two tin crystallizers. The crystallizers had refining rates of 3.5 and 8 tons per day. Both were designed and built in-house and were expected to be sought after once the plant was sold. Crystallizers are simple yet efficient mechanisms to remove metallic impurities from low-grade, dirty concentrates; most Chinese tin concentrates are both low-grade and dirty. Although Kimetal treated these grades, the plant operated more effectively on higher grades that did not damage sections that clogged up with impurities. Kimetal sourced high-grade tin concentrates principally from Africa, Australia, and China. All three sources had supply difficulties and could no longer effectively feed Kimetal's demand. Kimetal began operations in 1978 and was believed to have processed large amounts of nonquota tin concentrates from surrounding countries, including China, Indonesia, Malaysia, and Thailand. Kimetal faced strong competition from the two large Malaysian smelters, Datuk Keramat Smelting Co. and Malaysian Smelting Co., both of which had cost advantages owing to economies of scale.

Spain.—Altos Hornos de Vizcaya (AHV), one of Spain's two leading steel producers, reached an agreement with AMG Resources Ltd. (United Kingdom) to cooperate on tinplate recycling in Spain. AMG would be acting in an advisory capacity to Spain's municipal authorities to help introduce various used tin can collection schemes that have proved effective in the United Kingdom. Also, AMG would supply technology for the separation and processing of tinplate scrap from domestic waste. AHV is Spain's largest tinplate producer, with a current output of about 250,000 tons annually. Initially, it was planned to process all collected tinplated materials at an existing detinning plant in Rioja; as the program expanded, likely new plant sites were Madrid, Bilbao, and Barcelona.

Thailand.—Once the country's largest revenue producer among metals, tin continued to decline in relative importance. Other industries such as tourism, real estate, rubber, palm oil, and shrimp farming drew investment away from tin mining in the south where most tin reserves were located.

In addition, the rising tide of environmentalism affected mining in tourist areas and closed off Government forest areas from mining. In 1991, only 130 tin mines were operating, less than one-half the total before the 1985 "tin crisis." All 42 tin mines on the tourist island of Phuket were closed.

Toward yearend, Thai Pioneer Enterprise Co. announced plans to reopen its Pathum Thani tin smelter in early 1992. The plant had been closed since 1981. The firm said that the reopening was now possible since it had agreed with its creditors to restructure its \$16 million debt. The smelter's capacity is 5,000 tons of tin metal annually, and it was expected to process both domestic and imported tin concentrates.

Siam Tin Plate Co., a joint venture between Japanese and Thai firms, was launched. Initially, the steel black plate coils would be supplied by Nippon Steel Corp. (Japan). The plant would have a

capacity of 200,000 tons of tinplate annually.

United Kingdom.—The country's dwindling tin-mining activity continued to be focused in the historic Cornwall mining district. Mining costs here were reportedly among the highest in the world.

Carnon Holdings Ltd. announced the shutdown of its two mining operations and the termination of its entire 415-member work force. Carnon attributed the closure to a recent decision by the Government's Department of Trade and Industry to stop providing funds under an existing \$48 million loan agreement. The Government had originally agreed to the loan to assist in a 1988 employee purchase of Carnon in the aftermath of the collapse of the International Tin Council and its price support mechanism. In past years, the two Carnon tin mines, South Crofty and Wheal Jane, had been among the world's highest operating cost tin mines. But since 1986, Carnon had been able to reduce the average cost of producing 1 ton of tin-in-concentrate at these two mines by 50%, to about \$7,680 per ton. At the more efficient South Crofty operation, production costs had been lowered to about \$6,720 per ton and were still falling. Carnon intended to immediately flood the Wheal Jane Mine, making it unlikely the mine will ever be reopened. An application was entered to transform part of the site into a recreational complex. Mining at South Crofty also ceased, although Carnon maintained facilities there in hopes of attracting outside investors to reactivate the mine.

Tin mine operator Geevor Ltd. merged with the European Mining Finance Corp. Ltd., a mining fund company listed on the Luxembourg Stock Exchange. The Geevor tin mine near Pedeen, in the Cornwall district, has been under care and maintenance since 1990.

U.S.S.R.—Tin mining was conducted mostly in the far eastern regions of the country. The Khingansk tin mine in eastern Siberia proceeded with plans to expand its tin concentrate output to 3,000

tons annually by 1995 from 1,200 tons currently. Recently discovered deep tin ore bodies extended the mine's life.

A fire reportedly stopped production indefinitely in the tin mill of the Karanganda Steel Works in Kazakhstan. The blaze began when an oil line on the temper mill ruptured, completely destroying three electrolytic tinplating lines. Almost one-half of the tinplate used in the Soviet canning industry is produced in this tin mill, and there were fears that this outage would aggravate already existing food shortages. The U.S.S.R. reportedly sought emergency tinplate imports from several Western countries.

Zimbabwe.—The Government announced plans to privatize the country's largest tin mine, the Kamativi Mine. Legislation was expected to be passed that would enable the mine to be sold by the nationalized Zimbabwe Mining Development Corp. (ZMDC) to private investors or other mining corporations. Kamativi has been a high-cost producer and has had continuing financial problems since the 1985 international "tin crisis" and subsequent low market prices. ZMDC took over Kamativi in 1987 from the Industrial Development Corp. At midyear, ZMDC announced the layoff of 900 people out of a total work force of 1,362. The aim was to reduce costs. Underground mining was to be gradually phased out. Future production would be from the open pit section of the mine.

Current Research

In the United Kingdom, AEA Industrial Technology Ltd. announced development of a new type of catalyst for automobile catalytic converters that uses a mixture of tin oxide and various other oxides such as those of copper, chromium, and aluminum. It would compete with the widely used platinum-rhodium combination. It is produced using a process known as sol-gel, which involves the mixing of the catalyst with a solvent; the mixture is then applied to the substrate in the form of a rubbery gel by spinning or dipping. The solvent is later

driven off, leaving a solid catalyst. The main advantage of the sol-gel technique is that it gives control over the particle size during the preparation process, providing a more porous catalyst and thus a large surface area for the chemical conversion reactions to take place on. The tin oxide catalyst would be cheaper to produce than precious-metal materials, but offers no advantage in lower operating temperatures. Legislation in Europe, the world's largest car market, will require catalytic converters on all cars by January 1993.

In the United Kingdom, Vertifoam International Ltd. announced development of a new approach to polyurethane foam production. For years, both organo-tin and inorganic tin compounds have found substantial use as important industrial catalysts, with one of those applications being the production of polyurethane polymers. The worldwide consumption of these compounds in the production of polyurethanes is estimated to be about 3,000 tons annually. Polyurethanes form a wide range of materials, including flexible and rigid foams, solid elastomers, hard coatings, and adhesives. Flexible foam is usually produced using either slab or molding techniques. Vertifoam's new procedure has the foam conveyed vertically instead of horizontally. Among the claimed advantages are a thinner outer skin with lower trim losses, a more uniform foam density, greater efficiency of chemical usage, and much lower emission of hazardous vapors.

Also in the United Kingdom, the International Tin Research Institute announced development of a stable, noncyanide electrolyte for depositing a wide range of tin-zinc alloy coatings. Tin-zinc coatings have excellent corrosion resistance and are considered potential alternatives to cadmium in many applications. Until now, however, they could be deposited only from a cyanide-base bath, which is difficult to operate on a production scale. The new, nontoxic solution is reported to have good throwing power, produces dense and nonporous deposits, and is suitable for rack, barrel, and brush plating.

OUTLOOK

Supply

The supply of tin for the United States is expected to continue to originate primarily in Asia and South America and to enter the country in the form of refined tin metal. While some promising tin deposits exist in the United States, primarily in Alaska, these are not expected to become major production sites during the next 10 years, especially if tin prices remain low. The NDS is expected to continue to be a modest source of tin supply because the stockpile goal is substantially lower than the current inventory. Increased scrap recovery, both through alloy recycling and detinning, is a possibility, and that could help ameliorate the Nation's dependence on imported tin.

Worldwide, the oversupply of tin that has existed since the early 1980's appears likely to persist for at least a few more years. The advent of several new tin mines in countries like Brazil and China appears likely.

Demand

The demand for primary tin in the United States is forecast to be static in the next few years. There appears to be some chance that tinplate may regain a small portion of the beverage can market in the next few years, especially if tin can recycling increases and if tinplate can maintain or widen its cost advantage over aluminum.

Among the major metals, tin has had a relatively good record with regard to toxicity and the environment, and this aspect may help tin gain market share at the expense of more troublesome metals. In particular, if regulations continue to negatively impact the use of lead in applications such as solder, the demand for tin as the complimentary alloy component may increase.

Worldwide, new tinplating lines are being built in developing countries, and tinplate traditionally is a stronger competitor than aluminum in canmaking

markets outside of the United States. Therefore, the outlook for overall tin demand is for modest growth of about 1% annually in the next few years.

Numerous research efforts in recent years have resulted in new applications for tin that could result in small-scale increases in tin consumption in future years, but there have recently been no major new applications.

¹Data for 1987 derived in part from the Monthly Statistical Bulletin of the International Tin Council, London and, for 1988-90, UNCTAD. Wherever possible, total smelter output has been separated into primary (from ores and concentrates) and secondary (tin metal recovered from old scrap). This table reflects metal production at the first measurable stage of metal output. Table includes data available through June 30, 1992.

[‡]Reported figure.

TITANIUM

By Joseph Gambogi

Mr. Gambogi, a physical scientist with 9 years of Government and industry experience, has been a commodity specialist since 1988. Domestic survey data were prepared by Giovanni C. Jacarepaqua, statistical assistant; international data tables were prepared by William L. Zajac, Chief, Section of International Data.

Titanium (Ti) is a lightweight metal well known for corrosion resistance and its high strength-to-weight ratio. Titanium comprises about 0.62% of the Earth's crust and occurs primarily in the minerals anatase, brookite, ilmenite, leucoxene, perovskite, rutile, and sphene. Although titanium is best known for its use as a metal alloy, titanium is primarily used in the form of titanium dioxide (TiO_2) and is used widely as a white pigment in paints, paper, and plastics. Other minor uses of titanium minerals include ceramics, chemicals, welding rod coatings, heavy aggregate, and steel furnace flux.

Global demand for TiO_2 pigments was estimated to be 2.85 million metric tons while capacity stood at about 3.59 million tons. Capacity expansions continued to move forward, including a 90,000-ton-per-year facility in De Lisle, MS, and an 80,000-ton-per-year facility in Lake Charles, LA. However, environmental regulations in Europe and North America brought pressure to close older pigment plants.

A global oversupply of titanium concentrates caused several mining expansion projects to be delayed. The surplus of supply also caused Australian producers of titanium concentrates to curtail production levels.

A slow global economy and reductions in aerospace markets had a significant negative impact upon demand in the titanium metal industry. World sponge capacity was estimated to be 117,000 tons. While one U.S. producer permanently closed its 10,900-ton-per-

year sponge facility, another U.S. producer proceeded with plans for a 10,000-ton-per-year expansion.

Despite a sluggish economic environment, domestic production and consumption of titanium pigments increased slightly in 1991. Contrary to pigment consumption, consumption of titanium concentrates (ilmenite, slag, rutile, and synthetic rutile) decreased slightly. The United States relied on imports for about three-fourths of its TiO_2 consumption in concentrates. Cuts in defense spending and commercial aerospace combined with inventory reductions caused a significant decrease in domestic production and shipments of sponge metal and mill products. Shipments of titanium metal castings increased significantly.

DOMESTIC DATA COVERAGE

Consumption data for titanium raw materials are developed by the U.S. Bureau of Mines from one voluntary survey of domestic operations. Of the 29 operations canvassed, 28 responded, representing 99.9% of the data in tables 6 and 11. Data for one nonrespondent was estimated based on prior-year consumption levels.

BACKGROUND

Definitions, Grades, and Specifications

Ilmenite is the most abundant titanium mineral, with the chemical formula FeTiO_3 and theoretical composition of

52.7% TiO_2 and 47.3% FeO . However, the term "ilmenite" is also used to include material that has been oxidized and leached during weathering, containing up to 70% TiO_2 , about 25% to 30% iron oxides, and about 5% of oxides of other elements. When the alteration is extreme, the residual material is essentially amorphous to finely crystalline TiO_2 and is called leucoxene.

Rutile is essentially crystalline TiO_2 , and commercial concentrates usually contain about 95% TiO_2 . Synthetic rutile or rutile substitutes are derived from ilmenite by processes involving oxidation and reduction treatments followed by leaching of iron. Synthetic rutile concentrates approach rutile in chemical composition but, being residual leached grains, are porous and composed of very fine crystallites, while natural rutile grains are usually single crystals.

Anatase also is crystalline TiO_2 , but has a different crystal structure than rutile. Anatase is not yet available commercially, but large deposits of anatase-bearing ore in Brazil are being developed.

Commercially available titaniferous slags made by electric furnace smelting of ilmenite with carbon contain 70% to 85% TiO_2 . Slags being produced at the end of 1991 were 80% TiO_2 slag from Sorel, Quebec; 85% TiO_2 slag from Richards Bay, Republic of South Africa; and 75% TiO_2 slag from Tyssedahl, Norway.

Titanium tetrachloride (TiCl_4), the intermediate compound from which titanium metal and chloride-process TiO_2 are manufactured, is a colorless to pale

yellow liquid at room temperature, with a boiling point of 136° C.

Titanium sponge metal is the primary metal form obtained by vapor-phase reduction of $TiCl_4$ with magnesium or sodium metal. It is called sponge because of its appearance and high porosity. Titanium ingot for forging into billet and mill products is obtained by melting sponge in a vacuum-arc furnace, with or without scrap titanium or alloying additions. Specifications for titanium sponge for the National Defense Stockpile (NDS) are given in table 1.

Titanium dioxide pigment is characterized by its purity, refractive index, particle size, and surface properties. The particle size is critical and must be closely controlled within the range of about 0.2 to 0.4 micrometer to develop optimum pigment properties. The superiority of TiO_2 as a white pigment is due mainly to its high refractive index and resulting light-scattering ability, which impart excellent hiding power and brightness. Titanium dioxide pigments are produced as two major types: rutile and anatase. Rutile-type pigment, less reactive with paint vehicles in sunlight than is the anatase type, is preferred for use in outdoor paints. Anatase pigment has a bluer tone than the rutile type, is somewhat softer, and is used mainly in indoor paints and in paper manufacturing.

Specifications for natural rutile for the NDS are shown in table 2. There are no rigid specifications for raw materials to be used as feed for making $TiCl_4$ for metals or pigment manufacture, or for ilmenite or slag to be used in the sulfate pigment process. However, certain impurities such as chromium, columbium, manganese, phosphorus, and vanadium can seriously impair pigment properties, so these impurities are an important consideration in the selection of concentrates for pigment production. Concentrates to be used for making $TiCl_4$ should be low in calcium and magnesium, which form high-boiling-point chlorides that cause trouble in fluid-bed chlorinators. Chemical compositions of typical commercial titanium concentrates

are shown in table 3. (See tables 2 and 3.)

Industry Structure

The titanium industry is moderately integrated from raw materials to semifinished products. The world's largest TiO_2 producer, E. I. du Pont de Nemours & Co. Inc. (Du Pont), obtains ilmenite, rutile, and leucoxene from its own mines in Florida and from various suppliers in other countries, mainly Australia. NL Industries Inc. for many years has supplied ilmenite to its European pigment plants from its mine at Tellnes, Norway. A smelting plant at Tyssedahl, Norway, has been processing part of the Tellnes ilmenite to produce titanium slag for the same market. The Tioxide Group PLC, United Kingdom, owns a 40% share of Westralian Sands Ltd. in Australia. Hanson Industries PLC, United Kingdom, owner of SCM Chemicals Inc., has a 49% interest in Renison Goldfields Consolidated Ltd. (RGC), the major producer of titanium minerals in Australia. A joint venture called Tiwest exists between Minproc Holdings Ltd. and Kerr-McGee Chemical Corp. in Western Australia involving the mining and concentrating of ilmenite, processing of the ilmenite to make synthetic rutile, and manufacture of TiO_2 from the synthetic rutile. Nearly all of the remaining TiO_2 pigment manufacturers buy their raw materials from independent producers of titanium concentrates.

Outside of China and the U.S.S.R., sponge metal producers do not own their own titanium mine. Titanium Metals Corp. of America (TIMET) purchases Australian rutile and manufactures $TiCl_4$, the intermediate compound universally used for commercial production of titanium metal. The other two U.S. titanium metal producers purchase $TiCl_4$ from a TiO_2 pigment manufacturer. Titanium mineral raw materials are purchased also for use in welding rod coatings, chemicals, and fiberglass.

The United States accounts for about 26% of the world's sponge production capacity. Titanium dioxide pigment

output in 1991 came from about 60 separate facilities ranging in annual capacity from a few thousand metric tons to almost 300,000 tons. In 1991, the United States accounted for about 40% of the world's TiO_2 pigment capacity. Significant pigment capacity also exists in France, the Federal Republic of Germany, Japan, and the United Kingdom.

The world's four largest TiO_2 pigment producers are: Du Pont, with plants in the United States and in Mexico; Tioxide, with two domestic plants and facilities in Australia, Canada, France, Italy, Spain, and the Republic of South Africa; SCM Chemicals, with plants in Australia, the United Kingdom, and the United States; and Kronos Inc., with producing plants in Belgium, Canada, the Federal Republic of Germany, and Norway.

U.S. companies, mainly Du Pont, SCM, Kronos, and Kerr-McGee, own or control almost one-half of the world productive capacity for TiO_2 pigments. The remaining portion is owned principally by large chemical firms or groups such as Bayer AG of the Federal Republic of Germany, Ishihara Sangyo Kaisha Ltd. (ISK) of Japan, and Kemira Oy of Finland.

Technology

Exploration.—Hard-rock ilmenite deposits, because of their inherent magnetic properties, are readily amenable to the application of aeromagnetic and ground-magnetic geophysical surveys. These deposits generally respond to such surveys by reflecting abnormally positive magnetic intensities, although in some cases negative magnetic anomalies may result. Once such anomalies are mapped, further exploration may take place in the form of detailed geological observations and ultimately drilling to test the anomalies and delineate the associated ilmenite deposit.

If initial diamond drilling indicates an economic deposit, development drilling proceeds on a set grid pattern of about 200 or 300 feet. Intermediate holes are drilled to fill in major gaps in information on geologic structure or ore

continuations. Drill cores are visually logged and split for chemical assay to determine TiO_2 and iron content.

Sand deposits of titanium minerals are mostly near continental margins where erosion of regional granitic and metamorphic rocks containing ilmenite and rutile has led to accumulation of these minerals in coastal plain sediments. Working and reworking of these sediments by ocean waves on beaches and in streams resulted in various degrees of sand sorting and concentration by particle size, density, and resistance to abrasion. Well-sorted sands are much more likely hosts for ilmenite, rutile, and other heavy minerals than are unsorted sands.

Titanium minerals are dark in color, and their concentration in predominantly quartz sands is often readily visible. Initial discovery has therefore often been made through surface observation. In exploration, hand panning of samples has been a very useful exploration tool.

Some titanium mineral ore bodies are detectable by ground or airborne magnetometer surveys or, if monazite or zircon is present, by low-level radiometric surveys.

Drilling to determine the extent of sand deposits in the first phase of development should be done to a depth of at least 50 feet and preferably 100 feet. The type of drill needed will depend on the nature of the ground, including the presence of clay, hard-pan, roots, stumps, and other organic material, as well as the depth of the water table.

Approximate minimum requirements for an economic sand deposit of titanium minerals include reserves of 300,000 to 1 million tons of TiO_2 content in rutile or ilmenite and heavy-mineral content in the ore of 1% to 5%, depending on the mix of ilmenite, rutile, and other valuable minerals.

Mining and Concentration.—For mining sand deposits of titanium minerals, a dredge is usually used. This may be bucket-ladder type but is more likely to be suction type. The dredge floats in its own pond, digging forward and stacking tailings aft. Rough concentration, the separation of heavy

minerals from the lighter quartz-feldspar-mica fraction, is usually accomplished by wet-gravity methods. The Humphreys spiral has been standard for this separation since its introduction about 1940, but pinched-slucice separators of various designs have also been used. In Australia, the Reichert cone concentrator, which operates on the pinched-slucice principle, has been successful for large-tonnage operations. Flotation has also been used to some degree. For separating the minerals from stream-type deposits, jigs are usually chosen because they are the concentrating device least sensitive to extreme grain-size variation.

The final wet-mill concentrate is dried, usually in a rotary kiln, prior to further treatment. The subsequent flowsheet depends on the mineral assemblage to be treated. Ilmenite and rutile are usually removed together by electrostatic separation. The ilmenite-rutile conductor fraction of dried wet-mill concentrate is then subjected to high-intensity magnetic separation, yielding a final ilmenite product. The rutile fraction is further cleaned by screening and additional electrostatic separation. Zircon and monazite products are recovered from the nonconductor fraction of the wet-mill concentrate by a combination of gravity, electrostatic, and high-intensity magnetic separation.

Ilmenite is also mined from two hard-rock deposits, one in Canada and one in Norway. The ore bodies are massive, and open pit mining is practiced.

At Tellnes, Norway, the ore is crushed, ground, and subjected to wet-magnetic separation to recover magnetite. An ilmenite concentrate containing about 44.5% TiO_2 is recovered by flotation of the nonmagnetic portion, as was formerly done at the MacIntyre Development, Tahawus, NY, where ilmenite mining ceased in 1982.

At Allard Lake, Quebec, ore at 32% to 36% TiO_2 is shipped from the mine to the beneficiation plant at Sorel, Quebec; some of the ore is shipped to steel companies as a substitute for fluorspar flux. For upgrading to slag, the ore is

crushed and ground, concentrated by gravity methods, roasted to remove sulfur, mixed with a reducing agent, and smelted in an electric arc furnace. A high-purity pig iron is produced. The titanium is concentrated in the slag, known as Sorelslag, which contains 80% TiO_2 . Since the iron content of the slag is low, its use reduces the quantity of iron sulfate in the liquid effluent of sulfate process pigment plants. Because of its relatively high content of magnesium and calcium, which cause operating problems during chlorination, Sorelslag is not used to make TiCl_4 .

At Richards Bay, Republic of South Africa, both rutile and ilmenite are produced from heavy-mineral sand deposits. The ilmenite, containing about 50% TiO_2 , is relatively low in magnesium and calcium and is smelted with carbon in an electric furnace to produce an 85% TiO_2 slag. Because of its low content of the above impurities, the Richards Bay (RB) slag is acceptable for manufacturing TiCl_4 and is also a feed material for the sulfate pigment process.

Materials made from ilmenite that have a TiO_2 content approaching that of natural rutile are known as synthetic rutile or beneficiated ilmenite. Processes to produce rutile substitutes from ilmenite fall into three general classes: those in which the iron is completely reduced to metal and separated from the reaction mass either physically or chemically, those in which iron is reduced to the ferrous state and chemically leached away from the titanium, and those in which the ilmenite is selectively chlorinated to remove iron and other impurities. The RB slag described in the previous section may also be regarded as a rutile substitute because of its high grade (85% TiO_2) and suitability for the manufacture of TiCl_4 .

Pigment Production.—Titanium dioxide pigment is produced commercially by two methods that require different raw materials. In the sulfate process, ilmenite or titanium slag is reacted with sulfuric acid, a portion of the iron sulfate formed may be crystallized and removed, and titanium hydroxide is precipitated by hydrolysis,

filtered, and calcined. In the chloride process, rutile is converted to $TiCl_4$ by chlorination at 850° to 950° C in the presence of petroleum coke. All U.S. commercial chloride-process plants use fluid-bed chlorinators, although static-bed systems can be used for this purpose.

Titanium tetrachloride so prepared may be used either in making pigment, or with additional purification, for reduction to metal. In making pigment, the $TiCl_4$ is oxidized with air or oxygen at about $1,000^\circ$ C, and the resulting fine-size TiO_2 is calcined at 500° to 600° C to remove residual chlorine and any hydrochloric acid that may have formed in the reaction. Aluminum chloride is added to the $TiCl_4$ to ensure that virtually all of the titanium is oxidized in the rutile crystalline form.

Recoveries of TiO_2 in pigment are approximately 90% and 80% to 85% for chloride process and sulfate process plants, respectively.

Metal Production.—Feed materials needed for metal production are the same as those for chloride-process pigment because formation of $TiCl_4$ is required in both cases. Rutile and rutile substitutes are the only titanium raw materials used for metal production in the market economy countries.

Titanium sponge is produced by reducing $TiCl_4$ with sodium or magnesium under an inert atmosphere at temperatures up to $1,040^\circ$ C. Residual chlorides are removed by vacuum distillation, inert gas sweep, or after cooling and crushing, by leaching in very dilute acid. The sponge is compacted, usually with some scrap and alloying additions, and made into ingot by two or more successive vacuum-arc melting operations.

Recycling.—Scrap titanium generally accounts for 40% to 50% of ingot production. Scrap is generated by producers of ingot and mill products and by consumers of mill products in fabricating finished products or components. It is estimated that up to 75% of titanium ingot metal becomes

scrap during processing to finished parts. However, the proportion of scrap is gradually being lowered because of increased use of castings and other near net-shape technologies.

Clean and well-segregated scrap, processed to remove impurities, is blended with sponge metal and alloying constituents and remelted to ingot. Remelting is mainly by vacuum-arc consumable-electrode processing. Electron-beam and plasma-arc cold-hearth melting is also used, especially for chips and turnings. Cold-hearth melting is very effective in ensuring removal of high-density inclusions, such as tungsten carbide tool particles, which settle out in the hearth area during melting. A substantial quantity of titanium scrap, particularly unprocessed turnings, is consumed directly or in making ferrotitanium for use in steel and other alloys.

Economic Factors

Prices.—The price of rutile pigments and titanium sponge in constant dollars decreased 20% and 14%, respectively, from 1969 through 1972, as shown in table 4. Reflecting a sharp increase in pigment demand, the constant dollar price rose 32% in 1974. The pigment price did not surpass that level until 1989, following 6 consecutive years of record-high demand. An economic downturn in 1990 and 1991, coupled with new capacity, caused a drop in pigment prices. The titanium sponge price reached a record high in 1980 because of unprecedented demand for commercial aircraft, then dropped sharply in 1982 and 1983 following a severe downturn in the commercial aircraft market. Although sponge consumption was near record-high levels in 1989, the constant dollar price was several percent below the moderate levels of 1975-77. The decline in sponge consumption in 1990 and 1991 was reflected by a decrease in price. Published prices of titanium concentrates and products in 1990-91 are listed in table 15. (See table 4.)

Costs.—Construction cost of a 110,000-ton-per-year synthetic rutile plant completed in 1977 at Mobile, AL, was reportedly \$53 million, or about \$480 per annual ton of product.

The cost of constructing a new 82,000-ton-per-year chloride-process pigment plant is about \$2,500 per ton of annual capacity. Sulfate-process plants, including neutralization facilities, were said to cost considerably more. The operating costs for chloride plants, which may be operated continuously and are more easily automated, reportedly were as much as 30% lower than those for sulfate plants. The cost of finishing titanium pigment for marketing is about the same for both processes and composes a significant portion of the total costs. Mineral raw material costs in the sulfate process are appreciably lower than those in chloride-process plants that use rutile as feed material.

Plant costs for producing titanium sponge are very high. The estimated cost per annual ton of capacity is about \$12,000 to \$15,000. Raw material costs for producing titanium sponge are about the same, whether reduction is with sodium or magnesium, and the selection of one reductant over the other depends on local market economics.

Tariffs.—The duties shown in table 5 reflect results of the Tokyo Round of Multilateral Trade Negotiations completed in 1979 under which tariffs on many items were reduced in several stages over the period January 1, 1980, to January 1, 1987. (See table 5.)

Depletion Provisions.—The depletion allowance for ilmenite and rutile is 22% when mined from domestic deposits and 14% from foreign deposits.

Operating Factors

Environmental Requirements.—Heavy-mineral sand mining presents few serious environmental hazards. The land is restored by returning the bulk of the sand after removal of the ore minerals and may even be improved in low, flat

areas. Dune areas can be left in nearly their original form, and the sand can be stabilized by seeding and replanting.

The major environmental problem in the titanium industry is the disposal of wastes from pigment-producing processes that use ilmenite, generating up to 3.5 tons of waste per ton of product. Solutions to this problem required the development of methods to neutralize and control the effluent now produced by the sulfate pigment process, mainly a solution of waste sulfuric acid and ferrous sulfate heptahydrate. Deep well disposal has been used for waste ferric chloride produced when ilmenite is used to make $TiCl_4$. In processes for making synthetic rutile, the effluent solutions are treated to regenerate the original leaching agent, such as hydrochloric acid, which is recycled, and to form useful byproducts such as sodium sulfate, ammonium sulfate, and iron oxide. In sulfate-process technology, there is a strong trend away from disposal of waste materials in streams or in the ocean. Both U.S. sulfate-process producers now are using waste treatment plants that neutralize acid effluent with limestone and lime and produce gypsum and iron oxide byproducts. Such neutralization processes add about \$100 per ton to the cost of the TiO_2 pigment product. The sale of all byproducts recovers only a small fraction of this cost.

In 1989, the Environmental Protection Agency (EPA) published a newly revised interpretation of the Bevill exclusion, which exempts mineral processing wastes from regulation under subtitle C of the Resource Conservation and Recovery Act (RCRA). EPA's revised interpretation addressed the definition of mineral processing and established high-volume and low-hazard criteria for waste streams to be retained within the Bevill exclusion.¹ Subsequent proposed rulemaking, published in 1990, applied this revised interpretation to 20 waste streams that were conditionally retained in the Bevill exclusion.² In the TiO_2 - $TiCl_4$ sector, chloride processing waste solids were retained, passing both the high-volume and low-hazard criteria. However, other waste streams in this

sector were not retained: sulfate process waste acids, having failed to pass the low-hazard criterion; and sulfate process waste solids, chloride process waste acids, and titanium leach liquor, which all failed the high-volume criterion. EPA estimated compliance costs for the sulfate process portion of the titanium dioxide sector to average 0.8% of the value of shipments for the affected facilities.

Toxicity.—Titanium is a nontoxic material, as demonstrated by the use of TiO_2 in cosmetics and the use of titanium for making pacemakers and other implant devices for humans. However, some titanium compounds can be hazardous; for example, $TiCl_4$, which reacts violently with water or moisture in the air, forming TiO_2 and hydrochloric acid.

Energy Requirements.—According to a 1975 study for the U.S. Bureau of Mines, energy requirements for alluvial mine production are about 5.1 million British thermal units (Btu's) per ton of TiO_2 in concentrate. Production of pigment requires about 75 to 112 million Btu's per ton of TiO_2 , depending on the process and feed material used. Titanium sponge production uses from 408 to 466 million Btu's per ton of metal, of which about 248 to 270 million Btu's is required to regenerate the reductant and chlorine. The conversion of sponge metal to titanium ingot requires an additional 46 million to 57 million Btu's per ton of titanium ingot.³

ANNUAL REVIEW

Legislation and Government Programs

In May, the EPA made a final determination that none of the 20 wastes that were conditionally excluded from regulation under subtitle C of RCRA would be regulated as hazardous. The wastes, including waste solids from titanium tetrachloride processing, may be included in a special subtitle D regulatory process being developed for nonhazardous mining extraction and beneficiation wastes. (See table 6.)

Strategic Considerations

Security of Supply.—Although imports supply a very large proportion of domestic consumption of titanium concentrates, these imports come predominantly from Australia and Canada, which have historically been reliable and politically stable suppliers.

Import reliance, defined as imports less exports plus adjustments for inventory changes, may be used as a measure of dependence on foreign sources of supply. Expressed as a percentage of consumption, import reliance for ilmenite, including high TiO_2 slag made from ilmenite, was 35% in 1980 but increased to about 80% in the 1982-84 period because of cessation of production at two U.S. ilmenite mines. Ilmenite import reliance through 1991 generally has been in the 70% to 80% range. Import reliance for rutile declined from about 90% in 1980 to about 60% in 1983, and in later years it has remained in the 60% to 70% range because of increased production of synthetic rutile. However, this decline was at the expense of increased import reliance for ilmenite, because the domestic synthetic rutile was made from Australian ilmenite.

Dependence on foreign rutile sources could be eased or eliminated in an emergency in two ways, using current commercial processing methods: (1) Synthetic rutile could be made from domestic ilmenite now being mined in Florida or ilmenite that could be mined from other deposits, such as the Tennessee ilmenite sand deposits. (2) Titanium tetrachloride for metal production could be made directly from ilmenite, as is done by Du Pont for TiO_2 pigment manufacture.

Another possible solution to this problem is the development of new processes that utilize domestic ilmenite and perovskite that contain too much calcium and magnesium to be used directly for making $TiCl_4$. Availability of such processes would encourage production of domestic ilmenite, which fell from about 450,000 tons of contained TiO_2 in 1975 to about 165,000 tons of TiO_2 in 1982. In 1991, ilmenite mine

production capacity was about 200,000 tons per year of contained TiO_2 .

Import reliance for titanium sponge as a percentage of consumption has ranged from 0% to 16% between 1980 and 1991, and the United States was a net exporter in 1990. Titanium concentrates currently used to make $TiCl_4$ for metal production are mostly imported rutile and synthetic rutile, but domestic concentrates could be used for this purpose in an emergency, possibly at higher cost.

Stockpile.—Rutile and titanium sponge metal are included in the list of strategic and critical materials for stockpiling purposes. Titanium sponge has been acquired periodically for the NDS from domestic producers and from producers in Japan and the United Kingdom. Rutile for the NDS was acquired mainly in the early sixties from Australia.

The Government's NDS goal for titanium sponge metal remained at 176,901 tons. The NDS inventory in December contained 23,555 tons of specification metal and 9,857 tons of nonspecification material. The NDS goal for rutile was unchanged at 96,162 tons. The total rutile stockpile inventory at yearend was 35,549 tons, including 51 tons of nonspecification material.

Issues

U.S. Ore Supply.—Although the United States has large reserves of titanium in the form of ilmenite, nearly all of U.S. titanium sponge production has been derived from imported rutile and synthetic rutile. This heavy reliance on foreign concentrates has developed because most producers of $TiCl_4$, the intermediate compound used to make titanium and a large part of the world's TiO_2 pigment, prefer rutile or synthetic rutile over ilmenite as plant feed material. Possible ways of better utilizing U.S. ilmenite resources and reducing U.S. dependence on foreign sources of titanium concentrates are discussed previously.

Fluctuations in Metal Demand.—A major problem affecting the titanium industry is the wide fluctuations in demand caused by changes in requirements for both military and commercial aircraft programs. Titanium sponge producers have repeatedly increased capacity in response to anticipated demand and have then been left with excess capacity when those programs were canceled or cut back. It has been suggested that the aerospace industry could help stabilize demand and match supply to demand by better long-range planning and forecasting of their requirements and greater use of multiyear contracts. In the event that additional capacity is needed quickly in a national emergency, incentives such as loan guarantees and a guaranteed floor price for purchases from new capacity could be used, as authorized under the Defense Production Act. Further diversification of titanium into nonaerospace industrial applications would also help stabilize titanium demand.

Production

Concentrates.—U.S. producers of ilmenite in 1991 were Associated Minerals (USA) Ltd. Inc. (AMU) at Green Cove Springs, FL; Du Pont at Starke and Highland, FL, both from mineral sands deposits; P. W. Gillibrand Co., Simi Valley, CA, as a coproduct of its rock, sand, and gravel operations; and Nord Ilmenite Corp., Jackson, NJ, from a previously mined mineral sands deposit. AMU was the only U.S. producer of natural rutile. Kerr-McGee was the sole domestic producer of synthetic rutile, at Mobile, AL. Interest continued in exploration and potential development of mineral sands in North Carolina and Virginia. Several companies have conducted detailed drilling and feasibility studies and mining at one or more of these deposits could begin by 1993.

Du Pont had previously announced plans to begin mining mineral sands at the company's new operation in Maxville, FL, in 1992. However, startup for this

project has been delayed until sometime in 1993.

Ferrotitanium.—Ferrotitanium was produced by Galt Alloys Inc., Canton, OH; HTP Co., Sharon, PA; and Shieldalloy Metallurgical Corp., Newfield, NJ. Two grades were produced—a 40%- and a 70%-titanium grade.

Metal.—At yearend 1991, RMI Titanium Co. made plans to permanently close its sodium and titanium metal reduction facilities at Ashtabula, OH. In October, RMI had made concessionary wage and benefit proposals to the local unions that represented the employees at Ashtabula. However, no agreements could be reached, and notices were given to the 369 employees at the plant. Pending the termination of its sponge production capability, RMI entered into two long-term purchase agreements with domestic and foreign sources. The expected closure would eliminate 10,900 tons per year of sponge capacity as well as 140,000 tons of sodium chloride and 22,700 tons of sodium and sodium hypochlorite capacity.

Oregon Metallurgical Corp. (Ormet) entered into an agreement with Oregon Steel whereby Oregon Steel would roll titanium plate for Ormet at its facility in Portland, OR. Ormet had shipped its slabs to a rolling mill in Pennsylvania. The move was expected to significantly reduce lead time and transportation costs.

Ormet brought on-line a vacuum-creep flattener capable of producing high-grade titanium plate nearly as thin as sheet. The new system avoided the use of a forge press, which introduces waviness and bowing when used to produce thin plate. Most of the design and construction was done in-house. The flattener was designed to process up to 6 tons of plate per run with a projected 40 runs per year. The finished plate was reported to have tolerances of 0.005 to 0.010 inch.⁴

Howmet announced plans to consolidate its machining and production activities. The plans included closing its

machining operations at its Whitehall, CT, facility and merging these operations into its Plymouth, MI, facility. In addition, the melt activities from Plymouth would be integrated into Howmet's facility in Dover, NJ.

TIMET held a groundbreaking ceremony to mark the construction of a vacuum-distilled titanium sponge plant in Henderson, NV. In exchange for a possible 25% equity interest in TIMET, Union Titanium Sponge, a Japanese consortium, was expected to provide the majority of the financing for the project. The members of Union Titanium included Toho Titanium Co., Nippon Mining Co., Nippon Steel Corp., and Mitsui Co. Technology for the new furnace was being provided by Toho, and the construction was being conducted by Jacobs Engineering Co. The new facility was expected to produce 10,000 tons per year of sponge. TIMET's capacity in 1991 was 12,700 tons per year. When the new facility is completed, TIMET planned to decommission 8,200 tons of old capacity leaving 14,500 tons per year of capacity. TIMET expected the new capacity to be more cost efficient and yield a higher purity product.

NKK Corp. sold its 40% stake in International Light Metals to Martin Marietta Corp. The sale marks NKK's withdrawal from its 6-year joint venture with Martin Marietta.

In response to a need identified by the jet engine industry, Axel Johnson Metals Inc. installed a state-of-the-art electron beam hearth furnace capable of processing up to 4,500 tons of titanium ingot annually. The furnace was reported to be primarily for commercial aerospace use.

In November, Teledyne Allvac commissioned a fully automated bar and rod mill at Richburg, SC. The new mill was supplied with billet from Teledyne's nearby melting and forging facilities at Monroe, SC.⁵ (See tables 7 and 8.)

Titanium Dioxide Pigments.—U.S. production of TiO₂ pigments increased in 1991. Producing plants operated at 87% of their 1,135,000 tons per year of capacity.

Kronos Inc. began trial operations of a 80,000-ton-per-year chloride-based plant in Lake Charles, LA. The plant was expected to be commissioned in 1992.

Du Pont started a new line at its De Lisle, MS, titanium pigment plant. The new line adds 90,000 metric tons per year of new capacity based on the chloride process. (See tables 9 and 10.)

Consumption and Uses

Concentrates.—Total U.S. consumption of TiO₂ in concentrates decreased about 2% from the 1990 level. This decline was mainly attributed to a slowing economy. Although consumption in ilmenite increased by 7%, consumption in slag and rutile decreased by 7% and 3%, respectively. Pigments constituted 95% of total TiO₂ consumption by end use. (See table 11.)

Ferrotitanium.—Reported consumption of titanium in the form of ferrotitanium and scrap in steel and other alloys decreased by about 17%.

Metal.—Net shipments of mill products fell by about 35%, and sponge production also decreased by 41%. Consumption of scrap for remelting supplied a calculated 45.7% of ingot feedstock compared with 40.7% in 1990. Castings shipments increased by 26%.

Mill product shipments by product type were forging and extrusion billet, 48%; sheet, strip, plate, extrusions, and other, 38%; and rod and bar, 14%.

Estimated U.S. mill product usage, by application, was as follows: commercial aircraft, 41%; military aerospace, 37%; chemical industry, including pulp and paper, 10%; powerplant condensers, 4%; naval and other marine uses, 3%; medical implants, 1%; and other uses, mainly oil drilling, flue gas desulfurization, and automotive, 4%.

Current use of titanium in large commercial aircraft represents about 6% of aircraft empty weight. Titanium is utilized where high-strength toughness, heat resistance, and high structural efficiency are required. Typical aircraft

uses are for structural forgings, such as the landing gear beam in the Boeing 757; wing skins for the F-14 and F-15 fighter aircraft; rotor parts for helicopter systems; B-1B fracture-critical forgings and wing support sections; and rotor discs and compressor blades on various engines.

Future trends in consumption point toward a higher percentage of titanium in commercial aircraft. Boeing Co. forecasted that 9% of the new 777 airframe would probably be constructed of titanium.⁶ The forecast is significantly higher than the average titanium percentage used in most commercial aircraft to date. Specific areas where titanium has been chosen for this aircraft include the fuselage, wing and landing gear structures, flap tracks, cockpit windshield frames, environmental and deicing ducting, and portions in and under the galleys.

Major nonaerospace industrial uses are mainly those requiring superior resistance to corrosion.

Pigment.—Apparent domestic consumption of TiO₂ pigments was about 958,000 tons, about 4% more than that in 1990. (See tables 12 and 13.)

Stocks

The TiO₂ content of inventories of ilmenite decreased by 26% while inventories of rutile increased 22%. Overall TiO₂ content of concentrate stocks decreased by 3%. Stocks of TiO₂ pigment increased by 17% to 72,000 tons. (See table 14.)

Markets and Prices

Published prices of ilmenite and titanium slag concentrates fell slightly during 1991. Meanwhile, prices for rutile rose moderately. Titanium dioxide pigment prices decreased slightly during 1991. (See table 15.)

Published prices of titanium sponge prices and mill products were unchanged during most of the year. However, according to industry sources, transaction

prices for metal products decreased significantly. Owing to a lack of demand, scrap metal prices also fell significantly during the year.

Foreign Trade

Imports of titanium raw materials increased by 11% from those in 1990. On the basis of TiO_2 content, principal import sources for raw materials were the Republic of South Africa, 46%; Australia, 33%; Sierra Leone, 11%; and Canada, 9%. In 1991, the Republic of South Africa surpassed Australia as the leading import source for concentrates. (See tables 16, 17, 18, and 19.)

World Review

Capacity.—The data in table 20 are rated capacities for mines and beneficiation plants, sponge metal facilities, and TiO_2 pigment plants as of December 31, 1991. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time at a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and temporarily closed facilities that, in the opinion of the author, can be brought into production within a short period of time and with minimum capital expenditure.

Mine and mill capacity for the production of titanium concentrates, metal production plant capacity, and TiO_2 pigment plant capacity are generally based on close to 365 days per year of operation, 3 shifts per day. Capacity figures are based on information obtained from the producing companies, from news items, and from U.S. Bureau of Mines estimates. (See table 20.)

Reserves.—U.S. and world reserves and reserve base data for titanium are shown in tables 21 and 22. U.S. reserves of 7.8 million tons of TiO_2 in ilmenite and 300,000 tons of TiO_2 in rutile occur

mainly in ancient beach sand deposits in Florida. Ilmenite concentrates from the U.S. sand deposits contain about 60% to 65% TiO_2 , while those from rock deposits contain 45% to 50% TiO_2 . The U.S. reserve base of 34.7 million tons of TiO_2 occurs as 23.5 million tons in ilmenite, 9.8 million tons in perovskite ($CaTiO_3$), and 1.4 million tons in rutile.

Other U.S. resources include additional rock deposits of ilmenite in California, Minnesota, New York, and Wyoming and sand deposits of ilmenite and/or rutile in Georgia, Idaho, New Jersey, North Carolina, Oregon, and South Carolina, as well as large quantities of accessory rutile in porphyry copper ores and mill tailings.

The U.S. Bureau of Mines is compiling a computerized file of worldwide mineral deposit data called the Minerals Availability System (MAS). When fully developed, MAS will provide a means of analyzing supply positions relative to available reserves, mineral-related land use issues, environmental issues, and a variety of problems associated with the mining, processing, and transporting of titanium and other commodities. Most of the resource data in tables 21 and 22 were derived from MAS reports.

Major titanium reserves in the United States are owned by Du Pont and AMU in Florida. Reserves in Australia are held mainly by Associated Minerals Consolidated Ltd. (AMC), a subsidiary of RGC; Consolidated Rutile Ltd.; Westralian Sands Ltd.; and Cable Sands Ltd. Reserves at Allard Lake, Quebec, Canada, are held by QIT-Fer et Titane Inc. (QIT), now a subsidiary of RTZ Corp. PLC. QIT also has a 50% interest in Richards Bay mineral sands deposits in the Republic of South Africa. Major deposits in Brazil, India, and Sri Lanka are held by the respective governments. NL Industries controls Titania A/S, owner of the large hard-rock deposit at Tellnes, Norway. (See tables 21 and 22.)

U.S. reported consumption of titanium dioxide in concentrates in 1991 was 1,086,000 tons. At this annual consumption rate, U.S. reserves of 8,000,000 tons would be sufficient for

only about 7 years, without imports. However, with the current level of import reliance at about 60% of reported consumption, these reserves would provide nearly a 20-year supply of titanium. The U.S. reserve base of 35 million tons TiO_2 content is equivalent to more than 30 times the 1991 domestic consumption level.

World production of TiO_2 in concentrates decreased slightly in 1991, in line with the slight decrease in world demand. However, production capacity for TiO_2 in concentrates increased by about 5%, and TiO_2 pigment production capacity increased by about 7% in 1991. Because of increased environmental regulations, particularly in Europe, regarding disposal of waste acid from sulfate-process TiO_2 plants, several producers have closed or invested in additional acid recycling equipment to reduce or eliminate acid disposal. (See table 23.)

Australia.—SCM Chemicals closed its 34,000-ton-per-year titanium pigment plant at Bunbury, Western Australia. The plant had been based on the sulfate process. In 1989, as a precursor to the closure, SCM had constructed a 70,000-ton-per-year plant based on the chloride process. In 1991, SCM produced pigment by both chloride- and sulfate-based technologies, and its global capacity was estimated to be 392,300 tons.

In Australia, estimated production of both ilmenite and rutile declined by about 15% to 20% as a result of a decrease in world demand for TiO_2 pigments. Cutbacks made by all the Australian producers, except the newly commissioned TiWest Joint Venture, contributed to the decrease in production.

AMC Mineral Sands Div. of RGC closed its Eneabba North mining site in early 1991, and production of sulfate-grade ilmenite at Capel was reduced to compensate for the closure of SCM's sulfate-route pigment plant at Bunbury. AMC's Eneabba West operation was providing additional mineral sands output, but production did not completely replace the lost production from Eneabba North.

The company also planned to close one of its 130,000-ton-per-year synthetic rutile kilns at Narngulu for 6 months.

Westralian Sands' Yoganup Extended mine remained closed since August 1990, and production from the company's Capel operations has decreased. Consolidated Rutile's operations in North Stradbroke Island, Queensland, also were closed during part of the year.

The new TiWest Joint Venture operation in Cooljarloo, which began producing ilmenite in 1990, started synthetic rutile production in January 1991. Production capacity at the synthetic rutile plant was reported to be 68,000 tons per year. Minproc Holdings Ltd. owned 50% of the TiWest Joint Venture.⁷

Brazil.—Owing to technical problems with the anatase concentrate and titanium $TiCl_4$, Companhia Vale do Rio Doce (CVRD) shut down its 50-ton-per-year titanium sponge pilot plant. CVRD was also reported to have signed an agreement with Du Pont to restudy technical and economic issues in the production process. Du Pont received Governmental approval for a 60,000-ton-per-year plant to produce pigment from anatase ore based on sulfate technology. At yearend, Du Pont was already close to completion of a 15,000-ton-per-year finishing plant at Uberaba, Minas Gerais State.

Cameroon.—Consolidated Rutile signed a joint-venture agreement with an arm of the Cameroon Government to mine a mineral sands deposit near Akonolinga, Cameroon. Consolidated Rutile reportedly plans to produce 50 tons of rutile annually for a 10-year period, although no startup date was established.

Canada.—QIT's 80%- TiO_2 slag production capacity reportedly was cut to 75% at its plant in Sorel during the latter half of the year. This plant supplied feedstock to sulfate-process TiO_2 pigment plants, and the production cutback resulted from a drop in pigment production.

Tioxide announced that it would construct a new chloride-process TiO_2 pigment plant at Becancour, Quebec. The new plant was expected to replace sulfate-based production at Tracy, Quebec. Completion of the new plant was scheduled for 1994, and the plant would use Tioxide's energy-efficient Independent Chlorination and Oxidation (ICON) process. Capacity at the plant was anticipated to be 60,000 tons per year of semiprocessed material. When completed, the Becancour facility would ship the semifinished product to the Tracy plant for final processing, and the sulfate-based pigment capacity at Tracy would be shut down.

France.—Tioxide began a program at its Calais, France, facility to improve environmental standards. The Calais project recycled acid within the sulfate-based plant. The process reconcentrated acid liquid effluent for use in pigment production and converted metallic sulfates into an ash suitable for landfill.⁸

India.—A commercial-scale titanium sponge facility was under construction at Tuticorin in Tamil Nadu. The facility was an initiative of the Indian Atomic Energy Commission and was anticipated to be capable of producing 1,000 tons per year when completed. In addition, a facility was expected to be constructed that would produce magnesium from seawater for the metal reduction plant.⁹

Japan.—According to preliminary Japanese Titanium Association statistics, during 1991, demand for sponge in Japan was 35% less than that of the previous year. Production at all three sponge producers, Showa Titanium Co. Ltd., Toho Titanium, and Osaka Titanium Co., Ltd., was reduced during the fourth quarter because of poor business conditions in both Japan and the United States.

Toho Titanium began to renovate its sponge facilities at Chigasaki in Kanagawa Prefecture. When completed, 7.4-ton furnaces would replace the existing 1.6-ton furnaces. The

renovations were not expected to change the facility's total capacity of 10,800 tons per year.

Osaka Titanium completed streamlining renovations of its titanium sponge plant. Sponge capacity at the plant was reported to be 15,000 tons per year.¹⁰ Osaka was also reported to be proceeding with plans to construct an additional furnace at its Amagasaki facility to increase ingot output to 4,680 tons per year. The new furnace was expected to be commissioned in 1992.¹¹

Korea, Republic of.—Du Pont received approval from the South Korean Government for a titanium pigment plant in Ulsan. The facility was reported to be a joint venture with Han Yang Chemical. When completed, the plant was anticipated to have a capacity of about 60,000 tons per year. The plant was expected to be completed in 1994.

Malaysia.—Tioxide made plans to commission a new pigment facility in 1992 at Telok Kalong in Terengganu. The new 50,000-ton-per-year facility was based on sulfate technology.

Mexico.—Du Pont was reported to be expanding capacity to 90,000 tons per year at its facility at Tampico, Mexico. The expansion was expected to be completed in 1992.

Netherlands.—American Cyanamid sold its 50% equity ownership in TDF Tiofine to Billiton Nederland BV. The sale resulted in Biliton's sole ownership of the Netherlands-based TiO_2 pigment producer.¹²

Saudi Arabia.—Late in the year, Crystal Pigment Co., a joint venture between Kerr-McGee (25%) and several Saudi Arabian investors, opened a 50,000-ton-per-year chloride-process pigment facility at Yanbu, Saudi Arabia. Technology at the plant was based on an ICI chloride process.

Sierra Leone.—Hazcare Pty. Ltd., a subsidiary of Pioneer Resources, signed a

prospecting license and Memorandum of Understanding covering the Rotifunk and Sembehun rutile, ilmenite, and zircon deposits. Inferred resources were reported to be 1,410,000 tons of rutile, 2,180,000 tons of ilmenite, and 128,000 tons of zircon. A program was scheduled to upgrade the resource to a measured category.¹³

South Africa, Republic of.—Shell SA and Rhombus Exploration (Rhoex) reportedly have signed an agreement to conduct a feasibility study on a mineral sands deposit in the Empageni district of Natal. Rhoex was responsible for conducting the geological work on the project.¹⁴ Meanwhile, Richards Bay Minerals increased its TiO₂ slag capacity to 1,000,000 tons per year by commissioning its fourth slag smelter.

Taiwan.—Du Pont continued construction of a 60,000-ton-per-year TiO₂ plant. The plant was expected to be commissioned in the fourth quarter of 1993.

United Kingdom.—In response to recently enacted environmental restrictions, SCM reduced capacity at its Stallingborough, England, TiO₂ pigment plant. The reduction eliminated pigment production based on sulfate process and brought the plant's capacity down to 95,000 tons per year.

Tioxide began a program at its Grimsby plant to improve environmental standards. The improvements include a neutralization process for the plant's effluent. The process, which has been used in Malaysia, would generate two grades of gypsum for plasterboard manufacture and landfill.¹⁵

U.S.S.R.—According to press reports, one of the four major sponge facilities in the former U.S.S.R. was forced to halt production after running out of raw materials. Because of a lack of hard currency, the Kamenogorsk plant in Kazakhstan was unable to purchase the raw materials to continue production.

The facility was reported to have an annual capacity of 20,000 tons per year.

Two TiO₂ pigment producers in the former U.S.S.R. were expected to increase their production levels to meet the growing demand in the country. Lakokraska planned to increase production at its Armianisk sulfate-process plant from 80,000 tons per year to 120,000 tons per year by 1992. Environmental problems with the plant's effluent would have to be solved before the local government will grant permission for the expansion. In 1991, production in the U.S.S.R. was estimated to be 120,000 tons per year, and demand was estimated to be 200,000 tons per year. Demand was expected to increase to 400,000 tons per year by 2000.

Current Research

Textron Specialty Metals, developer of a composite material made from a continuous silicon carbide filament embedded in titanium, was awarded an \$8.6 million contract to fabricate structural test components and develop material technology for the National Aerospace Plane (NASP). The NASP was conceived as a single stage to orbit craft without a supplemental launch vehicle. When completed, the NASP would travel at hypersonic speeds and be capable of taking off and landing on a runway. Since the silicon carbide-titanium material developed by Textron was determined to be capable of withstanding extremely high temperatures (1,600° F), the material was considered extremely suitable for the NASP application. The NASP program was being jointly funded by the Air Force and National Air and Space Administration.

In an effort to reduce U.S. dependence on imports of titanium, the U.S. Bureau of Mines investigated the recovery of titanium from perovskite (CaTiO₃). The untapped U.S. resource of perovskite includes an estimated 9.8 million tons in Colorado. The process being investigated is an acid sulfation method, which would extract about 97% of the titanium and columbium as well as 70% to 90% of rare earths from perovskite concentrates.

The process may be an economically viable method to produce pigment-grade TiO₂.

OUTLOOK

According to industry reports, consumption of titanium pigment in North America is expected to grow at 2.1% annually to 1995. Meanwhile, demand in Western Europe is expected to grow at 2.6% per year. In Asia and Oceania, demand is predicted to increase by 4.3% to 1995. Although producers added 177,000 tons of annual pigment capacity from 1985 to 1990 and are scheduled to add 295,000 tons by 1995, further capacity expansions are expected to be required to meet demand. Future expansions are anticipated in areas with relatively high demand such as Asia, Latin America, and the Middle East.¹⁶

The outlook for the titanium metal industry is unclear. Cuts in military aerospace spending will continue to affect the industry for some time. However, the titanium content in commercial aircraft is expected to grow, and titanium metal producers are aggressively pursuing nonaerospace markets. An ample supply of titanium metal should be available to meet domestic and global needs for several years.

The development of newly discovered deposits and the continued development of processing technologies are expected to ensure an adequate supply of titanium concentrates for several years. Growth in consumption of concentrates is dependent on consumption by titanium pigments.

TABLE 2
NATIONAL STOCKPILE
PURCHASE SPECIFICATION:
SUMMARY OF RUTILE
CHEMICAL AND PHYSICAL¹
REQUIREMENTS

	Percentage by weight (dry basis)
Chemical requirements:²	
Titanium dioxide	95.00
Ferric oxide	1.0
Silica	1.3
Phosphorous pentoxide	.1
Sulfur	—
Zirconium dioxide	1.0
Alumina	.8
Vanadium pentoxide	.8
Chromium oxide	.8
Magnesium oxide plus calcium oxide	.3
Tin	.1
Manganese	—
Columbium pentoxide	.6

¹All rutile shall pass a U.S. Standard Sieve No. 30 (ASTM Designation E-11) with not more than 1% passing a U.S. Standard Sieve No. 200.

²All of the amounts are maximums except for titanium dioxide, which is a minimum. For radioactive identification, report for each lot the percent by weight of naturally occurring thorium, uranium, or combination of the two.

^aEstimated. ^bRevised. W Withheld to avoid disclosing company proprietary data; not included in "Total."

¹Table excludes production of unbeneficiated anatase ore in Brazil, in metric tons, as follows: 1987—3,344,318; 1988—3,400,000; 1989—3,500,000 (estimated); 1990—3,000,000 (estimated, revised); and 1991—3,000,000 (estimated). This material reportedly contains 20% TiO₂. Table contains data available through June 17, 1992.

²Ilmenite is also produced in Canada and in the Republic of South Africa, but this output is not included here because an estimated 90% of it is duplicative of output reported under "Titaniferous slag," and the rest is used for purposes other than production of titanium commodities, principally as steel furnace flux and heavy aggregate.

³Reported figure.

⁴Contains 80% TiO₂.

⁵Contains 85% TiO₂.

TUNGSTEN

By Gerald R. Smith

Mr. Smith, a physical scientist with 28 years of research and commodity experience with the U.S. Bureau of Mines, has been the commodity specialist for tungsten since 1986. Domestic survey data were prepared by Cheryl Mack, statistical assistant; the world production table was prepared by Ronald Hatch, international data coordinator.

The unique high-temperature properties of tungsten and its alloys can be utilized advantageously in the production of numerous end-use items. The high melting point, high density, good corrosion resistance, and good thermal and electrical conductivity properties of tungsten and its alloys and the excellent cutting and wear-resistant properties of its carbide continue to provide important items for consumption in both the domestic and military sectors.

Total domestic consumption of tungsten in primary end-use categories decreased by about 6% in 1991 compared with that of 1990. Weakness during the last half of the year in the demand for cemented carbides in the combined cutting tool, mining tool, oil drilling equipment, and wear-resistant component industries contributed significantly to this decline. Demand for other tungsten-containing products such as steels, superalloys, and mill products also decreased during the year.

The average price for wolframite concentrate on the world market increased by 22% in 1991, while scheelite prices remained essentially unchanged compared with those of 1990. Most U.S. tungsten mines still remained closed, as the owners and operators viewed their operations as continuing to be noncompetitive at existing prices.

An Orderly Marketing Agreement (OMA) limiting imports of ammonium paratungstate (APT) and tungstic acid from China since October 1, 1987, was allowed to expire on September 30, 1991. No further trade restrictions were placed on these materials for the remainder of the year. On October 28, 1991,

however, a final decision was made by the International Trade Commission (ITC) to place a tariff of 151% on imports of tungsten ore concentrates from China.

A summary of the important U.S. and international statistics for 1991 and the previous 4 years are shown in table 1.

DOMESTIC DATA COVERAGE

Domestic production data for tungsten are developed by the U.S. Bureau of Mines by means of three separate, voluntary surveys. These surveys are "Tungsten Ore and Concentrate," "Tungsten Concentrate and Tungsten Products," and "Tungsten Concentrate." Of the 47 known mining and processing operations to which survey requests were sent, 96% responded, and are represented in the production and stock totals shown in table 1.

BACKGROUND

Definitions

Tungsten, a silvery gray metal, has an atomic number of 74 and an atomic weight of 183.92. Its most outstanding physical property is its high melting point of 3,410° C, the highest of all metals. Tungsten is one of the heaviest of elements, with a density of 19.3 grams per cubic centimeter at 20° C. It has good corrosion resistance, good thermal and electrical conductivity, and a low coefficient of expansion. At temperatures above 1,650° C, tungsten has the highest tensile strength of all metals.

Tungsten concentrate is sold in units of tungsten trioxide (WO₃). In the United

States, sales are based on the short ton unit of WO₃. This is equivalent to 1% of a short ton, or 20 pounds of WO₃ and contains 7.19 kilograms (15.86 pounds) of tungsten. In most other countries, tungsten is sold in the metric ton unit (mtu) and contains 7.93 kilograms (17.48 pounds) of tungsten.

Natural or synthetic scheelite concentrate, in nodular form, is ideal for direct addition to steel melts because the calcium is removed as slag. Fine material in either synthetic or natural scheelite is not desirable because of high dust losses. Wolframite concentrate is not satisfactory for steelmaking because of the manganese and tin content.

Tungsten ores and concentrates are converted into the following intermediate products: APT, tungstic acid, sodium tungstate, tungsten metal powder, and tungsten carbide powder. Most of the APT is reduced to tungsten metal powder, which then is processed into tungsten carbide powder.

Tungsten alloys and tungsten mill products such as rod, wire, and sheet are produced from hydrogen-reduced tungsten metal powder. The tungsten carbide produced from powder is cemented, usually with cobalt, to form various cutting and wear-resistant tools and parts.

Tungsten chemicals (APT, tungstic acid, and sodium tungstate) are produced as coproducts at some tungsten processing plants and as primary products at others. When not processed further into metal powder, they generally are used in the chemical industry.

Products for Trade and Industry

Tungsten materials can be divided into four major classes, depending on use: (1) a carbide in cutting and wear-resistant materials, and welding and hard-facing rods; (2) mill products made from essentially pure metal; (3) an alloy constituent in high-speed and tool and die steels, superalloys, and nonferrous alloys; and (4) various chemicals and compounds for nonmetallurgical applications.

The extreme hardness of tungsten carbide at temperatures exceeding 1,000° C makes it a preferred metalworking material for cutting edges of machine tools subject to intense wear or abrasion and for metal surfaces in forming and shaping dies. The mining and petroleum industries use tungsten carbide in drill bits, in the cutting edges of earth-moving equipment, and in crushing machinery. Tungsten carbide is used widely in wear parts of transportation and electrical equipment.

In most applications, tungsten carbide generally is cemented with a powdered cobalt metal binder by compaction and sintering. The cobalt content can range from about 3 to 25 weight-percent, with the higher content providing greater shock resistance at a sacrifice in hardness. Tantalum and/or titanium carbides are used in conjunction with tungsten carbide in certain cutting and chipping tools. Also, coatings such as titanium carbide, titanium nitride, and aluminum oxide on tungsten carbide are used extensively to increase the life of inserts for machining applications.

Mill products made from pure or substantially pure tungsten metal powder are used in significant quantities by the electrical and electronic industries. Tungsten wire is used as the filament in electric lamps and as cathodes for electronic tubes. Disks produced from tungsten rods or sheet are used in automotive distributor points, although this end use is declining as the number of automobiles with electronic ignition systems increases. They are also used as contact points in numerous manufactured products. Tungsten metal is employed as heat and radiation shielding, as electrodes

for inert-gas welding, as components of X-ray and cathode ray tubes, and as heating elements in high-temperature resistance furnaces. Tungsten metal is used by the aerospace industry because it retains its strength at elevated temperature in reducing or inert atmospheres. The use of tungsten as a heavy metal for counterweights and balances, especially by the aircraft industry, has been replaced, to a significant extent, by depleted uranium, which approaches the density of tungsten.

Cast tungsten carbide is used principally as a hard-facing material. In this application, carbide particles are applied by a welding process to provide an abrasion-resisting surface layer on the surface to be coated. The carbide may be initially in the form of rod or loose grains in a tube.

As an alloy constituent, tungsten is used primarily in the production of high-speed steels and tool and die steels. Hardness and oxidation resistance at elevated temperatures are the most important properties possessed by these steels, which are used for machinery and equipment in the metalworking, construction, and mining industries. Certain grades of stainless and other alloy steels contain tungsten to improve wear and abrasion resistance, shock resistance, corrosion resistance, and/or strength at high temperatures.

Tungsten is an important constituent in a wide variety of superalloys and nonferrous alloys. Tungsten-containing superalloys are being utilized increasingly in high-temperature applications for their high-temperature strength and oxidation resistance. Tungsten alloyed with copper or silver is used for electrical contacts to provide wear resistance with adequate electrical conductivity.

Nonmetallurgical applications of tungsten include chemicals used in textile dyes, paints, enamels, toners, and coloring glass. Certain tungsten compounds are luminescent and used as phosphors in pigments, X-ray screens, television picture tubes, and fluorescent lighting. Sodium tungstate is employed as a corrosion inhibitor and a fireproofing agent in textiles. APT is used in making

catalysts for the refining of petroleum. Among other chemical applications, tungsten compounds are used in chemical-vapor deposition, as catalysts in other chemical processing, and as laboratory reagents.

The chief nonindustrial use of tungsten is in armor-piercing ordnance, but this has been replaced, in part, by depleted uranium.

ANNUAL REVIEW

Legislation and Government Programs

The National Defense Authorization Acts covering fiscal years 1991 and 1992 included no authority for disposal of tungsten from the National Defense Stockpile for calendar year 1991.

In July 1991, the Department of Defense issued a report recommending revisions in stockpile goals, including a new proposed goal for stockpile-grade tungsten materials that was about 3,992 metric tons (8.8 million pounds) of contained tungsten less than the existing inventory level of approximately 26,470 metric tons (58.5 million pounds), shown in table 2. However, the National Defense Authorization Act for Fiscal Years 1992 and 1993, effective October 1, 1991, included no changes in the goal for tungsten materials in the National Defense Stockpile.

Strategic Minerals Corp., Danbury, CT, through its subsidiary U.S. Tungsten Corp., operator of the Pine Creek Mine, Bishop, CA, filed a petition on January 23, 1991, with the ITC charging that China was dumping tungsten ore concentrates on the U.S. market. Following its investigation of this case, the Department of Commerce, International Trade Administration (ITA), issued its final determination on September 20, 1991. Consistent with its preliminary findings of July 10, 1991, the ITA determined that imports of tungsten ore concentrates from China were being, or were likely to be, sold in the United States at less than fair market value and were declared subject to additional tariff. Accordingly, the U.S. Customs Service was directed to continue to suspend

liquidation (defer final import processing) of all entries of tungsten ore concentrates from China in a manner similar to that which it had been directed earlier following ITA's preliminary findings. Final import processing was contingent upon receipt of a cash deposit or posting of a bond on all such entries, the amount of which was equivalent to the established margin of 151%, that is, the extent to which the determined foreign market value exceeded the U.S. sales price. The merchandise covered by the ITA's investigation included all concentrated or upgraded forms of raw tungsten ore. Upon completion of its investigation, the ITA reported its findings to the ITC. Subsequently, the tariff decision became final on October 28, 1991, when the ITC, in a 4 to 0 vote of the Commissioners, ruled that a U.S. industry was materially injured or was threatened with material injury, by reason of imports of tungsten ore concentrates from China at less than fair market value. Under existing antidumping procedures, the imposed tariff will remain in effect indefinitely.

The OMA, limiting U.S. imports of APT and tungstic acid from China since October 1, 1987, was allowed to expire on September 30, 1991. The U.S. Government decision was made following final discussions and a subsequent vote by an interagency trade policy review group. Prior to the decision, U.S. Government and industry officials discussed the necessity for alternative trade control measures upon expiration of the OMA. Among the measures given significant consideration by the industry was the possibility of negotiating a new agreement with China that included additional downstream tungsten materials through metal powder and tungsten carbide powder.

Strategic Considerations

Tungsten is an important strategic material necessary for defense purposes, including the industrial base. Currently, the heavy-metal alloys of tungsten, containing 3% to 10% nickel and small quantities of iron or copper, are used in several of the smaller diameter projectiles

for penetrating armorplate. Cemented tungsten carbide parts, which exhibit excellent cutting and wear-resistant properties, are vital to the U.S. metalworking, machining, construction, transportation, mining, and oil and gas drilling industries. Tungsten mill products and powders are essential to the lamp and lighting industry as filaments and electrodes, to the electrical and electronic industries as wear-resistant, electrically conductive contact surfaces, and to the superalloy and steel industries as alloying components. The U.S. Department of Defense relies heavily on the maintenance of a broad domestic production base to cover mobilization contingencies. The entire tungsten industry, from mined ore to manufactured products, thus represents an important component of the U.S. defense policy. The Department of Defense continually assesses the U.S. ability to produce tungsten to ensure that this and other sources of supply are sufficient to meet current and projected levels of demand necessary to preserve the national defense. A proposal by the Department of Defense in mid-1991 contained a recommendation that the quantity of tungsten in the National Defense Stockpile be decreased by about 15%. Tungsten, like many other metals and materials in the stockpile, was being considered for sale, in part, as a result of changing political climates in the world and military downsizing.

Issues

During 1991, China continued to be the principal supplier of tungsten products to the world market. Although wolframite concentrate prices increased during the year, the price level for concentrates and intermediate materials remained too low for many market economy producers to compete on the world market. China's perceived failure to place adequate controls on its production, distribution, and pricing policies continued to dominate the discussions among domestic industry officials. Most tungsten mines in the United States remained closed or were

operated at reduced capacity during the year. Furthermore, market conditions generally offered little or no economic incentive for producers to explore or develop other tungsten resources, prompting a request to the U.S. Government for trade restraints on China. U.S. Tungsten Corp., a subsidiary of Strategic Metals Corp., Danbury, CT, and the operator of the Pine Creek tungsten mine and mill, Bishop, CA, filed a petition on behalf of the U.S. tungsten mining industry requesting relief from alleged dumping of tungsten ore concentrate by China. Subsequent investigations by the Department of Commerce's ITA and the ITC resulted in an affirmative antidumping ruling and the levying of a significant tariff on imports of ore concentrates from China. Although the antidumping ruling provided significant protection from imports of concentrate, related action regarding imports of certain downstream products added other uncertainties to the U.S. tungsten market. The expiration of the OMA limiting imports of APT and tungstic acid effectively eliminated all constraints on imports of downstream tungsten products from China. In subsequent discussions between Government and industry officials, the possibility of instituting trade restrictions on all downstream products through tungsten carbide powder was considered, but by yearend, no official request for an investigation was filed by the U.S. industry. Imports of tungsten from China, however, did shift noticeably from ore concentrates to downstream intermediate materials, including APT, tungsten oxide, and sodium tungstate, following the imposition of the antidumping tariff on ore concentrates.

Several internal constraints on production and sale of tungsten products reportedly were instituted by the Government of China during 1991. The effect of these constraints on the supply-demand balance for tungsten products on the world market will require additional time and further assessment.

Production

Tungsten mining activity in 1991 remained at a level near that of 1990 as the continued low prices for concentrate prevented the reopening of any closed mines. Recent statistical trends in domestic mine shipments and their corresponding values are shown in figures 1 and 2, respectively. A list of major concentrate producers and those processing the various stages of intermediate tungsten materials are shown in table 3. Net production statistics for tungsten metal powders, carbides, and chemicals are shown in table 4.

Curtis Tungsten Inc., Upland, CA, owner and operator of the Andrew Tungsten Mine near Los Angeles, CA, resumed mining in January 1991 after the mine was closed for about 5 months because of a severe drought.

Curtis Tungsten and GTE Products Corp., Chemical and Metallurgical Div., Towanda, PA, signed a long-term contract effective August 1, 1991, enabling GTE to purchase an appreciable quantity of scheelite concentrates from Curtis's Andrew Mine. GTE produces a wide range of tungsten products, much of which are processed from the concentrates. The 42-month-long contract will provide for GTE to receive monthly up to 54 metric tons of contained tungsten at prices that will vary depending upon market conditions. As part of the contract, GTE advanced working capital to Curtis to progressively increase the output of the mine.

U.S. Tungsten Corp., Bishop, CA, continued as the only other company producing tungsten concentrate. The Pine Creek Mine and mill again was operated on an intermittent basis at levels below capacity to provide supplemental feedstock to the company's APT conversion facility. Imported concentrate was the primary source of raw material.

Canada Tungsten Mining Corp. Ltd. maintained its suspension on conversion of concentrate to APT at its Fort Madison, IA, facility during 1991. The company continued, however, during the year to supply its customers with products from its inventories.

Consumption and Uses

Total domestic consumption of tungsten in primary end-use categories (table 5) decreased by about 6% in 1991 compared with that of 1990. Demand for cemented carbides in the combined cutting tool, mining tool, oil drilling equipment, and wear-resistant component industries weakened during the last half of the year, ending with a decrease of about 4% compared with that of 1990. Demand for other tungsten products, including specialty steels, superalloys, chemicals, and mill products made from metal powder, also weakened during the final 6 months of the year, accounting for the remaining 2% decrease in demand for tungsten products.

Overall weakness in the U.S. economy was the single most important factor influencing the decline in demand for tungsten products during 1991. As the weakness in industrial sectors, such as auto, aerospace, construction, mining, and oil drilling progressively deepened, so also did the demand for cemented carbide and other hard-metal and alloy components used in these end-use sectors. The decline in demand for cemented carbide wear-resistant components was due, in part, to a progressive decrease in oil drilling activity following the cessation of the war in the Mideast in January 1991. As prices for crude oil rose during the war, the number of operating oil rigs in the United States rose sharply. After reaching a high of 1,179 on December 12, 1990, the number of rigs decreased to 797 by the end of 1991, according to figures reported by the International Association of Drilling Contractors and Baker Hughes Inc.

Markets and Prices

The average price for wolframite concentrates increased by 22% in 1991 while the average price for scheelite concentrates remained nearly unchanged, according to quotations published in Metal Bulletin (table 6). Wolframite prices progressively increased during the first three quarters of the year, then remained stable during the last quarter of

the year. Although scheelite prices were slightly higher in the last 5 months of the year, the average for the year was down about 1% compared with that of 1990.

Domestic APT prices increased steadily during the first 8 months of 1991, consistent with the rising prices for wolframite concentrates. According to quotations in Metals Week, APT prices ranged from \$66.14 to \$68.34 per (mtu) in January, rising to a range of \$84.88 to \$87.63 in mid-August. By yearend, prices had declined to a level of \$72.75 to \$73.85 per mtu. European APT prices were considerably lower than the domestic prices in 1991. Metals Week quotations for European APT were 11%, 23%, and 15% below the U.S. prices in the comparable months of January, August, and December, respectively. On July 1, 1991, Metals Week began publishing the price for APT from Hong Kong that reflected market transactions for #1 Grade APT from China. The Hong Kong prices essentially paralleled the European prices during the initial reporting period but by yearend was about 6% higher at \$64.00 to \$68.00 per mtu. Prices for tungsten metal powder and tungsten carbide powder remained virtually unchanged during the year, quoted at \$22.00 and \$21.65 per kilogram, respectively.

Effective January 1, 1991, the International Tungsten Indicator (ITI) was discontinued as a price index of trade in tungsten concentrates. The ITI prices, quoted since July 1978, were a reflection of international business activity in concentrates. Contributions to the quoted price were provided by both tungsten-consuming and tungsten-producing members of the ITI. Reasons for the discontinuance of the ITI were reported to include the fact that many of the original contributors to the ITI were no longer involved in trading concentrates, the number of producer members were reduced by the closure of many tungsten mines, and a shift toward the purchase of intermediate products rather than concentrates was made by some consumer members.

Foreign Trade

Comprehensive lists of U.S. export and import trade statistics by material quantity and value and by country of destination and origin are shown in tables 7 through 15. Import tariff rates for the various materials are shown in table 16.

Total U.S. imports of tungsten materials increased by 57% in 1991 compared with that of 1990. China continued to be the dominant supplier, providing about 46% of all imported tungsten materials. Although China's share of the U.S. tungsten imports was down about 4 percentage points from that of 1990, the total quantity of tungsten materials imported from China increased from 5,432 metric tons of contained tungsten in 1990 to 7,088 metric tons in 1991. Imports of concentrate from China decreased in 1991 because of China's decision to suspend new sales during the year and also because of the restrictions placed on these imports through implementation of an antidumping ruling. Subsequently, imports of intermediate tungsten products from China increased. The changing pattern of these imports was evident after mid-July when a conditional antidumping tariff of 151% was initially imposed on imports of concentrate. According to Bureau of the Census statistics, imports of concentrates from China during the first 7 months of 1991 totaled 3,091 metric tons of contained tungsten. During this same period, the combined imports of the intermediates APT, sodium tungstate, and tungsten oxides totaled 710 metric tons. In the subsequent 5 months following the imposition of the tariff, imports of concentrate essentially ceased, as was expected. Correspondingly, the imports of intermediates from China during the last 5 months of 1991 totaled 2,345 metric tons of contained tungsten. In comparison, intermediates imported from China during the same period in 1990 amounted to 548 metric tons of tungsten.

World Review

Capacity.—The data in table 17 are rated capacity for mines and mills as of

December 31, 1991. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Mine capacity for tungsten is based on published reports, maximum production statistics, and estimates. The latter is utilized particularly for certain countries where capacity information is either incomplete or unavailable. Estimated annual mine production capacity increased by about 5% in 1991 compared with that of 1990. Recent production statistics and estimates indicated higher capacities in Bolivia, China, and Peru. These capacities were offset partially by estimated lower capacities in Burma, the Republic of Korea, and the former U.S.S.R.

Canada.—Novagold Resources, Canada, reportedly signed a letter of intent in early 1991 to purchase the Mount Pleasant Tungsten Mine, New Brunswick, from its joint owners, Billiton Metals Ltd., Canada, and Lac Minerals, Canada. Payment for the interest in the mine and its assets will be through net profit royalties resulting from the operation of the mine. Novagold, in turn, will exempt Billiton and Lac from any future environmental liabilities in connection with ownership and operation of the facilities. Although no decision was made by Novagold on when production would begin at the mine, one source speculated that it would be operated initially for recovery of its tin value. Underground reserves at the Mount Pleasant Mine consist of an estimated 36,000 metric tons of tungsten, 35,000 metric tons of tin, and 18,000 metric tons of molybdenum.

Annual concentrate production and consumption statistics for the world are shown in tables 18 and 19, respectively.

China.—New plans, rules, and policies affecting China's production and trade of tungsten products reportedly were implemented by the Chinese Government on January 1, 1991. These included reducing concentrate production by 30%, suspending exports of concentrate for a minimum of 6 months, and abolishing export subsidies on all tungsten materials. The latter action, according to some industry analysts, could shut down as many as 50 to 60 small, uneconomical tungsten-producing and tungsten-processing operations. A spokesman for China's Ministry of Foreign Economic Relations and Trade further stated that the suspension of exports of concentrate would remain in effect until a realignment of its tungsten mining industry was completed.

Subsequent to the preceding actions, the State Council, China's highest governing body, listed tungsten, along with three other resources, in a category to receive State protection. The State Council ordered the State Planning Commission, with the help of the China National Nonferrous Metals Industry Corp., to work out a plan for the medium- and long-term utilization of these resources. According to the Council's directive, mining as well as processing of these resources would be carried out through state-owned operations, although in select cases collectively owned operations would be allowed.

In additional efforts to restructure and further control the tungsten industry, the Chinese State Council issued a policy forbidding the construction of any new plants for production of APT and other intermediate tungsten materials. As part of this policy, announced late in the third quarter of 1991, all of the small, inefficient processing facilities would be closed. Only a few of the larger, more efficient and competitive plants would be protected in order to control the quantity and quality of the materials effectively.

European Community (EC).—During 1991, imports of tungsten concentrate, tungstic acid and oxide, and tungsten carbide powder and fused tungsten carbide from China continued to be subject to duties of 42.4%, 35%, and 33%, respectively. The alternative minimum price standards also remained in effect for specific exporters, China National Nonferrous Metals Import and Export Corp. (CNIEC), and China National Minerals and Metals Import and Export Corp. By yearend, EC officials reported that they were in the process of reviewing the established minimum price standards to determine their effectiveness. The undisclosed standards, particularly the one agreed upon for concentrate, remained a subject of speculation by industry analysts. A price of \$68.00 per mtu WO₃ reportedly was considered to be a feasible probability. The average price for wolframite concentrates was about \$46.00 as quoted in Metal Bulletin (London) during 1990 when the standards were established.

Hungary.—Tungfram Co. Ltd., a manufacturer of tungsten for lamp and lighting end-use products, disclosed that General Electric Co., Euclid, OH, had increased its share in the company to 75% from the previous 50%. As General Electric increased its interest in the European lighting market, Tungfram, in turn, was reported to be expanding its interest into the Mideast. By yearend, discussions with Saudi Arabian officials were nearing a final agreement that would allow for construction of a lighting factory in the eastern part of Saudi Arabia.

India.—Production of tungsten concentrate in India was expected to increase appreciably as a result of a decision in early 1991 to transfer the operation of the Degana Tungsten Mine from Rajasthan State Tungsten Development Corp. to Hindustan Zinc. The Degana Mine is in the Nagore district of the State of Rajasthan and has yielded up to 20 metric tons of tungsten in concentrate annually. According to a

report in India's Minerals and Metals Review, the added investment by Hindustan in the mine was projected to raise the annual output of the mine to 330 metric tons of tungsten. The action taken at Degana was part of an overall expansion plan for India's tungsten industry to support the anticipated doubling of the country's demand for tungsten products by the year 2000.

International Tungsten Industry Association (ITIA).—In April 1991, CNIEC rejoined the ITIA. Although no official reason was given for this decision, industry analysts speculated that it was related to policy changes within China affecting the production and marketing of their tungsten products. After being an original member of the ITIA in 1988, CNIEC left the organization in 1989. The official reason given at that time for its departure was that the ITIA, being essentially an industry, consumer-based association, already had one of its subsidiaries, Zhuzhou Cemented Carbide as a member.

Italy.—Under new guidelines set forth in a National Mining Policy Law in July 1991, tungsten was included among a group of metals regarded as essential to the country's economy. In addition, tungsten was listed as a priority metal eligible for funding of mine exploration outside of the country. Exploration projects that will receive preference will be those that increase the security of supply and stabilize prices while still being compatible with continuing domestic production.

Portugal.—Beralt Tin and Wolfram Ltd. signed an agreement with General Electric Co., Euclid, OH, in mid-1991 to provide the latter company with specified quantities of tungsten concentrate over a 5-year period beginning in 1992. Through its Portuguese subsidiary, Beralt owns 80.55% of the Panasqueira Tungsten Mine near Fundao. A 75% share of Beralt was purchased by Minorco SA, Portugal, from Charter Consolidated Ltd., United Kingdom, in

October 1990. The agreement will permit General Electric to purchase a significant portion of Beralt's annual production of wolframite concentrate at undisclosed fixed rates as well as varying market rates.

At the beginning of 1991, Minorco officials announced plans for a mine-deepening program at Panasqueira that will allow access to additional tungsten reserves 60 meters below the present lowest level. The program was expected to be completed in about 1 year, although no specific time was indicated for it to be initiated.

Spain.—Efforts continued during 1991 to reopen the La Parilla Tungsten Mine in Extremadura Province. Spanish labor unions again voiced their desire to have the mine reopened, pointing to the fact that, in addition to providing employment in the largely rural province, it would be the sole source of scheelite concentrate within the European Community. The owners of the mine, Banco de Credito Industrial and Banco Espanol de Credito, reportedly provided reinforcement to the efforts to reopen the mine by applying for subsidies from the Spanish Economy Ministry's Regional Development Commission.

United Nations Conference on Trade and Development (UNCTAD).—The UNCTAD Committee on Tungsten (COT) convened its 23d session in Geneva, Switzerland, in November 1991. During the discussions of the Sessional Working Group, a presentation by a representative from the UNCTAD Secretariat's office provided an overview of the status of the world tungsten industry. Estimates of world consumption and production of tungsten ore concentrates continued to show a statistical surplus of supply over demand. Economic slowdowns in the world's major economies were expected, in the short term, to exercise a negative influence on both trade and prices in the tungsten market. Several delegations voiced their agreement with this analysis in their prepared market statements. Some commented further that the market

also was complicated by the fact that, in certain markets, the value-added intermediates were being sold at essentially the same price as the ore concentrates. Concerns also were expressed by certain delegations over the increasing use of protectionism in the market, citing as examples the recent U.S. and European Commission (EC) import relief measures against China. China, in its market statement, assessed the world supply-demand imbalance in tungsten as being caused only by the sluggish demand in major consuming countries and not by overproduction.

The need to improve transparency in the UNCTAD statistics was expressed repeatedly during the meeting. Comments by the former U.S.S.R.'s delegation indicated that statistics, particularly those from the Republic of Russia, would be improved in the near future. According to the information available at the time of the meeting, the delegates expected to be able to provide some recent production and consumption data from the Russian Republic in time for the 1992 meeting. Data on imports of tungsten materials were not expected to be available. Although exports of tungsten materials were insignificant and thus did not influence the market, data on such trade activity were expected to be available should appreciable quantities of tungsten be exported in the future.

In a continued effort to promote greater industry participation in the COT, two technical discussions were presented by industry representatives. The first, by Dr. Zhengji Tao, of Zhuzhou Cemented Carbide Works, China, provided a 10-year overview of research and development (R & D) activity in tungsten metal and tungsten carbide powder. The second, by Dr. W. D. Schubert, of the Chemical Technology Institute, Austria, provided information on current trends and R & D activities in materials technology as it relates to tungsten and tungsten alloys and the possible impact these activities will have on the end-user market.

The issue of market stabilization received very little discussion during the meeting but was retained as an item on

the provisional agenda for the next meeting.

Based upon discussions held during the previous session of the COT, the COT sought and was awarded designation as an International Commodity Body (ICB). This provided access to the account for funding developmental activities within the Common Fund under UNCTAD. As a result, a separate item was added to the provisional agenda for this 23d session to consider project proposals for submission and possible financing under this account. The UNCTAD Secretariat representative prefaced the discussion on project proposals with a brief overview of information obtained while attending an ICB instructional seminar in September 1991. The Secretariat's presentation offered valuable incites toward achieving efficient and effective methods of utilizing the resources from the Common Fund. Procedures and criteria were established for the appraisal of projects for submission to the Common Fund. The basic language of this document was derived from one prepared by another ICB, The International Cotton Advisory Committee. In addition, language was included ensuring that no financial obligations would accrue to the COT as a result of any project, nor would any liability be incurred on individual members of the COT in association with the funding of such project.

Three project proposals relating to improving methods for the production of cemented carbides were submitted by the delegation from China. The Secretary-General of the International Tungsten Industry Association, representing its members, presented several research ideas for possible expansion to project proposal form. These included the extension of testing programs to improve health and safety in the tungsten work environment and the acceleration of efforts to find new uses for tungsten-containing materials, for example, as catalysts, corrosion inhibitors, pigments, and electrical conductor materials.

According to the adopted procedures and criteria, none of the proposed projects from China was deemed ready for a decision by the COT toward a

funding recommendation. Some specific questions were presented by UNCTAD that pertained to the financial contribution by China to the projects and the potential participation by other countries in the projects. It was agreed that the other delegations would provide written comments on China's proposals through the UNCTAD Secretariat's office by January 31, 1992. Based on these comments, China would be required to submit its revised versions to the Secretariat by February 29, 1992. The revised versions would then be considered at an ad hoc meeting to be held in May or June 1992. Any other proposals submitted 4 months prior to the convening of the ad hoc committee would also be considered at that time.

Current Research

Several studies relating to the high-velocity-oxy-fuel (HVOF) thermal spraying method for applying tungsten carbide-cobalt (WC-Co) coatings were reported during 1991. An important characteristic of the process is that it effectively spreads the sprayed particles into a denser and more wear-resistant coating than is possible using alternative spraying processes such as plasma spraying. It has been used on gas-turbine aircraft engine components, including compressor vanes and blades, bearing housings, and shrouds. In recent studies, HVOF coated WC-Co deposits were produced having a superior wear-resistant, mirror-finished surface comparable to the lapped surface roughness of cemented tungsten carbide.¹ Results of other research showed that the HVOF process yielded WC-Co coatings with excellent machinability and abrasive strength that exhibited good cohesive strength and low internal stress levels.² Sliding wear tests performed on these WC-12Co coatings on steel demonstrated excellent coating properties and wear performance. Similar satisfactory results were obtained in wear tests on coatings prepared by a high-energy plasma process.³

Modifications to existing cemented carbide technology also were investigated

in order to improve the performance of cemented carbide end-use items. The addition of self-lubricating, hexagonal boron nitride powder to WC-6.5Co powder improved the sliding-wear resistance of the resulting sintered material when compared to conventional cemented carbide material under dry, sliding test conditions.⁴ This improved performance was expected to be applied beneficially in bearing materials and mechanical seal devices. In another research effort, use of ultrafine WC powder enabled the production of corrosion and wear-resistant carbide parts without the incorporation of a Co binder.⁵ Satisfactory mechanical and chemical properties were evident in molds and mechanical seal parts prepared from this binderless material. Further research also showed that the mechanical and thermal shock properties of Co-bonded WC parts could be improved by the addition of metallic particles to the WC-Co composite.⁶ For example, increased fracture toughness was achieved in hot pressed and sintered WC-10Co composites that had been interspersed with molybdenum and niobium particles. Indentation techniques used to measure crack growth resistance and to study the crack-particle interactions in these composites showed that crack growth was impeded specifically by large niobium particles.

During 1991, research efforts also focused on evaluating the applicability of certain tungsten-containing materials to specific space technology systems. Using a tungsten metal-lithium hydride radiation shield material, optimum shield design was determined for a nuclear thermal propulsion system.⁷ With this design, the radiation incident upon all components of the propulsion system, as well as the electronic control system, was able to be maintained within the acceptable limits required for reliable and safe space mission operations. Other researchers also reported on the unique advantage of using a tungsten-fiber-reinforced niobium matrix composite for space power system applications.⁸ Specifically, this composite was considered as component material in the fuel containment and structural

support systems. A related space technology study included determinations of the feasibility of using certain tungsten-base alloys as high-temperature materials in both thermal and electric nuclear propulsion systems.⁹

Results of investigations reported by several researchers indicated improvement in the quality of plasma sprayed WC-Co coatings. In one study, plasma sprayed coatings sealed with a nickel-phosphorus alloy by electroless plating and pressed isostatically at 600° to 1,000° C and pressures of 0.9 to 5.0 mega Pascals exhibited superior wear-resistance compared with the as-sprayed coatings.¹⁰ In another study, researchers reported that a post-deposition-heat-treatment/quenching procedure revealed improved adhesion of plasma sprayed WC-Co coatings to a steel substrate.¹¹ This was achieved through increased metallurgical bonding at the coating-substrate interface. Use of the heat-treatment/quenching method also resulted in a significant increase in the hardness of the WC-Co coatings. In subsequent bend and impact tests, the heat-treated coatings exhibited beneficial residual compressive stress. Abrasive wear tests showed enhanced durability of the coatings and improved wear performance compared to coatings not subjected to a post-deposition-heat-treatment/quenching procedure. In an additional study, the quality of WC-Co coatings produced with a high-velocity plasma spray process (Gator Gard) was enhanced by conducting the spraying procedure in a low-pressure inert environment.¹² This vacuum plasma spray (VPS) deposition process significantly increased the hardness of the coating and extended the practical spray distance by up to 5 times more than was possible when the high-velocity spray process was conducted in air.

A new method for production of an ultrafine (0.05 micrometer) WC powder was reported by researchers during the year.¹³ Carburization of the tungsten was achieved during a 10-minute reaction period in a microwave-induced carbon monoxide plasma, yielding 99.96% WC particles containing 0.04% free carbon. In addition to producing finer WC

particles, the process was significantly less energy intensive than that of conventional processes in which the WC is synthesized from the elements. The demand for submicron WC powder continued to increase in response to the need for the harder, stronger, and more impact resistant cutting and wear-resistant cemented carbide components that can be produced with the finer powder.

An advanced semiconductor production method using chemically vapor-deposited tungsten as the wiring medium was reported during the year.¹⁴ If proven successful, the new method reportedly could be employed to produce computer chips with 64 times greater memory capacity than the most advanced chips now in production.

OUTLOOK

Based upon apparent consumption data accumulated during the first half of 1992, the total annual demand for tungsten materials in the United States in 1992 was estimated to be about 9,600 metric tons of contained tungsten. This would represent a decline in apparent consumption of approximately 5% compared with that of 1991. According to industry reports, a slow economic recovery in 1992 would continue to hold down the demand for tungsten in key sectors such as metalcutting and metalworking but modest growth could be expected in certain specialty carbide sectors as well as mining and construction equipment. In addition to the effect of economic factors, any growth in tungsten demand will continue to be buffered by the effects of substitution in the cutting and wear-resistant component industries as well as by technological improvements within the industry that result in more efficient use of tungsten.

The changing political philosophies in the former U.S.S.R. and Eastern Europe will effectively decrease the world demand for tungsten in the short term as the transition from militarized to industrialized economies occurs.

Supplies of tungsten concentrate and intermediate materials for U.S. consumption are expected to be sufficient

in 1992 in spite of the continued lack of production of concentrates at domestic tungsten mines. The increase in consumer stocks of concentrate, imported during 1991, as well as the apparent oversupply of concentrates and intermediate tungsten products on the world market, will likely continue to serve the U.S. tungsten needs well into 1993.

VANADIUM

By Henry E. Hilliard

Mr. Hilliard, a physical scientist with more than 20 years' U.S. Bureau of Mines experience, has been the commodity specialist for vanadium since 1986. Domestic survey data were prepared by Lisa Harley, statistical assistant; and international data tables were prepared by Ronald L. Hatch, international data specialist.

The principal use of vanadium is as an alloying element in steel. The addition of small amounts of vanadium, often less than 1%, to an ordinary carbon steel can significantly increase its strength and improve both its toughness and ductility. Such high-strength low-alloy (HSLA) steels are attractive in the construction of highrise buildings, bridges, large-diameter pipelines, and automobiles because of the weight savings obtained. Vanadium-aluminum alloys of titanium are widely used in the aerospace industry. Oxides and chlorides of vanadium play important roles as catalysts in the production of sulfuric acid and other key organic chemicals.

The U.S. Bureau of Mines began reporting statistical data on vanadium in the metric system of units in the 1990 Annual Report. Throughout this report, data will be reported in kilograms (kg) and metric tons (tons) unless otherwise stated. The English system of units will no longer be used to report statistical data in official U.S. Bureau of Mines reports.

In 1991, steelmaking continued to account for more than 80% of domestic vanadium demand. Consumption declined for the third consecutive year from 4,100 metric tons in 1990 to 3,300 tons in 1991. Imports of vanadium raw materials decreased overall compared with those of 1990. Imports of ores, slag, and residues were the lowest since 1986. Exports also decreased sharply from the near record levels in 1989 and 1990.

The downward pressure on prices of vanadium that began in the later part of 1990 showed no sign of relenting in 1991 as demand in most end-use sectors,

especially specialty steels, continued to soften. In addition to the drop in demand brought about by the economic recession, new steel rolling technology, which can impart the same characteristics as were previously achieved by alloying steel with vanadium, had an adverse effect on demand. Columbium can be substituted for vanadium in many applications, and this is affecting vanadium requirements. The market also suffered from oversupply, with output exceeding demand by 2,268 tons or about 5 million pounds.

The pattern of vanadium use in the United States is not expected to change significantly in the near future, but the level of consumption will be subject to fluctuations in domestic and global steel production.

DOMESTIC DATA COVERAGE

Domestic consumption data for vanadium are developed by the U.S. Bureau of Mines from a voluntary survey of all known domestic consumers. In 1991, there were 83 responses to the consumption survey, representing 81% of the total canvassed. These 83 respondents are estimated to have accounted for 95% of total domestic consumption, or about 3,121 tons. The estimated consumption of nonrespondents, derived using their past consumption relationships, trends, and data from nonsurvey sources, was about 164 tons. The consumption quantity of 3,285 tons shown in table 1 is the U.S. Bureau of Mines' estimate of total U.S. (reported) vanadium consumption.

BACKGROUND

Definitions, Grades, and Specifications

The term ferrovanadium as used by the U.S. Bureau of Mines includes vanadium-carbon-iron-nitrogen proprietary alloys as well as the conventional forms of ferrovanadium. Some of the more common commercial products are listed in table 2. A standard specification for ferrovanadium has been developed by the American Society for Testing Materials (ASTM).¹

Aluminum-vanadium master alloys contain fixed ratios of vanadium to aluminum and are used in the manufacture of titanium alloys. Amounts of vanadium up to 1 weight-percent improve the strength of titanium-base alloys and promote their thermal stability in the presence of moderate amounts of aluminum. When amounts greater than 4 weight-percent are added, the titanium-base alloy can be significantly strengthened by heat treatment. The three most important commercial titanium alloys containing vanadium are Ti-6Al-4V, Ti-6Al-4V-2Sn, and Ti-8Al-1Mo-1V. The Ti-6Al-4V alloy presently accounts for more than 50% of the titanium-base alloy market.

Products for Trade and Industry

Vanadium is usually traded on the international market in the form of technical grade V_2O_5 and 50% to 80% FeV. Most world exports of vanadium

raw material are in the form of vanadium-bearing iron slag from China and the Republic of South Africa, while U.S. and Western European converters are the major importers of these materials. U.S. and Western European converters are the major exporters of downstream vanadium products such as vanadium oxides and FeV to the many small consuming countries. These converters also compete for the major markets for pentoxide and FeV exported to Japan and the Republic of Korea. Trade in ferrovanadium is dominated by the major European and U.S. converters. A large part of this trade is within Europe, but exports are also made to many other consuming countries, particularly by the Federal Republic of Germany.

Industry Structure

The vanadium industry has a five-tiered structure with facilities on six continents. As expected, mines and oilfields form the base of the structure (figure 1). Since 1979, an estimated 83% of world production has come from vanadiferous magnetite (Fe_3O_4). The principal sources of the magnetite ore were China, the Republic of South Africa, and the U.S.S.R. World vanadium production for 1987-91 is shown in table 17. The other 17% of the vanadium was recovered from other petroliferous materials and spent catalysts.

The second tier is a set of economically unrelated facilities that include (1) pig iron plants with slag recovery units, (2) elemental phosphorus smelters, and (3) generators of petroleum residues, fly ash, and spent catalysts that contain vanadium either as the active material or as a contaminant.

The third tier consists of (1) acid leaching plants with solvent extraction circuits and (2) salt roasting operations. Technical-grade V_2O_5 and NH_4VO_3 are the principal products at this level.

In order to have an easily marketable product, it is customary at this point to either convert the oxides into an alloy or upgrade their purity to greater than 98.5

weight-percent. The two traditional alloy products have been the 80 weight-percent ferrovanadium and 35 weight-percent aluminum-vanadium master alloy. Variations of five different reduction processes are currently in use throughout the world, with aluminum, carbon, or silicon serving as the reductant. These conversion and upgrading plants, which form the fourth tier of the structure, may be a considerable distance from the mills and slag plants and frequently blend feed materials to improve recovery.

Of the more than 30 privately owned vanadium companies, only 1, the Republic of South Africa's Highveld, operates facilities at all 4 lower levels and can be considered totally integrated. Highveld has plants that process vanadiferous magnetite ores from the Bushveld Igneous Complex. Two other producers, Shieldalloy Metallurgical Corp. and Stratcor, have extensive operations on the second, third, and fourth tiers. Shieldalloy traditionally used Highveld slag as its starting material for low vanadium grades of ferrovanadium.

The fifth tier is composed of producers of vanadium specialty alloys, high-purity vanadium metal, primary vanadium chemicals, and vanadium catalysts. Reading Alloys Inc., Akzo Chemical, and Teledyne Wah Chang Albany illustrate the diversity of operations at this level.

The Republic of South Africa is the world's largest producer of ore and vanadium-bearing slag. Its annual production of more than 17,000 tons is approached only by production in the U.S.S.R. The bulk of Soviet production is consumed internally or by other Eastern European countries. Other major producers include China and the United States. Canada, Japan, and Western Europe are heavily dependent on imports of vanadium slag and pentoxide from the Republic of South Africa. Any disruption of South African supplies could seriously upset the balance between vanadium supply and demand.

Geology-Resources

Vanadium is found in many parts of the world, usually in association with other minerals. There are few ores from which vanadium can be economically extracted as a single product. It is, therefore, often extracted as a byproduct or coproduct in the production of other elements, such as iron, phosphorus, or uranium. Increasing amounts are being recovered from petroleum residues and spent catalysts. The world also has extensive subeconomic resources of vanadium contained in oil sands, carbonaceous shale, and bauxite.

The crustal abundance of vanadium is estimated to be 100 to 150 parts per million (ppm), about twice that of copper, 10 times that of lead, and almost 100 times that of molybdenum.² As a result, trace vanadium mineralization occurs in a wide range of geologic provinces and environments. At the same time, ore deposits of vanadium are rare because much of the vanadium in igneous rocks occurs dispersed in the relatively insoluble trivalent state and is substituting for ferric iron in ferromagnesian silicates, magnetite, ilmenite, and chromite. Because of the substitutional phenomenon at the atomic level, vanadium is more abundant in mafic (those high in magnesium and iron) than silicic rocks. Gabbros and norites typically contain 200 to 300 ppm vanadium compared with 5 to 80 ppm for granites. When mafic rocks weather in a humid climate, the vanadium remains in the trivalent state or is weakly oxidized to the relatively insoluble tetravalent state. In either case, the vanadium is captured along with aluminum in the residual clays. Subsequent leaching of the clays can produce bauxite and lateritic iron ores that contain 400 to 500 ppm vanadium. When mafic rocks are intensely oxidized in an arid climate, some of the vanadium is converted to the pentavalent state. The pentavalent cation is considerably more soluble than the trivalent cation, is readily dissolved by ground water, and can be transported over long distances. This transport phenomenon can be observed in arid parts of Western Australia where carnotite precipitates from ground water in calcreted drainage systems.³ At

Yeelirrie, for example, thin films of carnotite were formed in the voids and cavities of river fill when ground water percolated through a tertiary river channel.

Organic materials frequently play a key role in the depositional process by helping to create a reducing environment. At many locations on the Colorado Plateau, carnotite, tyuyamunite, and other secondary uranium-vanadium minerals replace fossil logs and other carbonized plant debris. Some of the best examples of this phenomenon can be seen in the Monument Valley and White Canyon districts where uranium-vanadium ores have been deposited in paleochannels of the Shinarump Member of the Upper Triassic Chinle Formation. Fossils in the Shinarump indicate that the stream channels were cut into the underlying Moenkopi mudstones and then filled with sands, pebbles, and plant debris before the end of the Triassic Period 195 million years ago. Although the uranium-vanadium ores are associated with plant remains, the two elements were precipitated from aqueous solutions percolating through the stream channels long after the host sandstones and conglomerates had formed. The genesis and age of the mineralization remain controversial.

The role of vanadium during the formation of fossil fuels is obscure. There appears to be a relationship between the relatively high concentration of vanadium in coal and petroleum and the burial and subsequent degradation processes that apparently formed the fuels from organisms. The structures of the vanadyl porphyrins found in crude oil are approximately identical to the structures of chlorophyll (magnesium-centered porphyrins present in green plants) and hemoglobin (iron-centered porphyrins present in the red corpuscles of blood). The ratio of vanadium to nickel in crude oil is a function of the oxidation-reduction potential (Eh), the hydrogen ion activity (pH), and sulfide activity of the environment in which the oil source rocks were deposited. The two metals both form stable metallo-organic complexes in the high molecular weight fractions of

crude oil.⁴ Cleavage of these vanadium and nickel bonds will not occur unless the crude oil is subjected to a temperature greater than 300° C. As a result, the vanadium-to-nickel ratio remains constant for a specific reservoir even when the lower molecular weight components migrate away. The ratio is therefore useful in identifying unmetamorphosed crude oil from different depositional facies of the same source rock.

Technology

Mining.—In the United States, vanadium is recovered as a principal mine product, as a coproduct from carnotite ores, and from ferrophosphorus slag as a byproduct in the production of elemental phosphorus. Increasingly, it is also being recovered from petroleum refinery residues, fly ash, and spent catalysts. In China and the Republic of South Africa, vanadium is recovered as a byproduct of pig iron production from titaniferous magnetite.

Processing.—The steel industry accounts for more than 80% of the world's consumption of vanadium as an additive to steel. It is added to the steelmaking process as a ferrovanadium alloy, which is produced commercially by the reduction of vanadium pentoxide or vanadium-bearing slag with aluminum, carbon, or ferrosilicon.

The first stage in the processing of vanadium-bearing ore is the production of an oxide concentrate. The ore is crushed, ground, screened, and mixed with a sodium salt. This mixture is roasted at about 850° C to convert the oxides to water soluble sodium metavanadate. The vanadium is extracted by leaching with water and precipitated at pH 3 as sodium hexavanadate (red cake) by the addition of sulfuric acid. The red cake is fused at 700° C to yield a dense, black product that is sold as technical-grade vanadium pentoxide. Technical-grade vanadium pentoxide contains a minimum of 86 weight-percent pentoxide and a maximum 8 weight-percent sodium oxide. The red cake may be further

purified by dissolving it in an aqueous solution of sodium carbonate. Aluminum, iron, and silicate impurities precipitate from solution upon pH adjustment. Ammonium metavanadate is then precipitated by the addition of ammonium chloride. The precipitate is calcined to give a vanadium pentoxide product of greater than 99.8% purity.

Vanadium is extracted as a coproduct with uranium from carnotite by direct leaching of the ore with sulfuric acid. An alternative method is roasting the ore followed by countercurrent leaching with dilute sulfuric acid. In some cases, the first leach may be with a sodium carbonate solution. The uranium and vanadium are then separated from the pregnant liquor by liquid-liquid extraction techniques.

More recently spent catalysts have become a major source of vanadium. The catalyst may be either oxidation catalyst used in the production of sulfuric acid and maleic anhydride or fluid cracking catalyst used in refining petroleum. Vanadium is recovered by first roasting the material in a controlled atmosphere in order to solubilize the vanadium and other trace metals; e.g., molybdenum and nickel. It is then milled, leached, and filtered to enable the separation of solids from the solution containing vanadium. The solutions go through various precipitation steps prior to the precipitation of vanadium as ammonium metavanadate, which is then decomposed and fused to form V₂O₅ or used directly to make other vanadium chemicals.

In China and the Republic of South Africa, vanadium is concentrated in slag resulting from the production of pig iron from magnetite ore. The ore, containing 1.5% to 2.5% vanadium pentoxide, is partially reduced with coal in rotary kilns. The ore is then melted in an enclosed furnace that produces a slag containing most of the titanium and pig iron containing most of the vanadium. After the titanium-bearing slag is removed, the molten pig iron is blown with oxygen to form a slag containing 12 to 24 weight-percent vanadium pentoxide. The slag is separated from the molten

metal and may then be used as a high-grade vanadium raw material in the usual roast-leach process.

In the aluminothermic process for preparing ferrovanadium, a mixture of technical-grade pentoxide, aluminum, iron scrap, and a flux are charged into an electric furnace, and the reaction between aluminum and pentoxide is initiated. The reaction is highly exothermic, producing very high temperatures. The temperature can be controlled by adjusting the particle size of the reactants and the feed rate of the charge and by using partially reduced pentoxide or by replacing some of the aluminum by a milder reductant. Ferrovanadium containing up to 80 weight-percent vanadium can be produced by this method.

Ferrovanadium can also be prepared by the thermit reaction, in which vanadium and iron oxides are coreduced by aluminum granules in a magnesia-lined steel vessel or in a water-cooled crucible. The reaction is initiated by a barium peroxide-aluminum ignition charge. This method is also used to prepare vanadium-aluminum master alloys for the titanium industry.

The production of ferrovanadium by the reduction of vanadium concentrates with silicon involves a two-stage process in which technical-grade vanadium pentoxide, ferrosilicon, lime, and fluorspar are heated in an electric furnace. An iron alloy containing about 30% vanadium but undesirable amounts of silicon is produced. The silicon content of the alloy can be reduced by adding more pentoxide and lime to effect the extraction of most of the silicon into the slag phase. An alternative process involves the formation of a vanadium-silicon alloy by the reaction of vanadium pentoxide, silica, and coke in the presence of a flux in an arc furnace. The molten metal reacts with vanadium pentoxide yielding ferrovanadium. The silicon reduction method has not been used extensively.

A process developed by Foot Mineral Co., Cambridge, OH (now Shieldalloy Metallurgical Corp.), has been used to produce tonnage quantities of ferrovanadium. This process involves the

reaction of vanadium-bearing iron slag with silica, flux, and a carbon reductant followed by refinement by vanadium pentoxide. The reaction takes place in a submerged electric arc furnace yielding a ferrovanadium alloy containing about 40 weight-percent vanadium, 3.5 weight-percent silicon, 3.8 weight-percent manganese, 0.1 weight-percent carbon, and the remainder iron.

Substitutes

Various metals, such as columbium, manganese, molybdenum, titanium, and tungsten, are, to some degree, interchangeable with vanadium. So far there are no substitutes for vanadium in the all-important aerospace titanium alloys, which were used in jet engine mountings and wing structures. High-purity vanadium compounds were used as catalysts in the production of sulfuric acid, maleic anhydride, and in pollution control technology where it was required to remove hydrogen sulfide gas from flu gases (Stretford Process). In only a few chemical applications could platinum and nickel replace vanadium catalyst.

Economic Factors

Prices.—Highveld Steel & Vanadium Corp. of the Republic of South Africa produced more than 60% of market economy countries' vanadium in 1991. Even though the bulk of Highveld's production was in the form of vanadium-bearing iron slag, its pentoxide price was seen as the benchmark worldwide, with other suppliers indexing some of their contracts on the price. South African producers, who set their prices quarterly, were charging \$2.95 per pound for V_2O_5 in first quarter 1991. By the fourth quarter, the price had fallen to \$2.60 per pound; spot, or free market, prices were even lower at about \$2.35 per pound. Highveld's prices were down from \$7.50 per pound in second quarter 1989 and \$5.00 in first quarter 1990. In Europe, the price of FeV hovered around the \$11.00 per kilogram vanadium content level for most of the year. The failure of the prices to advance as expected was

attributed to the continuing depressed demand for steel in Europe and the United States. Slack demand in the FeV market was balanced by reduced output from European converters and also by the fall in free market supplies of South African V_2O_5 . The poor performance of vanadium prices over this period reflected an oversupplied market and low demand as major consumers reduced their usage of vanadium.

Tariffs.—U.S. import duties on selected vanadium items as of January 1, 1991, are listed in table 3. The tariff listing includes rates for both most-favored-nation (MFN) and non-MFN status.

Operating Factors

Environmental Requirements.—Because some segments of the geochemical cycle of uranium and thorium coincide with the vanadium cycle, the environmental considerations of vanadium mining are frequently linked to the management of radioactive mine wastes. In addition to careful placement and containment of tailings ponds, special attention must be given to preventing or limiting radioactive contamination of ground water aquifers and to the impoundment and long-term storage of mill tailings and mine waste to control radon daughter exhalation.

In 1982, the Environmental Protection Agency (EPA) published a regulation dealing specifically with the mining of both vanadium ores and uranium-radium-vanadium ores.⁵ Under these rules, the concentration of uranium in mine drainage must be less than 4 milligrams per liter per day for 30 consecutive days. In addition, the U.S. Nuclear Regulatory Commission has issued two regulatory guides dealing with personnel monitoring at uranium mills and processing facilities. The two guides delineate techniques for performing a bioassay on workers routinely exposed to airborne yellowcake (U_3O_8) or airborne uranium ore dust.⁶

In October 1983, EPA published rules dealing with the stabilization and long-term control of mill tailings at inactive

uranium-vanadium processing sites.⁷ These rules, which took effect on December 6, 1983, required uranium-vanadium mill operators to install plastic liners or other protective barriers under their tailings piles to prevent uranium, its radioactive daughter products, and nonradioactive toxic substances such as selenium from contaminating ground waters. Each tailings pond was required to have an earthen cover to minimize emissions and prevent erosion of the sandy surface by wind and rain. The rules also limited radon release from the surface of the pile to 20 picocuries per square meter per second.

Toxicity.—Vanadium compounds are irritants chiefly to the conjunctiva and respiratory tract. Prolonged exposure may lead to respiratory irritations with mucus discharge and lower respiratory tract irritation with bronchitis and chest pains.⁸ Other noted effects of vanadium and its compounds have included contact dermatitis, conjunctivitis, and discoloration of the tongue. Vanadium in high concentrations may alter metabolic processes in animals and humans. The reported toxic effects of exposure to vanadium compounds have been acute, never chronic. Toxic effects vary with the compound involved; e.g., vanadium oxytrichloride (VOCl_3) liberates hydrogen chloride gas, and the oral lethal dose (LD_{50}) for V_2O_5 dust in rats is 23 milligrams per kilograms of body weight.⁹ The lethal dose value is used to express the toxicity of many compounds and is determined by experiment. As used here, it is milligrams of V_2O_5 per kilogram of body weight (taken by mouth) that is lethal to 50% of the experimental animals.

Vanadium metal and its alloys pose no particular health or safety hazard, but they do react violently with certain materials, including bromine trifluoride (BrF_3), chlorine, and some strong acids. The toxicity of vanadium alloys depends upon other components in the alloy.

The adopted threshold limit values for time weighted averages for airborne vanadium, including oxide and metal dusts of vanadium, is 0.5 milligrams per

cubic meter; the value for fumes of vanadium compounds is 0.05 milligrams per cubic meter. These limits are for normal 8-hour workday and 40-hour workweek exposures. The short-term exposure limit is 1.5 milligrams per cubic meter for dust.¹⁰ The ammonium salts of vanadic acid and vanadium pentoxide have been listed as toxic constituents in solid wastes under the Resource Conservation and Recovery Act.¹¹

ANNUAL REVIEW

Legislation and Government Programs

In July, Department of Defense officials issued a report calling for cutting the National Defense Stockpile (NDS) in half. The report revealed that, over time, the Department would like to reduce the stockpile to \$5.6 billion from the current \$9.1 billion. If the Department of Defense plan had been approved by Congress, a number of commodities, including vanadium, would have been removed from the stockpile goal and would become excess material. In fiscal 1991, any stockpile disposal or acquisition had to be authorized by Congress. This new proposal would have given the Defense Logistics Agency (DLA) authority to set stockpile requirements, and thus buy and sell materials, without prior congressional approval. Department of Defense officials maintained that its new goals continue to meet the requirements for a 3-year conventional war, based on current data. The plan would have taken place at the end of September. The U.S. mining industry and foreign governments dependent on mineral revenues opposed any attempts to dispose of commodities even though DLA maintained its sales would not significantly disrupt the market. Likewise, many of the acquisitions faced opposition from special interest groups who would like to use the money elsewhere. The Department of Defense based its recommendations on the fact that major realignments in the perceived threat of war with the U.S.S.R. and short-term stabilization of problems in mineral-rich Republic of South Africa

created a new war scenario and revised structure for stockpile materials. As a result of the changed threat, the current inventory of materials, valued at about \$9.1 billion, could be safely reduced to about \$5.6 billion, according to the Department of Defense. However, final legislation adopted by House and Senate conference negotiations in November mandated that defense stockpile disposals and acquisitions for fiscal 1992 continue to be limited and monitored by Congress. Disposals must still be balanced equally by acquisitions and upgrades, but at a level that is 20% lower than that in 1990.

In December 1990, the Government of Argentina petitioned for duty-free treatment for ferrovanadium (HTS subheading 7202.92.00) under the General Systems of Preferences (GSP). In its request, Argentina stated that (1) this product has not been exported to the United States; (2) duty-free treatment of this product was accorded to certain other countries under the Caribbean Basin Economic Recovery Act and the United States-Israel Free-Trade Agreement; (3) the U.S. steel industry would benefit from a lower priced product; and (4) duty-free treatment would more than double the current Argentinean production level, thereby increasing (Argentinean) employment. The list of materials accorded GSP status is revised annually.

Opposing Argentina, Affiliated Metals and Minerals Inc. argued that (1) duty-free treatment would likely drive one of the few domestic producers out of the market by adding another competitor to a small-size market, and (2) duty-free imports of FeV would increase the level of unused industry capacity and cause unemployment in this labor-intensive industry. Shieldalloy and U.S. Vanadium also opposed the petition, noting that FeV has been treated by the U.S. Government as a "strategic and critical" mineral in the NDS. According to these producers, extending duty-free treatment would only serve to further decrease domestic FeV production and increase U.S. dependency on foreign sources. The petition was denied by the U.S. Trade representative in February.

Strategic Considerations

Vanadium is classified as a strategic and critical material because of the significant import dependence of the United States for its vanadium supply and because of the essential use of vanadium in equipment for defense, energy, and transportation.

Steel producers in the market economy countries (MEC) of the United States, Japan, and Western Europe shared a common concern about lack of economically viable domestic vanadium raw materials. Also, MEC vanadium supply was from only a few sources, chiefly China and the Republic of South Africa and from just three or four suppliers in these countries. China was expected to soon become a net importer of vanadium, leaving only South Africa and perhaps the Commonwealth of Independent States as the only major sources. Japan and Western Europe are more heavily dependent on imports than the United States.

The status of goals and inventories of vanadium materials in the NDS at the end of 1991 is given in table 4. No changes in goals were made. However, U.S. Vanadium Corp., Hot Springs, AR, completed the upgrade of 1.93 million pounds of stockpiled V_2O_5 to Grade B fused flake.

Issues

Prior to about 1984-85, more than one-half of the vanadium mined in the United States was recovered as a coproduct with uranium from sandstone mined on the Colorado Plateau. Companies recovering vanadium from uranium ores were hurt by the downturn in nuclear powerplant construction in the aftermath of the Three Mile Island nuclear reactor accident and the subsequent reduced demand for enriched uranium. Worldwide recession, high interest rates, and the cancellation of powerplant construction in the United States caused the Nuclear Exchange Corp. (Nuexco) exchange value of uranium oxide (U_3O_8) to decline from \$40.75 per pound in early 1980 to less than \$10.00 per pound in 1991. The

exchange value is Nuexco's judgment of the price at which transactions for significant quantities of uranium concentrates could be concluded on a specified date. Value is based on bids to buy and offers to sell, as well as recently completed and pending transactions.

A direct result of the price decrease was mill closing and decommissioning, personnel cutbacks, and canceled development and expansion plans. This unstable situation had the potential for creating a much higher degree of dependence by the United States on South African and Chinese imports. However, some of the slack was taken up by increased recovery of vanadium from petroleum residues, including spent petroleum catalysts. Recovery of vanadium from this source began during the 1973 and 1978 Arab oil embargoes. After being cut off from light crude from the Middle East, refiners were forced to process crude oils with high-sulfur and high-metal content. The trend toward heavier, sour crude and a tightening of sulfur restrictions on fuel products led to the development of the "Flexicoking" process, which concentrated 99% of the metals in the feed in a 2% solid purge from the system. This material has become an important source of vanadium, and in some instances, molybdenum and nickel. At the same time, the combustion of increasingly metalliferous fuel oils at powerplants created a second source of feed materials in the form of fly ash and boiler scale. More V_2O_5 produced in the United States is now being recovered from refinery residues, fly ash, boiler scale, and spent catalysts than ever before. In 1991, the United States recovered 2,250 tons of vanadium oxides from these petroliferous materials, most of which were imported. While this is essentially unchanged from that of 1990, production from residues and spent catalysts as a percentage of reported consumption increased from 56% to 69% in 1991.

Production

Vanadium is often considered to be an uncommon element, but actually its

abundance in the Earth's crust is comparable to or greater than that of copper, nickel, and zinc. Although there is a plentiful supply of vanadium, it is one of the most expensive elements to recover. In most cases, whether vanadium occurs as a primary ore, a coproduct, or in petroleum, the vanadium content of the material usually runs 1.5% V_2O_5 or less. V_2O_5 is the principal starting material for the production of all vanadium compounds. Therefore, when one speaks of vanadium production or the supply side of the industry, only those involved in the production of V_2O_5 should be included.

At yearend, there were five companies producing V_2O_5 in the United States. Of these, one was a totally integrated company that produced V_2O_5 , vanadium chemicals, FeV, and other vanadium alloys. The others produced mainly V_2O_5 from a variety of raw materials.

Consumption, Uses, and Stocks

Vanadium has been used as an alloying element in steel since 1902, when it was first added to tool steels used for high-speed machining operations. It was found that vanadium prevented grain growth in tungsten-bearing steels and enabled the steels to maintain their hardness at the high temperatures generated in tool steels during high-speed machining. Vanadium is also widely used in high-temperature steels used in steam powerplants. Chromium-vanadium steels are used for steel pipes and headers, and molybdenum-vanadium steels are used for rotors because of the high creep resistance produced by vanadium carbides.

Metallurgical applications accounted for more than 95% of vanadium consumption, with about 83% for steelmaking. Relatively small quantities of vanadium were used for alloying with nonferrous metals, mostly aluminum. Nonmetallurgical applications included catalysts, ceramics, and vanadium chemicals. The dominant nonmetallurgical use was in catalyst. Much less was consumed in ceramic and electronics (batteries).

Reported consumers' and producers' stocks of vanadium oxides, metal, alloys, and chemicals at yearend totaled 935 tons of contained vanadium; at yearend 1990, the number was 1,082 tons.

Foreign Trade

Overall U.S. exports of vanadium products were down by more than 50% in 1991. In decreasing order, Canada, Belgium-Luxembourg, Brazil, Japan, and Mexico were the leading importers of U.S. materials. Most countries imported almost exclusively V_2O_5 . Canada, the Republic of Korea, and Venezuela also imported substantial quantities of FeV. Exports of V_2O_5 totaled 700 tons gross weight, less than one-third of 1990 exports. Exports of FeV totaled 178 tons gross weight, down from 334 tons in 1990.

Imports for consumption of downstream vanadium compounds increased slightly in 1991; imports of raw materials, slag, ash, etc., were down sharply. FeV imports totaled 524 tons gross weight, up from 305 tons in 1990. The imported FeV averaged 81% vanadium, with a mean custom value of \$12.79 per kilogram of contained vanadium, down from \$13.57 in 1990. Canada was the leading source of FeV, with shipments of 131 tons, followed by Austria, 109 tons, and Belgium, 71 tons. Vanadium pentoxide imports totaled 133 tons of contained vanadium, up from 83 tons in 1990; the average declared value was \$3.22 per pound of contained vanadium, down from \$5.15 in 1990. Imports for consumption of vanadium-bearing slag totaled only about 178 tons of contained vanadium, all from the Republic of South Africa. An assortment of petroleum residues, spent catalyst, and fly ash totaling about 1,300 tons of V_2O_5 was imported from a variety of countries.

World Review

Industry Structure.—Vanadium was traded on the world market in vanadium-bearing slag, petroleum residues, technical-grade V_2O_5 , and FeV. The

Republic of South Africa was the largest producer with more than 60% of the MEC market. Most of the Republic of South Africa's exports of vanadium were in the form of vanadium-bearing iron slag. Japan and Western Europe were the chief importers of this material. The United States imported slag from the Republic of South Africa, and fly ash, petroleum residues, and spent catalyst from many other sources. The large importers of vanadium raw materials, e.g., slag, were the chief exporters of V_2O_5 , FeV, and other downstream vanadium products. This trade was dominated by a few large West European converters who competed not only within Europe, but also exported to many large and small consumers outside of Europe. Reliable statistics from the U.S.S.R. were not available, but it is believed to be second only to the Republic of South Africa in vanadium production. All Soviet trade was thought to be with other East European countries.

Capacity.—The data in table 15 are rated capacity for mills producing vanadium oxides as of December 31, 1991. Included in this data is capacity to produce vanadium-bearing slag and petroleum coke. Rated capacity is defined as the maximum quantity of product that can be produced on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgement of the author, can be brought back into production within a short period with minimum capital expenditure.

Australia.—Western Australia has large deposits of magnetite ores containing vanadium and titanium. The deposits consist of a large magnetite-rich intrusive rock. A chemical analysis of the material, undertaken more than 20 years ago, found about 0.32% V_2O_5 . This deposit was ignored for many years because of the low price of vanadium.

As the price of vanadium climbed from 1987 through 1989, Precious Metals Australia (PMA) reevaluated the deposit at its wholly owned Wagoo Hills Project in the Murchison District of Western Australia. This time, the titanium and vanadium mineralization was found to grade up to 0.93% V_2O_5 and 12% titanium dioxide (TiO_2). The deposit lies within a distinct and reasonably well-defined geologic structure known as Shepard's Discordant Zone (SDZ), which extends along a 10-mile strike within PMA's property. The latest sampling was carried out across the SDZ in areas of abundant titanomagnetite surface rock with samples collected at 2- and 6-yard intervals. Analysis of the samples indicated that the region was likely to contain up to 40 million tons of high-iron magnetite ore containing an average of 0.75% V_2O_5 and as much as 12% titanium.¹²

Preliminary metallurgical work suggested that a magnetite concentrate could be produced from grinding and magnetic separation. A \$70 million mine development and processing plant was planned to produce about 2,100 tons of V_2O_5 per year. PMA was determined to continue the development of this project despite low vanadium prices in 1990 and even lower prices in 1991. PMA officials believed Australian mining and materials handling technology to be more efficient than methods used in the Republic of South Africa. They also believed that the Australian ore would be easier to process. PMA has the disadvantage of higher energy costs.

Canada.—Agra Industries Ltd. of Saskatoon, Saskatchewan, teamed with Renzy Mines Ltd. and Fairfax Financial Holdings Ltd. of Toronto, Ontario, to construct a vanadium pentoxide facility at Fort McMurry, Alberta. The plant, which cost about \$14 million, was designed to extract about 2.5 million pounds per year of V_2O_5 from waste fly ash produced by the Suncor Inc. oil sands plant.¹³

Carbovan began production of vanadic acid (HVO_3) in September 1990 and shipped the material to consumers in

Canada and the United States. After less than a year of operation, Carbovan suspended operations indefinitely. Twenty-eight workers were laid off, and equipment was mothballed in May. The stoppage was attributed to the depressed market for vanadium that eroded revenues to the point where the plant was no longer economically viable. Agra Industries, the primary shareholder in the project, noted that free market V_2O_5 was selling for only \$2.50 per pound in May, well below Carbovan's cost of production. In addition to low V_2O_5 prices, high interest rates and the high value of the Canadian dollar were also named as reasons for the closure.

South Africa, Republic of.—Total vanadium production, estimated at about 24,000 tons as V_2O_5 , declined for the second consecutive year. Production in 1990 was reported to be 30,535 tons.¹⁴

After about 2 years in the market, Union Steel Co. (Usko) quit the vanadium business and sold its vanadium assets to Rhombus Vanadium (Rhovan) for the nominal sum of R1.0. Soon after the sale Rhovan announced that its vanadium mine and the Usko plant would be closed indefinitely. Under terms of the sale agreement, Usko, which invested about R60 million in its vanadium plant, paid Rhovan R19 million in cash for what was described as damages for cancellation of Rhovan's 20-year contract to supply Usko with 250,000 tons per year of magnetite. The payment was to be made by March 31, 1992, and included interest. Rhovan officials did not rule out the possibility of reopening the mine and plant at some later date, stressing that it possessed large, high-quality reserves, and now a plant to process them into V_2O_5 . The plant had a theoretical capacity of 19.8 million pounds V_2O_5 per year. The plant, which was commissioned in September 1990, began production at the intermediate rate of 3.6 million pounds per year and eventually reached 6 million, far short of its design capacity. Continuous technical problems and the low price of V_2O_5 caused Usko to suffer large losses and the eventual sale of its vanadium operations. Meanwhile,

Vanadium Technologies (Vantec), formerly the vanadium interest of Vansa Vanadium, expected to complete modification of its V_2O_5 plant in early March 1992. The modifications were designed to improve operating efficiency. Coincidentally, they will also increase V_2O_5 capacity by about 33%. Production from the plant was expected to reach the market in the second quarter of 1992.

Vansa's vanadium operations had been idle since November 1990 when the company took the view that the vanadium market was severely depressed and no improvement could be seen in the short- or medium-term. Vantec gambled that despite current market conditions, the plant could be a viable operation in the long-term.

Highveld Steel & Vanadium Corp., the world's largest vanadium producer, announced in August that it plans to locally convert a portion of its vanadium-bearing slag output into V_2O_5 . The company will spend R10 million at its Vantra division (closed since August 1991) to enable up to 20% of its slag output to be converted to V_2O_5 . Highveld assured its slag customers in Europe, Japan, and the United States that the move would not affect its commitment to supply them with slag.

Other established producers in the Republic of South Africa apart from Highveld are Vametco in Bophuthatswana and Transvaal Alloys, which produced V_2O_5 and other vanadium chemicals. The Republic of South Africa's domestic consumption of vanadium was believed to be about 1% of its total production.

OUTLOOK

An economic recession held various world economies and the world vanadium industry in check during 1991. A number of signs point to impending recovery. However, the end of any economic slowdown would take time to affect the vanadium industry. If the turnaround were to begin in early 1992, it would be late in the year before the vanadium industry would see a return to profit and growth.

Some realignment and restructuring of the industry took place in 1991, with the shutdown of plants, acquisitions and divestiture of businesses, and idling of plant capacity—a trend likely to continue throughout 1992. In short, 1992 promises to be a year of rebuilding for the vanadium industry. It will be a year for rebuilding markets and thus sales, earnings, and profitability.

Any upturn in the economy will help the vanadium industry, but it is not likely to see the growth rate prevalent in the late 1980's, and the vanadium industry will probably lag the general economy in turning around. Working against rapid turnaround are a number of factors, including low demand for vanadium in still weak, major end-use markets. Chief among these is the steel industry (construction and automobiles). Commercial construction is very weak and will continue to be so for some time as vacancy rates in office buildings remain high across the country. There are some hopeful signs in the residential market. The auto industry, on the other hand, seems unable to fully rebound. Throughout the year, sales of domestically produced automobiles were weak, down 20% from the same period in 1990. The constraints on demand have had a number of deleterious effects on the vanadium industry, including lower capacity utilization and prices. Some vanadium capacity, the Precious Metals Australia project for example, still was expected to come on-stream in the near future, thus almost guaranteeing that capacity use is not going to rebound as the industry would like.

World demand is forecast to increase by an average of 2% per year, with total world demand reaching 45,000 tons by the year 2000. World production in 1991 was estimated to have been more than 30,000 tons, including about 2,300 tons produced in the United States from petroleum residues and spent catalysts. U.S. production from domestic ores and concentrates was not reported.

Long-term prospects for this highly cyclical industry depend on a number of factors. Producers will certainly be adversely affected by any future

economic downturn. Because of restructuring and downsizing that occurred in the industry during the last recession, the industry will be better able to cope with a recession than it was in the early 1980's. Traditional forces, such as the demand for motor vehicles and machinery, the level of economic activity, and the use of substitute materials, will continue to be of central importance. The strength of the U.S. dollar and its trade effects will also influence the industry's long-term future.

More than 95% of the demand for vanadium is driven by steel and nonferrous metallurgical applications. This dependence of the vanadium industry on the demand for steel products is not likely to change in the near future. The remaining demand is driven by chemicals applications. The reader is referred to the outlook section of the Iron and Steel Annual Report for more information on the long-term outlook for the steel industry.

Total	3,003	3,678	3,278	3,197	3,139
Grand total	33,045	35,409	35,945	33,803	29,574

^aEstimated. W Withheld to avoid disclosing company proprietary data; not included in "Total."

¹In addition to the countries listed, vanadium is also recovered from petroleum residues in Germany, the U.S.S.R., and several other European countries, but available information is insufficient to make reliable estimates. Table includes data available through July 9, 1992.

²Production in this section is credited to the country that was the origin of the vanadiferous raw material.

³Includes production for Bophuthatswana.

⁴Data on vanadium content of vanadium slag are estimated on the basis of a reported tonnage of vanadium-bearing slag (gross weight) multiplied by an assumed grade of 14.1% vanadium.

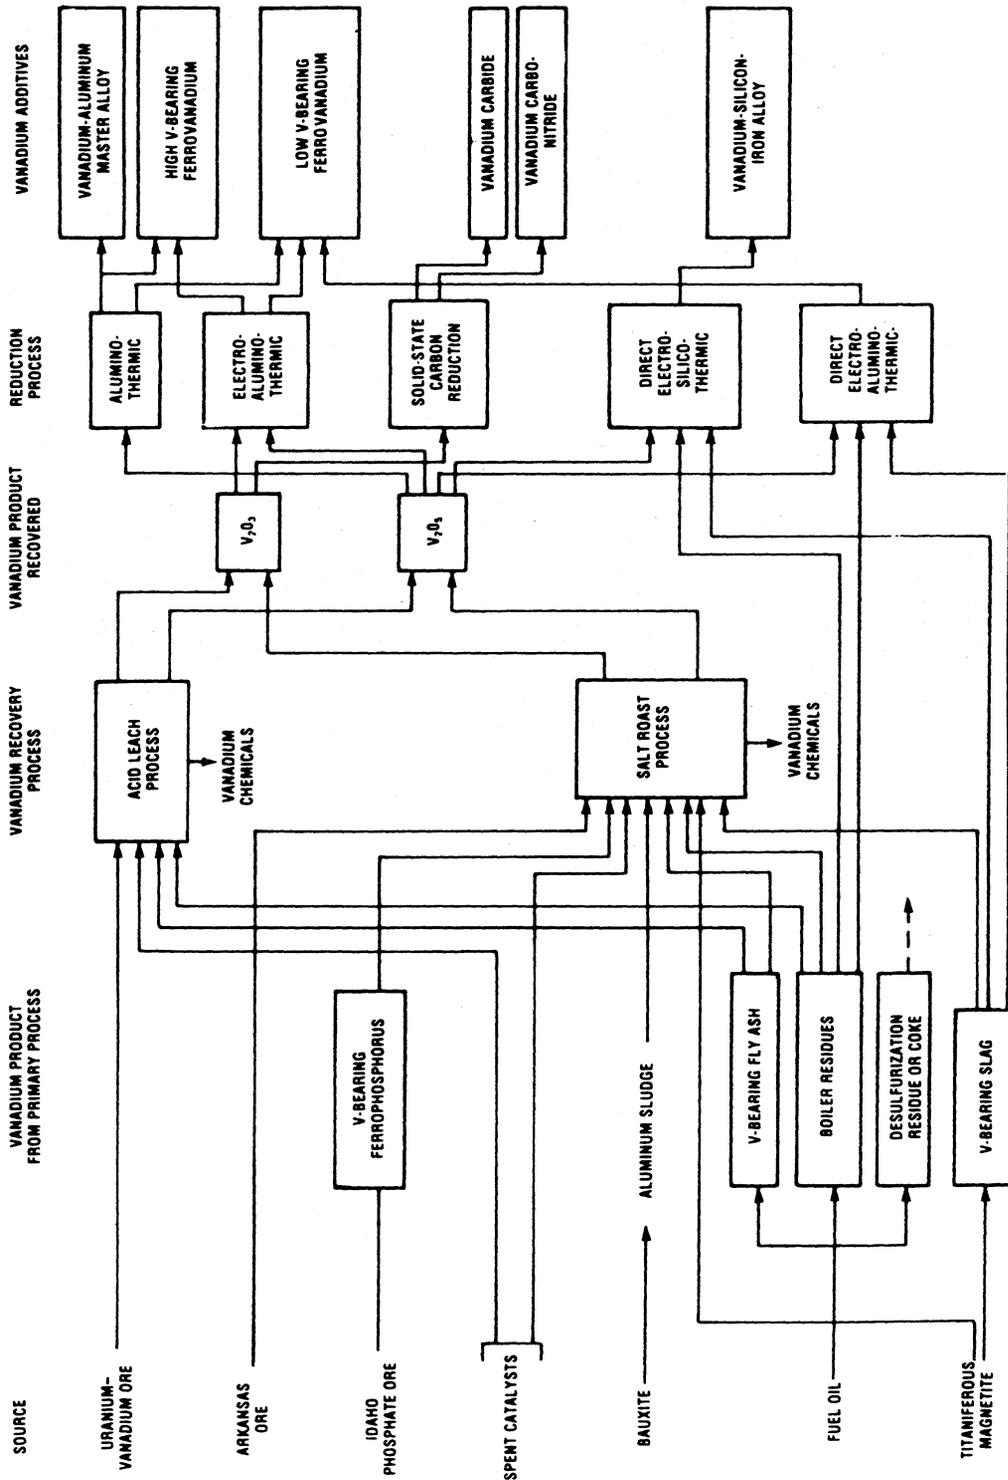

⁵Reported figure.

⁶Excludes U.S. production.

⁷Production in this section credited to the country where the vanadiferous product is extracted; available information is inadequate to permit crediting this output back to the country of origin of the vanadiferous raw material.

GENERALIZED FLOWSHEET FOR THE PROCESSING OF VANADIFEROUS RAW MATERIALS

FIGURE 1

VERMICULITE

By Michael J. Potter

Mr. Potter, a physical scientist, has been the commodity specialist for vermiculite since 1989. Domestic survey data were prepared by Tonya Hardin, statistical assistant; and the international data table was prepared by Brad Colquitt, international data coordinator.

Vermiculite is a micaceous mineral that rapidly expands upon heating to produce a low-density material. The expanded (exfoliated) product is used as lightweight aggregate and thermal insulation in construction applications; as a fertilizer carrier and soil conditioner in agriculture; and as a filler and texturizer for plastics and rubber, among many other uses.

DOMESTIC DATA COVERAGE

Domestic production data for vermiculite were developed by the Bureau from two separate, voluntary surveys, one for domestic mine operations and the other for exfoliation plant operations. Of the five known mine-mill operations (including one dismantled) to which a survey request was sent, data or estimated data were received from three operations by the canvass closeout date. Data for the two nonrespondents were estimated by the U.S. Bureau of Mines. Of the 31 known active exfoliating plants to which a survey request was sent, data were obtained from 26. This represented 63% of the total exfoliated vermiculite sold and used shown in table 1. The five nonrespondents' data were estimated by the Bureau using previous years' production levels. (See table 1.)

PRODUCTION

U.S. vermiculite concentrate sold and used was 185,000 short tons, a decrease from that of the previous year, according to the U.S. Bureau of Mines. The tonnage of exfoliated vermiculite sold and used was 150,000 tons, also a decrease from that of 1990. Construction activity continued to be at a reduced level,

lowering demand for vermiculite in that market sector.

W.R. Grace & Co. was believed to have been the largest domestic producer of vermiculite concentrate with sales of material from its Libby, MT, location (from stockpiles) and from its operation at Enoree, SC. Other producers during the year were Virginia Vermiculite Ltd., near Woodruff, SC, and in Louisa County, VA, and Patterson Vermiculite Co., Enoree, SC. South Carolina, with three operations, was the leading producing State for the fifth consecutive year.

Domestic sales of exfoliated vermiculite by 14 known producers came from 31 plants in 19 States. Of these plants, 20 in 16 States were operated by W.R. Grace. In descending order of output sold and used, the principal exfoliated vermiculite-producing States were estimated to be Ohio, South Carolina, Pennsylvania, New Jersey, California, Illinois, and Arkansas. (See tables 2 and 3.)

FOREIGN TRADE

Imports of vermiculite concentrate, an estimated 42,000 tons, were mainly from the Republic of South Africa.

WORLD REVIEW

The data in table 4 are rated annual capacity for vermiculite plants as of December 31, 1991. Rated capacity is defined as the maximum quantity of product that can be produced at a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine

operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgement of the author, can be brought into production within a short period of time with minimum capital expenditure. Plant capacity for vermiculite is based on engineering capacity provided by the companies or estimated by considering recent peak production during the past 5 years to be equal to rated capacity.

In Australia, Helix Resources NL was evaluating a vermiculite deposit at Bulbodney Creek, New South Wales. Drilling showed a measured resource of 770,000 tons of ore containing approximately 40% vermiculite. Testing thus far had indicated the absence of asbestos fibers.¹ (See tables 4 and 5.)

CURRENT RESEARCH

Sanitech, Inc. was testing a pilot circuit at a powerplant in Lorain, OH, to remove SO₂, NO_x, and residual particulates from flue gas. Granular sorbents containing magnesia and exfoliated vermiculite were being utilized. Regeneration would yield elemental sulfur, SO₂, and H₂S as byproducts.²

OUTLOOK

Some end uses of vermiculite, such as concrete and premixes, have been affected by a sluggish construction market and by substitute materials in recent years. The demand for vermiculite in agricultural uses in the near future should remain steady or show moderate growth. This is a reflection of new potting soils,

lawn care products, etc., and continuing interest in gardening and horticulture.

¹Estimated. ²Revised.

¹Excludes production by countries for which data are not available and for which general information is inadequate for formulation of reliable estimates. Table includes data available through July 13, 1992.

²In addition to the countries listed, Tanzania may produce vermiculite, but available information is inadequate to make reliable estimates of output levels, if any.

³Reported figure.

WOLLASTONITE AND ZEOLITES

By Michael J. Potter and Robert L. Virta

Mr. Potter, a physical scientist, has been the commodity specialist for wollastonite since 1976. Domestic survey data were prepared by Linder Roberts, statistical assistant.

Mr. Virta, a physical scientist with 16 years U.S. Bureau of Mines experience, has been the commodity specialist for natural zeolites since 1986. Domestic survey data were prepared by Linder Roberts, statistical assistant.

WOLLASTONITE

Wollastonite is natural calcium silicate and has a theoretical composition of $\text{CaO} \cdot \text{SiO}_2$. It has developed a significant role as a high-performance mineral filler in paint, plastics, and thermal board. It is used in asbestos replacement and in ceramics such as wall tile, where it promotes low shrinkage, good strength, low warpage, and fast firing.

Domestic sold and used data for wollastonite were developed by the U.S. Bureau of Mines by means of a voluntary survey. Both active operations responded, representing 100% of the total canvassed. Specific data were withheld to avoid disclosing company proprietary data.

The two U.S. producers were NYCO, a division of NYCO Minerals Inc., Essex County, NY, and R. T. Vanderbilt Co. Inc., Lewis County, NY. The tonnage of wollastonite sold or used in 1991 increased compared with that of the previous year.

NYCO approved a \$14 million appropriation to increase its wollastonite production by 50%. The 4-year program was to begin with the modernization and expansion of the company's 40-year-old plant in Willsboro, NY. New primary and secondary crushers would be installed and statistical process control added. NYCO was planning to open a new mine, Oak Hill.¹

Wollastonite is used as a filler in ceramic tile, paint, and plastics. It serves as an asbestos replacement in some

applications such as a reinforcement filler for boards and panels in various heat containment applications, including ovens, dryers, thermal ducting, and many other thermal applications. Wollastonite also replaces asbestos in certain cement formulations, in ceilings and floor tile, and in friction applications such as brake linings.

Prices from Industrial Minerals, December 1991, for wollastonite, exworks, converted to dollars per metric ton, were approximately \$278 to \$292 for acicular, minus 200 mesh; \$193 to \$204 for minus 325 mesh; and \$209 to \$215 for minus 400 mesh. Prices per metric ton for wollastonite, f.o.b. plant, bulk, were \$125 to \$177 for 200 mesh and \$235 for 325 mesh.

In Finland, the Partek Group is a major producer of industrial minerals. The company's primary minerals location is at Lappeenranta in southeastern Finland, near the Soviet border. At this site, wollastonite, cement, lime, ground and precipitated calcium carbonate, and mineral wool are produced. Wollastonite and calcium carbonate are coproducts of the same quarry. The ore contains 20% to 24% wollastonite, and the two coproducts are separated by froth flotation. Powder products are available in several sizes ranging from 70 mesh to 635 mesh. For plastics, especially polypropylene and polyamide, surface-treated grades are produced. Iron content averages 0.2% Fe_2O_3 . For filler grades the Fe_2O_3 content is restricted to 0.15%. Exports of wollastonite were approximately 70% to 75% of

production, with principal destinations being France, the Federal Republic of Germany, Italy, and Spain.²

A magnetic separator recently developed by International Process Systems, Inc., of Golden, CO, was said to have solved the problem of limited operating life of the very thin belts used in rare-earth magnetic roll separators. The new separator was developed for dry applications, with five basic magnetic strength levels being offered. Possible applications were said to include fine particles such as wollastonite and numerous other minerals.³

Wollastonite has unique properties, which should lead to continued growth in demand. In wall tile, a major end use, wollastonite promotes low shrinkage and warpage, good strength, and fast firing with decreased gas evolution. In the production of glass and glass fiber, wollastonite reduces energy requirements if used in place of limestone and sand. Another application, slag treatment for the steel industry, was being investigated.⁴ According to one source, growth in specialty surface-modified grades, fine and ultrafine grades, and high aspect ratio grades of wollastonite could exceed 10% annually.⁵

ZEOLITES

Zeolites are hydrated aluminosilicates of the alkaline and alkaline-earth metals. Approximately 40 natural zeolites have been identified over the past 200 years, the most common of which are analcime, chabazite, clinoptilolite, erionite,

ferrierite, heulandite, laumontite, mordenite, and phillipsite. Zeolites are commercially valuable because of their unique ion-exchange, molecular sieving, and catalytic properties.

Commercial zeolite deposits in the United States are associated with the alteration of volcanic tuffs in saline, alkaline lake deposits, and open hydrologic systems. The deposits are in Arizona, California, Idaho, Oregon, Nevada, New Mexico, Texas, Wyoming, and Utah. The major components of these deposits are chabazite, clinoptilolite, mordenite, and phillipsite. Erionite, orthoclase and plagioclase feldspar, montmorillonite, opal, quartz, and volcanic glass may be present in some deposits as minor components. The composition of these deposits was determined by the temperature and pressure of formation and the chemistry of the precursor volcanic glass and altering fluids. When the alteration process went to completion, the zeolite content of portions of some deposits approached 100%.

Conventional mining techniques were used in the mining of natural zeolites. The overburden was removed to permit access to the ore, and the ore was stripped for processing using front-end loaders or tractors equipped with ripper blades. The fractured ore was dried and then crushed using either jaw crushers or roller mills. The crushed ore was packaged directly for shipping or was screened to remove fine material when a granular product was required.

Nine companies mined or sold natural zeolites in the United States in 1991. Clinoptilolite was mined in Arizona, California, Nevada, New Mexico, Oregon, Texas, and Wyoming; chabazite was mined in Arizona. Total domestic production was 28,866 metric tons. Sales were 18,877 tons in 1991, an increase of 21% from that of 1990. (See table 1.)

Natural zeolites were used for pet litter, odor control, animal feed supplement, aquaculture, fertilizer carrier, desiccant, and wastewater cleanup, in decreasing order of consumption. Other applications include chemical carriers, aquarium filters, gas

adsorbents, water purification applications, and oil and/or grease adsorbent. The properties that made natural zeolites commercially valuable included ammonium adsorption (aquaculture, aquarium filters, odor control applications, pet litter, and water purification), moisture adsorption (desiccants, odor control, and pet litter), and ion-exchange capabilities (wastewater cleanup).

On November 5, 1991, the Environmental Protection Agency (EPA) issued a final rule under the Toxic Substances Control Act (TSCA) for erionite. Under section 5(a)(2) of TSCA, persons who intend to manufacture, import, or process erionite fiber for any new use must notify EPA at least 90 days before beginning that activity. EPA's decision is based on the results of animal inhalation and injection studies and epidemiological studies. The animal studies indicated that fibrous erionite was more potent than crocidolite asbestos for inducing malignant mesothelioma, a rare form of cancer. As a result of these studies, EPA classified fibrous erionite as a Category B1 or probable human carcinogen.⁶

The U.S. Bureau of Mines continued its research at the Reno Research Center on the removal of metals and other cations from water using natural zeolites. The ion-exchange capacities for 24 natural zeolite samples were determined for cadmium, copper, lead, nickel, and zinc. These samples were composed of chabazite, clinoptilolite, erionite, mordenite, and phillipsite. For cadmium, capacities ranged from 0.4 to 2.3 milliequivalents per gram; for copper, 0.33 to 2.73; for lead, 0.68 to 2.51; for nickel, 0.081 to 0.98; and for zinc, 0.12 to 1.68. Phillipsite had the largest exchange capacity for cadmium, copper, and lead. Erionite had the largest exchange capacity for zinc. Exchange tests for nickel are in progress. For low-ion concentration wastewater, phillipsite was found to be the most effective ion exchanger, reducing ion levels for aluminum, cobalt, copper, iron, manganese, and zinc to less than 1% of their original concentrations. The pH of

the solution increased from 1.8 to 8.5 after treatment. For high-ion concentration wastewater, clinoptilolite was the most effective zeolite tested, although the reduction in ion concentrations was significantly less than for low-ion concentration wastewaters. In another part of the research, attrition rates were tested. Samples containing chabazite exhibited the highest attrition. Samples containing clinoptilolite, erionite, and phillipsite exhibited the lowest attrition rates. Attrition rates are an important consideration for zeolite applications.

With the concern over the health risk posed by fibrous erionite increasing, there has been more interest in improving the methods of detection and quantification of this zeolite. Research conducted showed that erionite could be detected in tuffaceous rocks at levels of 100 parts per million to 500 parts per million using X-ray diffraction analysis. The low detection limits were accomplished by the use of long count times, profile fitting of the peaks, incident-beam Soller slits, and solvation of smectites with ethylene glycol. Count rates were increased by a factor of three when a solid-state silicon detector was used in place of the scintillation detector and monochromator system. Additionally, low-angle scatter of X-rays was reduced through the use of a helium atmosphere sample cell. These methods were applied to samples obtained from central Turkey. The detection and quantification of erionite in these tuffs was improved compared to estimates made using scanning electron microscopy. Tuffaceous samples from Yucca Mountain, Nevada, a possible site for a high-level radioactive water repository, were characterized to determine the distribution of erionite in the deposit.⁷

Paragon Resources NL obtained interests in several zeolite deposits in Lampung Province, Sumatra. One deposit near Mount Ratai is a high-purity clinoptilolite deposit. The company is testing the zeolite as an animal feed supplement and for odor control. Paragon Resources also has interests in two deposits near Panjang. One of the

deposits currently is being mined and sold for aquacultural applications.⁸

A method for determining reactions that occur within the zeolite structure was investigated. $\text{Mo}^{(12\text{CO})}_6$ was exchanged within the structure of zeolite Y, a large cavity zeolite, and the zeolite was annealed to equilibrate the system. ^{13}C O or $\text{P}(\text{CH}_3)_3$ was diffused into the cavity of the zeolite structure. The reaction between the $\text{Mo}^{(12\text{CO})}_6$ and the ^{13}C O or $\text{P}(\text{CH}_3)_3$ was observed using Fourier transform infrared spectroscopy to determine the reaction kinetics and mechanism. In one proposed mechanism, the $\text{Mo}^{(12\text{CO})}_6$ was released as a free molecule when excess $\text{P}(\text{CH}_3)_3$ was introduced into the α -cage of the zeolite structure. The attachment of the $\text{P}(\text{CH}_3)_3$ to the sodium ions lining the α -cage was thought to have caused the release of the $\text{Mo}^{(12\text{CO})}_6$. In the process of reattaching to the sodium ions, the $\text{Mo}^{(12\text{CO})}_6$ lost two CO ligands. The $\text{P}(\text{CH}_3)_3$ replaced the two lost ligands. The study demonstrated that kinetics studies of chemical reactions occurring in zeolite cavities is feasible.⁹

Research was conducted on recycling polypropylene using a zeolite catalyst. Polypropylene pellets were mixed with the synthetic zeolite H-ZSM-5 and heated to 350° C for 2 hours in a sealed vessel. The reaction products included C1 to C7 hydrocarbons, such as benzene, hexane, methane, propane, toluene, and xylene. A large portion of the reaction products were C3 and C4 hydrocarbons, which are components of gasoline.¹⁰

The synthetic zeolite industry continues to expand mainly in response to environmental concerns. J.M. Huber Corp. announced plans that it will reenter the synthetic zeolite field after an absence of several years.¹¹ Crosfield Chemicals announced that it would build a 55-thousand-ton-per-year zeolite facility in Illinois for detergent applications while Ethyl Corp. planned an expansion of its Houston plant.¹² PQ Corp. announced plans to build zeolite detergent plants in Georgia and Indiana.¹³

ZINC

By James H. Jolly

Mr. Jolly is a physical scientist (geologist) with more than 30 years of mining experience, including positions with Hecla Mining Co., Roan Selection Trust, and the U.S. Geological Survey. He has been a mineral commodity specialist for the U.S. Bureau of Mines for 19 years and the zinc specialist for the past 10 years. Domestic survey data were prepared by Tony E. Morris, statistical assistant. International production tables were prepared in collaboration with country specialists in the Bureau's Division of International Minerals.

Zinc is an essential element for human health and for the development and maintenance of modern society. It has been used by man in compounds, alloys, and metal for more than 2,000 years and has been surpassed only by aluminum, copper, and iron in historical quantity used. Zinc uses range from medicines and rubber to metal products. Its main use has been to provide corrosion protection for iron and steel. Since 1982, more than one-quarter million tons of zinc had been used to manufacture U.S. pennies.

The state of the domestic zinc industry was variable in 1991. Zinc mine output was the highest in 25 years, and smelters operated at high-capacity utilization rates. Refinery output was the highest since 1981. However, because of a slowing domestic economy, industrial consumption of zinc declined to its lowest level since 1983. The value of unmanufactured zinc exports, plus scrap, was about \$370 million, the same as that in 1990. Exported zinc concentrates accounted for 60% of the total export value and waste and scrap about 23%. The value of imports of scrap and unmanufactured zinc was \$785 million, down about \$300 million from that of 1990 and \$560 million from that of 1989, owing mainly to reduced demand and lower zinc prices.

Zinc prices tended to decline through midyear, but by yearend had returned to about the same level as at the start of the year. The yearend rise occurred despite rising stock levels and weakening world demand; some analysts attributed the

increase to manipulation of the London Metal Exchange (LME) market.

The figures for world mine and smelter outputs were, respectively, the second highest and third highest on record. In 1991, U.S. mines produced 7.5% of the world zinc output and U.S. smelters produced 5.3% of the world refined metal output. World zinc metal consumption was slightly less than 7 million tons for the second straight year, but nonetheless, 1991 was thought to be the fourth highest consumption year, historically. The United States continued to be the world's largest consumer of zinc metal, consuming about 13.3% of the world total. In 1990 and 1989, respectively, the United States accounted for 14.2% and 14.9% of world zinc metal consumption.

Zinc producers in North America dropped previous pricing mechanisms and adopted LME quotations as the basis for their cash and forward price transactions. The pricing change also led to the establishment of LME warehouses in the United States for good delivery of Special High Grade (SHG) metal registered by the LME.

DOMESTIC DATA COVERAGE

Domestic data for zinc were developed by the U.S. Bureau of Mines from five separate, voluntary surveys of U.S. operations. Typical of these was the "Slab Zinc" consumption survey sent out monthly or annually, depending on consumption quantities; small consumers are canvassed annually. Of the 288 operations to which the survey was sent, 263 responded, representing an estimated

91% of the total reported slab zinc consumption shown for 1991 in tables 1, 16, 17, and 18. Consumption by nonrespondents was estimated using prior-year consumption adjusted for industry trends.

Reported consumption of slab zinc, however, accounts for only 82% of apparent metal consumption. The difference between reported and apparent consumption is mainly the result of company requests over the past decade to be dropped from the canvass for company proprietary reasons or, principally, because of the work force burdens of filling out voluntary forms in addition to the plethora of current mandatory Government forms. To determine the distribution of apparent slab zinc consumption, table 15, the unaccounted for tonnage was prorated, based on known uncanvassed companies and use trends, and added to the reported quantities.

ANNUAL REVIEW

Strategic Considerations

Supply.—U.S. mine and smelter production and capacity can supply only about one-half of domestic zinc requirements in either normal or emergency periods. The domestic ore reserve base is large but could not be tapped adequately until after the first year or so in an emergency condition. Domestic smelter capacity is woefully lacking and by itself would be a limiting factor for increased refined zinc output. Inadequate zinc smelter capacity also

severely limits the Nation's ability to produce strategic and critical zinc byproduct elements such as cadmium, germanium, and indium.

Zinc mine production in Alaska accounts for about one-half of domestic output; however, all of this output is exported. Even if Alaskan zinc concentrates were redirected for U.S. consumption only, little domestic smelting capacity is available to process the material. U.S. mine output greatly exceeds smelter capacity, and in 1991, resulted in the net export of 336,000 tons of zinc in concentrate. An additional strategic factor related to Alaskan output is the fact that more than 80% of the State's production is inaccessible for 9 months of the year because of sea ice.

Although imports constitute a large proportion of U.S. zinc supply, about 60% of the zinc metal, concentrate, and compound imports comes from Canada and Mexico, and, therefore, the risk of supply disruption is low. Other traditional sources of zinc supply depend on sea transport, and the risk of supply disruption is considerably higher.

Stockpile.—A stockpile of zinc for national defense purposes has been maintained by the Government for more than 50 years. Materials in the National Defense Stockpile (NDS), managed by the Department of Defense since July 1988, can be released by the President if deemed necessary for defense or essential civilian purposes.

Just prior to and during World War II, the Government accumulated zinc stocks to ensure adequate supplies for national defense. Concerns related to national security after the war resulted in various stockpiling programs that evolved into the current NDS. The stockpile contained a record-high inventory of 1.44 million metric tons of zinc in 1959, but sales of zinc considered to be in excess of the stockpile goal reduced this inventory to 340,194 tons by the end of 1975. The most recent stockpile goal for zinc, 1.293 million tons, was established in April 1980, but no zinc had been purchased through 1991 to meet this goal. At the end of 1991, the zinc stockpile totaled

343,202 tons, including 2,625 tons of zinc contained in brass. Sharply lower goals for zinc have been proposed in the past few years, but none have been approved.

Production

Mine Production.—U.S. zinc mine output was up slightly despite the closing of five zinc-producing mining operations during the year. One new mine did, however, open early in the year. Formosa Resources Corp. completed underground development and mill construction at the Silver Butte Mine in Oregon and began production in April. Plans called for output of about 4,000 tons each of copper and zinc in concentrate annually from ores grading 3.57% copper, 2.98% zinc, and 1.7 ounces of silver per ton. Zinc output in concentrate was less than 1,000 tons in 1991.

The 20 leading U.S. zinc-producing mines accounted for more than 98% of production, with the 5 leading mines accounting for 60%. Alaska, for the second straight year, was the principal zinc-producing State, followed in order of output, by Tennessee, New York, Missouri, Colorado, and Montana. The leading domestic zinc mine producers were ASARCO Incorporated, Cominco Alaska Inc., Union Zinc Co., and Zinc Corporation of America (ZCA).

The Red Dog Mine in northwestern Alaska and the Greens Creek Mine on Admiralty Island accounted for all of Alaska's zinc production in 1991. The Red Dog Mine, which began operations in late 1989, was owned by NANA Regional Corp., Inc. and leased to Cominco Alaska Inc., a subsidiary of Cominco Ltd., which owns and operates the mining and processing facilities. NANA is paid a royalty that was scheduled to increase after the capital investment plus interest was recovered by the operating company.

In 1991, Cominco Alaska increased Red Dog zinc output almost 19% despite substantial declines in both ore grade and mill recovery. The average grade of zinc in ore milled fell to 22.5% zinc from 26.5% in 1990, whereas the mill

recovery averaged only 68%, down 10% from that of the previous year. The lower recovery was attributed to metallurgical problems associated with variable ore types in the deposit. Procedures were established for mining, sorting, and processing various ore types as the year progressed, but overall recoveries, reportedly, were still at unsatisfactory levels at yearend.

Increased production was the result of processing 60% more ore in 1991. For the year, the company milled 1.45 million tons of ore averaging 22.5% zinc, 6.6% lead, and 3.1 ounces of silver per ton and produced 372,600 tons of zinc concentrate averaging 57.1% zinc, 76,600 tons of lead concentrate averaging 57.2% lead, and 34,100 tons of bulk concentrate averaging 32.8% zinc and 20.9% lead. Ore reserves at yearend were 59.7 million tons averaging 18.4% zinc, 5.5% lead, and 3.0 ounces of silver per ton. An additional 14.2 million tons of lower grade ore was classed as inferred reserves.

The Greens Creek Joint Venture, a consortium 53% owned by RTZ Ltd. through its Kennecott subsidiary, Greens Creek Mining Co., and 47% owned by minority partners—Hecla Mining Co., Exalco Resources Corp., and CSX Alaska Mining Inc.—increased the production and reserves at its Greens Creek silver-zinc-gold-lead mine in 1991. Greens Creek Mining, the mine operator, milled 389,000 tons of ore grading 9.9% zinc, 4.0% lead, 22 ounces of silver per ton, and 0.1 ounce of gold per ton and produced 38,570 tons of zinc, 15,700 tons of lead, 7.8 million ounces of silver, and 37,500 ounces of gold in concentrates. Three types of concentrates—zinc, lead, and bulk zinc-lead—were produced; all were exported to foreign smelters. Exploration during 1991 more than doubled the ore reserves. At yearend, ore reserves were about 12.5 million tons averaging 12.8% zinc, 4.0% lead, 14.6 ounces of silver per ton, and 0.13 ounce of gold per ton.

In Tennessee, zinc was produced at six underground mines by Asarco and two divisions of Union Zinc—Jersey Miniere Zinc Co. (JMZ) and Jefferson City Zinc

Div. Asarco's production at four mines was 67,040 tons of zinc in concentrate, up 4,000 tons from that of 1990. At yearend, ore reserves at the four mines were 5.2 million tons averaging about 3.3% zinc, down slightly from the tonnage and grade reported at the end of 1990.

JMZ began restoration of its Idol zinc mine at Thornhill, TN, and planned to bring it on-stream in the first half of 1992 at an annual production rate of about 12,000 tons of zinc in concentrate. The mine, purchased from Kinghill Mines Inc. in December 1989, was last operated by the New Jersey Zinc Co. in 1981. Ore reserves were estimated to be about 5.5 million tons averaging about 3% zinc.

In Missouri, zinc was produced as a coproduct of lead at nine underground lead mines along the Viburnum Trend by three companies, Asarco, The Doe Run Co., and Cominco American Inc., a subsidiary of Cominco Ltd. According to Asarco's annual reports, zinc output in concentrate at the West Fork Mine was 12,600 tons, down about 600 tons from that of 1990, and at the Sweetwater Mine, production was 1,630 tons, down about 1,550 tons. At yearend, ore reserves at the West Fork Mine were 6.8 million tons averaging 1.37% zinc and 5.7% lead with some copper and silver, and at the Sweetwater Mine, 20.0 million tons of ore averaging 4.9% lead and 0.60% zinc. Zinc output at the Magmont Mine, a joint venture of Cominco American and Dresser Industries Inc., increased over that of 1990 owing to an increase in ore output. According to the Cominco annual report, the Magmont mill processed about 1.02 million tons of ore grading 1.0% zinc, yielding 8,450 tons of zinc in 14,200 tons of concentrate in 1991. Ore reserves continued to decline and were expected to be exhausted in about 3 years. At yearend, ore reserves totaled 2.7 million tons and averaged 8.7% lead, 1.3% zinc, and 0.4% copper.

Doe Run produced about 23,000 tons of zinc in 41,700 tons of zinc concentrate at its six lead mines and four mills in the fiscal year ended October 31. Fiscal 1990 zinc production was about 2,000

tons higher. The production decrease occurred largely because the company, in response to poor lead prices, initiated a program in April to reduce its annual output of lead by 55,000 tons in 1991. At the end of the fiscal year, Doe Run estimated its lead ore reserves to be 71 million tons averaging 4.75% lead; the zinc content in reserves was estimated to be 0.9% and copper, 0.3%.

In Idaho, zinc was produced in the Coeur d'Alene mining district at two mines, one of which, the Bunker Hill Mine at Kellogg, closed early in the year owing to financial problems exacerbated by low lead and zinc prices. In November 1990, The Star Phoenix Mining Co. had closed its leased Star zinc-lead-silver mine in the same district for similar reasons. Hecla increased the quantity of ore milled at its Lucky Friday Mine in 1991 but produced slightly less zinc in concentrate. For the year, the company milled 138,000 tons of ore, producing 2,870 tons of zinc, 17,100 tons of lead, 159 tons of copper, 1.85 million ounces of silver, and 928 ounces of gold in concentrates. Ore reserves declined 17% during the year and at yearend were 399,000 tons grading 12.8% lead, 2.8% zinc, and 15 ounces of silver per ton.

Equinox Resources Ltd. began production at the Van Stone open pit zinc-lead mine near Coville, WA, in April, but temporarily closed the operation in September owing to low lead and zinc prices. Mining ceased in August but the company continued the milling of accumulated stocks of lower grade ores. Equinox planned to bring the mine back on-stream when prices improved. At capacity, the operation was expected to produce 15,000 tons of zinc and 2,000 tons of lead in concentrate annually. Remaining ore reserves were estimated to total 2.5 million tons grading 5.7% zinc and 1.1% lead.

Cyprus Minerals Co. operated its Pinos Altos zinc-copper mine in New Mexico as a zinc mine in 1991 but closed it down in the second half of the year because of high operating costs and low zinc prices. Cyprus planned to convert the mine from a zinc to total copper operation within 6 months from the time of the closure.

Copper production was expected to begin in the first quarter of 1992, but no zinc output was planned. Cyprus produced 2,676 tons of zinc in concentrate in 1991, compared with 3,600 tons in 1990.

In Nevada, Alta Gold Co. discontinued mining at its Ward Mine in March owing to depressed metal prices, but continued milling into May at the Taylor Mill to process the balance of stockpiled ore. According to the company, no production was planned for 1992. In February, Alta Gold acquired 100% of the Taylor Mill and associated mineral properties from NERCO Exploration Co. for \$4.8 million; prior to this, the mill, which is 14 miles east of the Ward Mine, had been leased to Alta Gold. The mine and mill, which were started up in April 1990, operated for almost 1 year before closing. Production of metals in concentrates in 1991 and in 1990 (in parentheses) was as follows: zinc, 4,639 tons (9,488 tons); copper, 368 tons (480 tons); lead, 238 tons (832 tons); silver, 58,300 ounces (100,600 ounces); and cadmium, 27 tons (34 tons). Mine/mill zinc recovery was estimated to be 81%. At yearend, ore reserves totaled 690,000 tons averaging 6.27% zinc, 1.07% copper, 0.87% lead, and 2.3 ounces silver per ton.

In Montana, the Montana Tunnels Mining Co., a subsidiary of Pegasus Gold Inc., mined and milled 3.9 million tons of ore at its Montana Tunnels Mine in 1991; concentrates containing 16,000 tons of zinc, 6,500 tons of lead, 1.17 million ounces of silver, and 62,600 ounces of gold were produced. Zinc recovery was 86% in 1991. At yearend, proven and probable reserves were 27.5 million tons grading 0.61% zinc, 0.24% lead, and 0.32 ounce silver, and 0.021 ounce gold per ton. A mine life of 7 years was anticipated. In April, New Butte Mining Co. ceased operations at its zinc-producing mines at Butte, MT, because of poor metal prices.

In Colorado, zinc was produced as a coproduct of gold-silver operations at the Leadville Unit (managed by Asarco, but jointly owned with the Resurrection Mining Co.) and the Sunnyside Mine (owned by San Juan County Mining Venture, a company composed of Alta

Bay Venture (ABV), 67%, and Washington Mining Co., 33%). At the end of March, Alta Gold Co., 60% owner in ABV, relinquished its interest in the Sunnyside Mine venture to its partner, Echo Bay Mining Co., in exchange for indemnification against liabilities that may have occurred while the company was involved in the Sunnyside operation. In August, San Juan temporarily closed the Sunnyside Mine because of low lead, silver, and zinc prices. At Leadville, Asarco increased zinc output in concentrate to 13,400 tons, up 500 tons from that of 1990. Lead, silver, and gold production also increased, totaling 5,800 tons, 320,000 ounces, and 13,300 ounces, respectively, compared with 4,900 tons, 295,000 ounces, and 10,000 ounces produced in 1990. At yearend, ore reserves were 680,000 tons (down 121,000 tons from yearend 1990) grading 7.87% zinc, 3.64% lead, 1.7 ounces of silver per ton, and 0.08 ounce of gold per ton.

Smelter and Refinery Production.—Refined metal production was up slightly from that of 1990 and was the highest since 1981. Three companies, ZCA, JMZ, and Big River Zinc Co., operated four primary zinc refineries in 1991. Secondary zinc metal was produced at 12 secondary plants from waste and scrap materials; however, the largest producer of secondary zinc metal was ZCA at its primary electrothermic smelter at Monaca, PA. A substantial part of the plant's secondary feed was crude zinc calcine recovered from steelmaking, electric arc furnace (EAF) dust by a sister company, Horsehead Resource Development Co. (HRD). The largest producers of zinc metal at secondary plants were Huron Valley Steel Corp., Interamerican Zinc Co., and Gulf Metals Corp.

ZCA continued to upgrade the zinc production capacity of its Monaca, PA, smelter. Since 1988, about 35,000 metric tons had been added, raising plant capacity to about 136,000 tons in 1991. Most of the added capacity, however,

was expected to be dedicated to the processing of EAF zinc calcine.

The processing of EAF dust gained new urgency in 1991 because the dust, as of August, could no longer be disposed of unless it was treated first. EAF dust containing more than 15% zinc was required to be thermally treated to extract zinc and other components; dust with less than 15% was required to be treated or stabilized before disposal. Some zinc-rich EAF dusts continued to be exported to Mexico for treatment, but most was treated at HRD's plants in Illinois, Pennsylvania, and Tennessee. Two plasma-furnace facilities on-site at steelmaking facilities produced zinc metal from EAF dusts. Several other EAF processing plants were under development or planned. A list of operating and proposed domestic plants and capacities is given in table 10.

HRD signed a 10-year agreement in April with North Star Steel Co. whereby HRD would construct and operate a flame reactor facility at North Star's Beaumont, TX, steel plant to extract zinc from the steel plant's EAF dust. Laclede Steel Co. was constructing a 36,000-ton-per-year EAF-dust-processing facility at Alton, IL. Production was scheduled to start in early 1992.

Proposed amendments to the Resource Conservation and Recovery Act, if enacted, would prohibit the disposal of used tires in landfills and tire monofills without some form of treatment. Further, existing used-tire piles, estimated to contain 3 billion tires, were proposed to be eliminated by the year 2005. Because small amounts of zinc compounds, mainly oxide, are used as activators and accelerators in tire rubber formulations, tire processing could become a significant source of secondary zinc in the future.

In July, Oxford Energy Co. began zinc recovery at a new 30-MW, energy-generating, tire-burning plant in Sterling, CT. Oxford has operated a similar but smaller 15-MW unit at Modesto, CA, since 1988. Both plants generated zinc-rich fly ash which, after upgrading by calcining, was shipped to secondary plants for zinc recovery. At capacity, the

Sterling facility expected to burn up to 10 million tires per year for energy generation. A recovery of about 500 tons of zinc annually was also expected. Oxford was planning to have on-stream two additional tire-burning plants, at Buffalo, NY, and Las Vegas, NV, by 1995.

Zinc Oxide.—Domestic American- and French-process zinc oxide was produced entirely from zinc metal and scrap by eight companies in 1991. All but one company, Eagle Zinc Co. of Hillsboro, IL, produced French-process zinc oxide. Some impure oxide produced at secondary plants was sold directly for use in animal feeds and for agricultural purposes. The principal zinc oxide producers in 1991 were Asarco, Eagle Zinc, North American Oxide Inc., and ZCA. North America Oxide began production of French-process zinc oxide at its new 18,000-ton-per-year oxide plant at Clarksville, TN, in July. In the same month, Pigment and Chemicals Co. permanently closed the Memphis, TN, 18,000-ton-per-year zinc oxide plant operated by its subsidiary, Pasco Zinc Corp. The company cited poor market prospects, excessive North American production capacity, improved tire wear, and the loss of a major oxide market (substitution of metal shot for oxide in the electrogalvanizing process) for the closing of this plant and a plant of similar size in Canada 1 month earlier.

Byproduct Sulfur.—Production of sulfur in byproduct sulfuric acid at primary zinc plants was 136,800 tons, about 2,000 tons higher than production in 1990. Acid production at zinc plants in 1991 was valued at \$17.1 million.

Consumption and Uses

Zinc is found in a great many manufactured products, but its role is not obvious to the public because zinc tends to lose its identity in the products. Zinc-containing products were used extensively in 1991 for construction, transportation, electrical, machinery, and chemical

purposes. Zinc-coated steel sheet, structural shapes, fencing, storage tanks, fasteners, nails, and wire rope were widely used in all types of construction, including transmission and radar towers, industrial plants, culverts, roads, bridges, and airfields. Zinc sacrificial anodes were used to protect ship hulls, offshore drilling rigs, and submerged and buried steelwork, tanks, and pipes. Brass was used as shell casings in ammunition and in tubes, valves, motors, refrigeration equipment, heat exchangers, communication units, and electronic devices. Zinc die-cast parts, such as handles, grilles, bezels, brackets, locks, hinges, gauges, pumps, mounts, and housings, were used extensively in vehicles, machinery, business machines, appliances, household hardware, scientific equipment, and electronic equipment. Zinc dust was used in primers and paints; in alkaline dry cell batteries; in the sherardizing process to protectively coat nuts, bolts, and small parts; for the precipitation of noble metals from solution; and in the zinc industry for the removal of impurities, such as copper, cadmium, and lead, before electrolysis. The metal casings of zinc-carbon dry cell batteries were zinc. In 1991, about 23,000 tons of SHG zinc was used by the U.S. Mint to produce 9.3 billion pennies.

Zinc compounds were used in corrosion-inhibiting paint primers, chemical catalysts, welding and soldering fluxes, fungicides and pharmaceuticals, paints, rubber, phosphors for cathode tubes and radar scopes, ceramics, and additives to lubricating oils and greases. Zinc ferrites were used in electrical devices in transformers, coils, amplifiers, motors, and tuners, and in electronic devices in radio, television, and computers.

Domestic consumption of slab zinc fell about 60,000 tons to slightly more than 0.93 million tons in 1991. Galvanizing and electrogalvanizing, mainly for sheet and strip, continued to be the principal use of zinc metal, consuming an estimated 50%, followed by zinc-base die-cast alloys, 21%; brass alloys, 14%; and other uses, 15%. SHG accounted for about 55% of the reported slab zinc

consumed, followed by Prime Western (PW), 25%; High-Grade (HG), 12%; and other grades, 8%.

Overall, the construction sector of the economy was the largest consumer of zinc, accounting for an estimated 43%, followed by transportation, 20%; machinery, 12%; electrical, 12%; and other, 13%. Zinc metal accounted for about three-fourths of the total zinc in end-use products and zinc chemicals about one-fourth in 1991.

According to the American Iron and Steel Institute, reported shipments of domestically produced galvanized sheet and strip totaled 8.2 million tons, down 0.8 million tons from shipments in 1990. Trends in monthly shipments tended to follow the general trends in the economy, down in the first and fourth quarters of the year and generally up in the second and third quarters. Of the total shipments, electrogalvanized sheet accounted for 23% of the tonnage compared with 21% in 1990. The distribution of total shipments by industry sector in 1991 was as follows: automotive, 41%; service centers, 24%; construction, 18%; and other, including exports, 17%. Exports of galvanized sheet and strip totaled 275,000 tons versus imports of 1.38 million tons.

According to the Bureau of Census, zinc-base alloy die and foundry casting shipments totaled about 175,000 tons, down from 188,000 tons reported in 1990. The decline was attributable to a weaker economy in 1991. Zinc die-cast shipments by weight were estimated to have been equally distributed between automotive, hardware, and other uses.

Zinc consumption in the production of copper-base alloy by brass mills, ingotmakers, and foundries was down about 10,000 tons from that of 1990 according to the Copper Development Association Inc. (CDA). The brass and bronze industries were estimated to have consumed about 274,000 tons of zinc, of which about one-half was refined zinc metal and one-half was contained in brass and bronze scrap metal. According to CDA data, brass mills accounted for 85% of the total zinc consumed as metal and scrap in making copper-base alloys.

The zinc content in typical U.S.-manufactured automobiles was estimated to average about 40 pounds in 1991, the same as that in 1990. Diecastings accounted for about 19 pounds; corrosion protection via galvanizing and coatings, 18 pounds; and other, including rubber, brass, and zinc solder, 3 pounds.

The apparent domestic consumption of zinc oxide was about 150,000 tons, down from 165,000 tons in 1990 and 176,000 tons in 1989. Domestic production, exports and imports, also declined. Despite declining consumption, U.S. producers have increased their share of the U.S. zinc oxide market over the past 3 years, mainly at the expense of imports. Zinc oxide imports in 1991 were the lowest since 1984 and were about the same as those of 1988. Because the U.S. Bureau of Mines information on zinc oxide consumption by industry sector reflects only shipments as reported by the domestic producers, the consumption data listed in table 22 accounts for about 80% of the apparent market. Of the reported amounts, the rubber and chemical industries continued to be the principal consumers.

Stocks

Metal stocks held by domestic producers, consumers, and merchants continued to decline in 1991 and were at their lowest levels since the early years of World War II. In recent years, stock levels have tended to be in the 4- to 6-week consumption range, reflecting the general trend by consumers and merchants for lower inventories and just-in-time delivery. Metal stocks in the market economy countries (MEC), according to the International Lead and Zinc Study Group (ILZSG), were 657,000 tons at the end of 1991, up 107,000 tons from those at the end of 1990. Virtually all of the additional stocks were placed in LME warehouses; MEC industrial stocks tended to remain at 1990 levels.

Inventories of zinc in concentrate at domestic primary smelters totaled 29,000 tons at yearend compared with 35,500 tons at the end of 1990, according to the

American Bureau of Metal Statistics Inc. Concentrate stocks were at their lowest level in November.

Markets and Prices

All U.S. zinc producers switched to an LME price-basis in 1991. For zinc metal, they charged a premium, typically 3 to 5 cents per pound, over the LME price to cover importing costs—mainly tariffs, shipping, and insurance. At midyear, in efforts to maintain market share, domestic producers were forced on occasion to reduce their premiums on metal to less than 1 cent per pound.

Metals Week (MW) developed a new U.S. zinc price series to replace the producers' price series that ceased at yearend 1990. The new MW price, based on the daily LME spot price for SHG plus a premium that reflects market conditions, was used for the 1991 zinc price data in this report.

The LME established for the first time warehouses in the United States where LME registered metal could be picked up or delivered. The first such facility opened in February in Baltimore, MD. The LME planned to have additional warehouses in Chicago, IL; Long Beach, CA; Louisville, KY; New Haven, CT; and Toledo, OH, in operation by early 1992.

Zinc prices trended downward through June, continuing the general downtrend that began in July 1990. The Gulf War tended to halt the decline in the first third of the year but prices fell thereafter because of excessive world metal stocks, in part due to increased exports from Eastern European and socialist (EES) countries. Also exacerbating the price decline was the buildup of zinc concentrate stocks owing to large shipments of concentrate from arctic mines beginning in June. Prices were at their lowest levels in the summer months in the United States owing to continuing weak domestic and world demand and to reduced price premiums. Zinc prices rose in the last few months of the year to near the yearly high of January. This occurred despite the fact that there was little or no change in the underlying

market fundamentals. LME zinc stocks were at record levels, world demand was sluggish, and the market was generally oversupplied. Although several production cutbacks were anticipated, most analysts attributed the rise to speculative trading and short coverings at the LME.

Foreign Trade

The value of U.S. exports of basic zinc materials, including waste and scrap, was about \$375 million, up slightly from that of 1990 despite generally lower zinc prices in 1991. Exports of zinc concentrates accounted for 60% of the export value; scrap and zinc chemicals accounted for most of the remainder.

Exports of zinc in concentrates were the highest ever in 1991 and exceeded 1990's record high by 73%. Exports of zinc waste and scrap fell 12% in tonnage terms and 28% in value from those of 1990, but, nonetheless, these exports were the fourth highest in tonnage and value, historically.

General imports of zinc concentrate relative to imports for consumption continued to be high. The large disparity was due almost entirely to shipments of Canadian concentrate through Skagway, AK, to world markets. Imports of slab zinc and zinc oxide both fell, reflecting the general decline in domestic zinc consumption. The value of basic zinc imports was about \$785 million, down 28% from that of 1990.

World Review

Despite a general slowdown in the world economy, the world zinc industry continued at more or less the same level in 1991 as that in the previous year. Mine production was the second highest on record, whereas metal production exceeded 7 million tons for the fifth straight year and was the third highest ever recorded. However, zinc metal consumption, according to ILZSG, was less than 7 million tons in 1991. The imbalance between supply and consumption resulted in generally lower

zinc prices and increased world stock levels.

Higher mine output in Australia, Bolivia, China, Iran, Ireland, and Peru offset substantially lower output in Canada, Greenland, Mexico, Poland, the U.S.S.R., and Yugoslavia. Greenland became a nonproducer when its Black Angel Mine closed in 1990. World metal production followed the same general trend as mine production. Record-high production in the MEC exceeded production declines in the EES countries resulting in slightly higher world output than in 1990.

According to ILZSG, the MEC's consumed a record high 5.34 million tons of zinc metal compared with 5.25 million tons in 1990 and 5.20 million tons in 1989. The EES countries, on the other hand, were estimated in 1991 to have consumed only 1.63 million tons, 110,000 tons, and 28,000 tons less than those in 1990 and 1989, respectively. In 1991, the MEC accounted for slightly more than three-fourths of consumption and the EES countries slightly less than one-fourth. The world's leading consuming nations, in order of estimated consumption, were the United States, the U.S.S.R., Japan, and the Federal Republic of Germany. The United States, Japan, and Western Europe accounted for one-half of world consumption and about 70% of the MEC total. Based on ILZSG data, the principal uses of zinc metal in 1991 in the major MEC's were estimated to be as follows: galvanizing, 48%; brass and bronze, 19%; zinc-base alloys, 14%; chemicals, 8%; zinc semimanufactures, 7%; and other, 4%.

On a geographic basis, the Americas accounted for about 41% of world mine output. Europe, including the U.S.S.R., accounted for 24%; and Asia and Australia accounted for 17% and 15%, respectively. Despite 4 straight years of declining output, Canada remained the world's largest producer. Canada, together with Australia, China, Peru, the U.S.S.R., and the United States, accounted for 64% of the world's zinc mine production; 43 other countries accounted for the remaining 36%.

World exports of zinc concentrates totaled about 3.1 million tons, of which an estimated 90% was from the MEC. Australia, Canada, Peru, and the United States accounted for 75% of the MEC concentrate exports. Canada, Japan, the Republic of Korea, and the Western European countries were the largest importers.

World refined metal production was up about 30,000 tons over that of 1990. The U.S.S.R., the world's largest producer of zinc metal, was estimated to have produced 800,000 tons in 1991, about 11% less than that in the previous year. However, production declines in the U.S.S.R. and other countries were more than made up by small production increases in a number of countries, primarily Australia, Canada, China, France, Japan, Peru, Spain, and the United States. The MEC's and EES countries, respectively, accounted for 75% and 25% of world metal production. The largest producers—Canada, China, Japan, and the U.S.S.R.—accounted for 38% of world output in 1991; 33 other countries accounted for the remaining 62% of metal production.

World zinc mine capacity, based on the capacities of operating mines and temporarily closed mines expected to reopen, was about 8.39 million tons at the end of 1991, up about 45,000 tons from 1 year earlier. Twenty-nine mines closed in 1991, 10 mines opened, and 4 mines increased capacity. The Rampura-Agucha Mine in India, the Hajar Mine in Morocco, and the Sa Dena Hes Mine in Canada, each with zinc production capacities exceeding 50,000 tons, were the largest new mines to open. The Rubiales Mine in Spain (44,000-ton-per-year capacity) and the Lyon Lake Mine in Canada (30,000-ton-per-year capacity) were the largest in capacity terms to close permanently in 1991. Pasminco Ltd. permanently reduced the zinc capacity at its Elura Mine in Australia by two-thirds or by 57,000 tons owing to high costs.

World smelter capacity totaled about 8.36 million tons at yearend, up slightly more than 10,000 tons from that of 1990. One new greenfield smelter opened in India and four other smelters were being

expanded. The largest capacity expansion was a 100,000-ton-per-year increase at the Aviles smelter in Spain; the others planned capacity increases in the 10,000- to 25,000-ton range. Primary smelters in Austria, Germany, and Spain closed in 1991; the largest in capacity, 28,000 tons, was the Austrian smelter at Gailitz. According to ILZSG, an additional 458,000 tons of smelter capacity was scheduled to come on-stream by 1996. Greenfield smelters were under construction in China, India, Iran, Japan, and Thailand.

OUTLOOK

U.S. demand for zinc is forecast to rise slowly, increasing from slightly more than 0.93 million tons in 1991 to about 1.2 million tons by the year 2000. No major shifts in domestic zinc use are foreseen, although some present uses may yield further to substitution.

Although the United States has an adequate zinc resource base, imports are expected to continue to account for more than one-half of U.S. zinc supply in the next decade. Mine output is anticipated to approach historic high levels in the 1990's, but smelter capacity is expected to rise only modestly. No new primary zinc smelters are likely to be built in the United States during the 1990's owing to permitting delays and economic indecision caused by the uncertainty of environmental regulations and the long-term liability threat posed by Superfund legislation. Ironically, the United States is expected to be a major world exporter of zinc concentrates, and, at the same time, to remain the world's largest importer of refined zinc metal.

Secondary zinc recovery from waste and scrap is anticipated to be a strong growth sector for the zinc industry. Domestic secondary zinc production could increase substantially in the next decade and constitute the source of 40% of total U.S. zinc metal and compounds consumed annually by the year 2000. Increased secondary recovery is expected to be driven by public policies related to waste and scrap recycling, environment, and public health.

World zinc metal consumption is expected to continue upward, rising to about 8.5 million tons by the year 2000 from the 7 million tons consumed in 1991. No new major uses for zinc are expected. Traditional zinc uses, in meeting the needs of a rapidly growing and more affluent world population, are expected to be the driving force for increased zinc consumption in the next decade. However, growth is likely to be less in the early years of the decade because of monetary and restructuring problems associated with former EES nations.

World zinc resources and reserves are adequate to supply the increased demands of the 1990's. However, expected cumulative zinc mine output for the 1992-2000 period, about 73 million tons, will result in the extraction of about one-half of the 144 million tons of estimated 1991 world zinc ore reserves. (See table 41.)

Zia Technology of Texas Inc.	Caldwell, TX	Inclined rotary	1992	27,000	4,500
				533,200	93,700

¹Inactive.

TABLE 11
STOCKS AND CONSUMPTION OF NEW AND OLD ZINC SCRAP IN THE UNITED STATES IN 1991, BY TYPE OF SCRAP

(Metric tons, zinc content)

Type of scrap	Stocks, Jan. 1	Receipts	Consumption			Stocks, Dec. 31
			New scrap	Old scrap	Total	
Diecastings	256	4,321	—	4,345	4,345	232
Flue dust	W	7,804	4,298	4,292	8,590	W
Fragmentized diecastings	W	27,836	—	27,856	27,856	W
Galvanizer's dross	1,969	83,334	83,439	—	83,439	1,864
Old zinc ¹	90	1,341	—	1,372	1,372	59
Remelt die-cast slab	W	W	—	W	W	W
Remelt zinc ²	W	184	183	—	183	W
Skimmings and ashes ³	4,539	31,857	31,664	—	31,664	4,732
Steelmaking dust	—	44,573	22,287	22,286	44,573	—
Other ⁴	6,028	18,729	4,183	15,030	19,213	4,739
Total	12,882	219,979	146,054	75,181	221,235	11,626

W Withheld to avoid disclosing company proprietary data; included in "Other."

¹Includes engraver's plates and rod and die scrap.

²Includes new clippings.

³Includes sal skimmings and die-cast skimmings.

⁴Includes chemical residues and solutions and electrogalvanizing anodes.

TABLE 13
ZINC RECOVERED FROM SCRAP PROCESSED IN THE UNITED STATES, BY KIND OF SCRAP AND FORM OF RECOVERY

(Metric tons)

	1990		1991	
	KIND OF SCRAP			
New scrap:				
Zinc-base	97,914	118,232		
Copper-base	134,360	114,894		
Magnesium-base	181	181		
Total	232,455	233,307		
Old scrap:				
Zinc-base	86,607	95,206		
Copper-base	21,632	24,320		
Aluminum-base	512	661		
Magnesium-base	194	205		
Total	108,945	120,392		
Grand total	341,400	353,699		

FORM OF RECOVERY

Metal:		
Slab zinc	95,708	124,078
Zinc dust	24,105	22,750
Other ¹	11,804	8,595
Total	131,617	155,423
In zinc-base alloys	5,144	4,979
In brass and bronze	148,247	127,009
In other metal alloys	257	W
In chemical products:		
Zinc oxide (lead free)	34,726	34,394
Zinc sulfate	12,769	23,385
Zinc chloride	7,436	5,311
Miscellaneous	1,204	3,198
Total	209,783	198,276
Grand total	341,400	353,699

¹Revised. W Withheld to avoid disclosing company proprietary data; included in "Miscellaneous."

²Includes electrogalvanizing anodes and zinc content of slab made from remelt die-cast slab.

TABLE 12
PRODUCTION OF ZINC PRODUCTS FROM ZINC-BASE SCRAP IN THE UNITED STATES

(Metric tons)

Product	1987	1988	1989	1990	1991
Electrogalvanizing anodes	—	—	W	W	W
Redistilled slab zinc	82,589	88,492	97,90	95,708	124,078
Remelt die-cast slab	825	907	4,167	5,144	4,979
Other metal alloys	163	317	272	257	W
Other zinc metal products	6,741	8,016	5,564	1,804	9,137
Secondary zinc in chemical products	79,361	55,972	57,576	56,135	65,746
Zinc dust	28,620	24,205	24,909	24,105	22,750

¹Revised. W Withheld to avoid disclosing company proprietary data; included in "Other zinc metal products."

TABLE 14
U.S. CONSUMPTION OF ZINC

(Metric tons)

	1987	1988	1989	1990	1991
Slab zinc, apparent (rounded)	1,052,000	1,089,000	1,060,000	*992,000	933,000
Ores and concentrates (zinc content)	2,536	2,412	2,107	2,178	2,098
Secondary (zinc content) ¹	269,319	248,461	249,122	*245,692	229,621
Total (rounded)	1,324,000	1,340,000	1,311,000	*1,240,000	1,165,000

*Revised.

¹Excludes secondary slab and remelt zinc.

TABLE 15
ESTIMATED¹ APPARENT
CONSUMPTION OF SLAB ZINC,
ACCORDING TO INDUSTRY USE
AND PRODUCT

(Metric tons)

Industry use and product	1990	1991
Galvanizing:		
Sheet and strip	*381,400	343,900
Other	*124,500	120,700
Total	*505,900	464,600
Brass and bronze	*141,700	133,000
Zinc-base alloys	*205,000	199,700
Zinc oxide	*68,100	65,000
Other uses ²	*71,300	70,700
Estimated apparent consumption	*992,000	933,000

*Revised.

¹Based on reported slab zinc consumption.

²Includes zinc used in making zinc dust, wet batteries, desilverizing lead, powder, alloys, anodes, chemicals, castings, light metal alloys, rolled zinc, and miscellaneous uses not elsewhere specified.

TABLE 16
U.S. REPORTED CONSUMPTION
OF SLAB ZINC,
BY INDUSTRY USE AND
PRODUCT

(Metric tons)

Industry use and product	1990	1991
Galvanizing:		
Sheet and strip	*295,693	272,788
Other	*92,728	91,841
Total	*388,421	364,629
Brass and bronze	*104,276	97,952
Zinc-base alloy	171,771	169,883
Zinc oxide	67,532	64,035
Other uses ¹	*69,969	67,539
Grand total	*801,969	764,038

*Revised.

¹Includes zinc used in making zinc dust, wet batteries, desilverizing lead, powder, alloys, anodes, chemicals, castings, light metal alloys, rolled zinc, and miscellaneous uses not elsewhere specified.

TABLE 17
U.S. REPORTED CONSUMPTION OF SLAB ZINC IN 1991, BY INDUSTRY
USE AND GRADE

(Metric tons)

Industry use	Special High Grade	High-Grade	Prime Western	Remelt and other grades	Total ¹

ZIRCONIUM AND HAFNIUM

By David A. Templeton

Mr. Templeton is a physical scientist with the Branch of Industrial Minerals. He has covered zirconium and hafnium for about 4 years. Domestic survey data were prepared by the Section of Metals Data. World production data are provided by country specialists in the Division of International Minerals, and the data were compiled by Mr. Harold D. Willis.

Mine production of zircon—the primary ore mineral of zirconium and hafnium metal, oxide, and chemicals—remained at just above the 100,000-metric-ton level for the second year in a row. Zircon was recovered from two heavy-mineral mining operations in Florida and at a tailings rework project in New Jersey. As well as being a source for the aforementioned products, which collectively account for approximately 30,000 tons of annual consumption, zircon is also extensively used in refractories, foundry sands (including investment casting), and ceramic opacification. Zirconium and hafnium, which are both contained in zircon at a ratio of about 50:1, are mainstay nuclear metals used in reactor cores. Commercial-grade zirconium, unlike nuclear-grade, contains hafnium and is used in the chemical process industries because of its corrosion resistance. The two metals are only separated for nuclear purposes and for the following reason: Zirconium is relatively transparent to thermal neutrons, the steam-generating products of nuclear fission, and hafnium, having the opposite effect, is an excellent sink or absorber of them. It is for these reasons that zirconium-clad fuel rods and hafnium control rods make up the core of the reactor.

DOMESTIC DATA COVERAGE

Data in this report are collected from an assortment of sources. U.S. mine production of zircon sand is obtained by directly surveying the three producing mines, all of which responded. By collecting zircon consumption data from specific industries that consume it,

information regarding the production of downstream products can be obtained. Examples include oxide, metal, chemicals, refractories, abrasives, flour, frits, etc. However, due to lack of participation from larger industries (e.g., refractories), it is difficult to publish reliable consumption figures, so an estimate is used instead. In smaller industries where there may be only a small set of companies within the survey population representing an entire end use (e.g., abrasives, metal, chemicals), the data are not available for company proprietary reasons. It is for all these reasons that only estimated consumption numbers can be used for industry groupings.

Environmental Requirements

Processing of some mineral sands, and only by certain methods, results in the concentration of radioactive elements in the waste or byproduct streams. Monazite and xenotime, both rare-earth thorium phosphates, are culpable minerals in most cases because 100% separation of the full heavy-mineral suite is impossible to obtain within economic considerations. Even if it could all be removed, monazite inclusions within the zircon grains and/or ionic substitution of uranium, thorium, radium, and/or actinium for the zirconium and/or hafnium within the mineral lattice still results in some radioactive contamination. Monazite processing to obtain rare-earth elements results in a large byproduction of thorium nitrate. Because demand for thorium cannot keep pace with that for rare earths, large amounts of money have been spent to dispose of it in the low-

level storage sites at Barnwell, SC, and Hanford, WA. Processing of zircon and the titanium minerals is much less of a problem, because of lower concentrations in the bulk product that the consuming industries receive from the mining industry. However, because concentration does occur, in proportion to the throughput for a given sand's analysis, in the zirconium chemical and metal industries, they have long been adhering to federal code in the handling, storage, and disposal of the byproduct "source material." Generally, if the combined weight of uranium and thorium exceeds 0.05%, materials are considered to be sources for these radioactive elements. Domestic requirements for licensing source material, definitions, exemptions, and other pertinent information is found in the Code of Federal Regulations, Energy, 10, Part 40 (10CFR40).

Japan enacted strict importation and industrial guidelines on June 6, 1991, as a result of the July 1990 finding of radiation levels originating from titanium dioxide pigment plant wastes dumped in Okayama Prefecture. Basically, the policy, which was created via the cooperation and input from four government entities, addresses the following key areas: protection of residential areas near plants and dump sites, air quality, strict containment of ore and processing wastes, and limits on the allowable dose rates exhibited by ores.

Corrective measures to clean up two areas where the zirconium industry was born, in Albany, OR, have been completed after several years of debate at local, State, and Federal levels. The U.S. Bureau of Mines original Northwest

Electrodevelopment Laboratory (now the Albany Research Center), where the Kroll Process to produce zirconium sponge was invented, and Teledyne Wah Chang Albany have both completed their individual efforts.

ANNUAL REVIEW

Legislation and Government Programs

Negotiations neared conclusion between the U.S. Advanced Battery Consortium and the Ovonic Battery Co. of Troy, MI. Comprising the consortium are the Big Three domestic automobile manufacturers, the Electric Power Research Institute, and the Department of Energy. With funds of \$260 million available, the goal is to award multiple contracts for developing electric-car battery technology. Ovonic has developed a nickel-metal hydride battery as an alternative to nickel-cadmium and has already signed licensing agreements with companies worldwide. Among the signatories are consumer electronic firms and other battery companies. At least two of the agreements are with Asian automobile producers and are geared toward developing a prototype electric car, with the ultimate intent of mass production and consumer acceptance. Twenty-five years of research on rare-earth-nickel hydrides has overcome the obstacles to produce a viable battery capable of rechargeable service. The new battery, in which zirconium is a principal ingredient (also Ti, V, and Ni), is much simpler and more efficient to produce and offers higher energy densities per ounce of battery. Zirconium serves as one of the hydrogen storage elements (V and Ti too) and provides mechanical integrity to the hydrided and embrittled electrode when the battery is charged.

The Environmental Protection Agency's Office of Toxic Substances announced in the November 21, 1991, Federal Register that a priority review of refractory ceramic fibers (RCF's) was to begin. RCF's are produced by attenuating, via blowing or spinning, molten metal oxides such as zirconia, alumina, boria, silica,

and/or magnesia. Just as with many types of airborne particulate matter, RCF's were linked to various lung conditions in hamsters and rats. Current exposure estimates based on industry and available literature are 0.1 to 6.4 (sic, lowest high-end exposure because efficient production technology provides inherent containment) fibers per cubic centimeter (f/cc) for manufacturing environments, 0.02 to 56 f/cc for processing, and 0.01 to 25 f/cc during normal use. The notice also stated that the Occupational Safety and Health Administration was developing formal permissible exposure limits in cooperation with the RCF industry.

Issues

In 1989, the United States imported a total of 92 tons of zirconium metal from the U.S.S.R. There was none imported in 1990, but in 1991, the United States imported 1,388 kg of zirconia, either natural baddeleyite or synthetic, from the U.S.S.R. Since December 1990, the U.S. Bureau of Mines has received numerous inquiries from domestic brokers, traders, and import/export firms seeking potential markets for zirconium and hafnium, as well as other minerals and metals. All of the material being marketed was produced in the Soviet Union. The marketing attempt has thus far been mostly unsuccessful. Among the many reasons are: impurities and costs are too high; the markets are esoteric; and, sourcing another's material would impose on producer-consumer relationships that are, in some cases, decades old. Excluding the U.S.S.R., there are only three burgeoning producers of these metals; two of them are in the United States, the other in France. With two of the world's three non-Soviet producers located here, the effort would probably fare better elsewhere. More on this subject is under the World Review section at the end of the report.

Production

Mine production of zircon was again sharply lower than the level seen at the

end of the 1980's when the zircon market was at its peak. The 1990-91 production level of 100,000 tons is almost 20% below previous levels that neared 120,000 tons. Apparent consumption was also significantly lower and exemplifies the general economic slowdown, with no one individual consumption sector bearing the brunt. Domestic apparent consumption after the bust fell to consistent/constant levels approximating 105,000 tons, down 30% compared with the prebust, 3-year average of 152,000 tons. And while lower production accounts for a considerable reduction in apparent consumption, the reversal of imports and exports has exacerbated it. Imports are at drastically lower levels, between 50% and 75%, and exports are generally 50% higher, with the exception of 1989. (See table 1.)

Zirconium and hafnium metal continued to be produced at Albany, OR, and Ogden, UT, by Teledyne Wah Chang and Western Zirconium, respectively. Both companies used the Bureau-developed Kroll process to produce sponge metal. Both metals were also produced in the form of crystal bar. In the first method, zircon sand is chlorinated in a fluidized bed. The zirconium (plus hafnium) silicate thus becomes a tetrachloride of zirconium, hafnium, and silicon. The latter is removed, and the former two are separated via solvent extraction when nuclear-grade zirconium is required. The metal tetrachlorides are reacted with magnesium metal. The resulting magnesium chloride salt forms in bubbles throughout the melt. Once vacuum distilled to evacuate the magnesium chloride, the resulting porous mass of zirconium is quite sponge-like in appearance.

Zirconium crystal bar and hafnium crystal bar was also produced by sublimating each individual metal in an iodide atmosphere in the presence of a heated wire, itself composed of the particular metal being produced. The metal halide gas deposits its metal constituency on the wire, and the gas returns to further decompose the feed metal. The resulting bar is multifaceted from the growth of single crystals along

the length of the original wire, thus the term "crystal bar."

Countless other end products were also produced from zircon. High-volume production included refractory bricks and shapes, alumina-zirconia abrasives, foundry sands and investment castings, milled and micronized zircon, zirconium chemicals, and zirconia. The latter two are further used to produce many other products used in a wide range of applications. Examples of high-value production are cubic zirconia, technical zirconia ceramics, superalloy castings, zirconia textile refractories, and specialty chemicals.

Markets and Prices

The continued decline in zircon prices had a clear effect on world production and was most evident in Australia's output, which nearly halved, and the United States's steady rate after the marked drop last year. Although the Republic of South Africa showed a significant increase as a result of the expansion's completion, it was reported that much of the added production was stockpiled.

Continued recessionary conditions in the world's major zircon-consuming economies—viz., Europe, Japan, and the United States—put further downward pressure on the price of zircon. Exacerbating the decline was substitution in refractories, mainly by high-magnesia spinels and especially in Japan. The price for lower grades of baddeleyite (96% to 98% ZrO₂) was also affected by the decline in zircon prices. This grade competes with zirconia produced from zircon either by arc furnace, plasma torch, or wet chemistry (caustic fusion) methods. (See table 3.)

World Review

Australia.—Australian producers drastically scaled back production in response to weak demand from recessed economies and substitution inspired by recent record-high prices. As prices continued to reel downward, some mines closed temporarily or permanently while

other large projects opted to significantly scale back and/or switched to mining lower cost deposits. As was the situation in the United States, deposits under consideration for future development were generally put on hold, canceled, or paced to bring mines online coincident with the expected turnaround, estimates for which spanned the remainder of the decade.

Construction started in January on a zircon refractory plant, and the plant opened in December. The plant is near Consolidated Rutile Ltd.'s (CRL) zircon sand processing plant in Pinkenba, Brisbane, Queensland. Noncoincidentally, CRL is a 45% joint-venture partner with the French glass conglomerate SEPR, which holds 55% interest in the joint venture, SEPR Australia Pty. Ltd.

India.—Indian Rare Earths Ltd. and Kerala Minerals and Metals Ltd., both Government companies, sought to enter a joint venture to exploit a deposit at Neendakara, on the coast of the Arabian Sea, in Kerala. The 22-km-long ore body is 4 km wide, 1 km onshore and 3 km offshore, and was estimated to contain reserves valued at \$10 billion dollars.

Work began on a titanium and zirconium sponge metal production plant in the Chidambaranar district of Tamil Nadu. The project is managed by the Nuclear Fuel Complex in Hyderabad and has design capacity to annually produce 1,000 tons of titanium and 300 tons of zirconium. Feed material for the plant will come from another facility under development in Manavalakurichi, also in Tamil Nadu. The two-phase project is planned first to increase dry frit production to 600 tons per year, and then to produce raw material for cubic zirconia diamond simulants.

Indonesia.—An alluvial gold and heavy-mineral operation that began in 1988 in Central Kalimantan neared completion. The Ampalit Mine, estimated to contain 13,500 tons of zircon, has produced a heavy-mineral byproduct containing roughly 50% zircon or roughly 33% ZrO₂. Original intentions to upgrade the

zircon to a world standard of 65% ZrO₂ were either put on hold or only nominally successful, as evidenced by published advertisements seeking bids on an 8- to 10,000-ton stockpile containing 49% to 51% ZrO₂. The company, P.T. Ampalit Mas Perdana, is jointly owned by an Australian company, Plesart Pty. Ltd. (85%), and an Indonesian company, P.T. Wisma Budi Kesti (15%). Company plans were to move plant equipment to another site 13 km south following depletion of the deposit. The new deposit was estimated to have reserves capable of producing more than 28,000 tons of zircon over its 7-year life. The Bureau's country specialist estimated that 1989 production was 2,500 tons. This estimate has been used to amend the world production table for the years 1989 through 1991.

Japan.—Magnesium Elektron Ltd., the United Kingdom parent company of the Flemington, NJ-based subsidiary, began chemical production at two sites in Japan through another Alcan Group sibling, the Nippon Light Metal Co. Nikkei-MEL, the new joint venture, planned manufacture of zirconium chemicals for catalysts and optical fibers, as well as traditional markets.

Sierra Leone.—Pioneer Resources set ground for a formal agreement with its subsidiary, Hazcare Pty. Ltd., to move ahead with the development of the Rotifunk and Sembehun heavy-mineral deposits. The mineral assemblages are similar to the nearby Pejabu deposit that is operated by Sierra Rutile and will serve as an example in the economic modeling. The inferred resources total 3.72 million tons, of which 130,000 tons is zircon, the remainder ilmenite and rutile. A drilling program to measure and prove up the ore body and a feasibility study were to follow/predicate the agreement.

Sierra Rutile produced 1,119 tons of zircon in 1991. Production was halted due to the severely depressed market. Long stockpiled while mining and mineral recovery concentrated on titanium minerals, current and future working

deposits are of sufficient zircon grade to dress the full suite of heavy minerals. Sierra Rutile Ltd. uses a U.S. patented amine froth flotation process that separates an upgradable, zircon-rich concentrate from the titanium minerals. The impetus for the development was the gradual accumulation of a 200,000-ton stockpile of considerable grade coupled with the necessity of improving on traditional separation techniques to improve the metallurgical balance of the final products, ilmenite, rutile, and zircon.

South Africa, Republic of.—Shell South Africa Minerals Div. and Rhombus Exploration Ltd. undertook a comprehensive feasibility study on three deposits within 40 km of the Richards Bay port. The study was expected to be completed in 1992. The deposit, in the Empageni district of northern Natal, was estimated to contain a combined heavy-mineral resource of 10 million tons, 1.1 million tons of which is zircon. Preliminary plans envisaged annual zircon production of 30,000 tons for 20 years.

U.S.S.R.—With the breakup of the U.S.S.R. came the first information concerning zirconium production facilities there. Long suspected by many and known by some, the existence of plants there was first strongly evidenced last December (1990) by a spate of marketing efforts by domestic commodity traders and brokers. After the first full year of marketing, the writer had received almost 100 calls for information concerning zirconium markets in the United States. Most of the investigators described lots, many of which were said to be warehoused in Antwerp, Rotterdam, and Amsterdam or elsewhere in Europe, pertaining to zirconium ingot, crystal bar, plate, and rods. Many of the efforts were duplicated, as descriptions were identical or quite similar. With the non-most-favored-nation (Non-MFN) status remaining in place for all of the Republics except for Lithuania, Latvia, and Estonia, which quickly acted to be recognized as MFN, the prohibitive import tariffs of 25% and 45% on

unwrought and wrought metal remained in place.

Insofar as plants in the former U.S.S.R. are concerned, the only information that has been gleaned relates to two plants, one in Dnieprodzer, Ukraine, and the other in Glasov, Russia. The former is called the Pridneprovsky Chemical Plant and is said to produce zirconium ingots and zirconium fluoride through a calciothermic reduction process. The Chepetsky Mechanical Plant, in Glasov, is said to specialize in producing zirconium crystal bar.

Kovdor Mining and Dressing Mill produces apatite, baddeleyite, and iron ore on the Kola Peninsula in Russia. The mining concern made arrangements in September for BM Trading AS to modernize the production of each ore in a three-phase project, the first of which addresses baddeleyite, a natural zirconium oxide mineral. The goal is to increase the percentage of baddeleyite extracted from the ore to 40%.

Current Research

Westinghouse Electric Corp.'s new nuclear alloy, Zirlo,¹ was further tested in 1991. The alloy, which began its first field tests in 1988 at North Anna in Virginia, is lower in tin than the zircalloys and, in addition, has 1% niobium. The reported result is an alloy with higher strength and corrosion resistance that can remain in the pile of pressurized water reactors longer without the deleterious growth and creep rates suffered by other alloys in this extreme environment.

Among other recent developments in nuclear fuel was Westinghouse's integral fuel burnable absorber (IFBA), a zirconium boride coating on uranium fuel pellets. The IFBA replaces former modes of absorbers, which are mounted as assemblies in control rod guide thimbles.

The catalytic affects of zirconium hydride on hydrocarbons (alkanes) were established by French researchers at the Institut de Recherches sur la Catalyse in Villeurbanne. Neopentane was converted to isobutane and methane; isobutane was converted to propane and methane; and,

propane was converted to ethane and methane. At temperatures of 50° C, the hydrogenolysis conversions were controllable so that one or the other of the end products was obtainable, but at higher temperatures the primary and secondary reactions had higher rates of hydrogenolysis and both end products were obtained. The catalytic performance was attributed to the strong bonding between the zirconium atoms and the silica support and the high electrophilic nature of the zirconium hydride complex.²

Martin Marietta Energy Systems, Inc., received a patent covering the preparation and composition of a new ceramic alloy containing oxides of cerium, hafnium, and zirconium metal. The new material is "transformation toughened," just as in other zirconias, by the volumetric expansion that occurs upon the internal structural transformation from the tetragonal to monoclinic phase. Having the general formula $Ce_xHf_yZr_{(1-x-y)}O_2$, the alloy typically contains between 5 and 15 mol percent ceria, 40 mol percent hafnia, and the balance zirconia.

Two separate innovations concerning the production of yttria-stabilized zirconia via wet chemistry were developed in Japan. The first method utilized an inorganic zirconia sol, as opposed to conventional organic alkoxide, as the starting raw material. Yttrium oxide was then added, and the mixture was powdered and calcined. The sintered product was then comminuted a final time. Because particle size of the starting material can be adjusted, the method is said to be amenable to many molding methods and end products. In the other process, developed by the Tokyo-based Chichibu Cement Corp. and funded by Japanese Government Science and Technology Corp., zirconium oxychloride and yttrium chloride were blended with urea and water prior to autoclaving. Upon increase in temperature, the urea decomposes into ammonium and carbon dioxide; the ammonium in turn reacts with the precursor chemicals, thus causing a slurry of zirconia and yttria to precipitate. Residual ammonium ions were removed from the slurry via a

proprietary technique, and a crystalline solid results.

Efforts by Japan's National Aerospace Laboratory to develop materials with the heat resistance of ceramics and the strength of metals has resulted in several "functionally gradient materials" (FGM) that contain zirconia. Because dissociation can occur in composites and coatings due to dissimilar rates of thermal expansion, the idea behind FGM's is to join the two materials via graduating from one to another on an atomic scale so that there is no joint for faults to arise (e.g., fatigue, rupture, galling, etc.) The 5-year project, which began in 1986, had, by 1989, produced two zirconia-specific FGM's, one incorporating nickel and the other a nickel-chromium alloy. Early methods for producing FGM's relied on plasma spraying or chemical vapor deposition, processes that took hours to produce. In this, the last year of the project, two companies have produced FGM's using methods that apply electrical current to starting materials under pressure. A titanium and partially stabilized zirconia FGM was developed by Fujitsu Ltd. that changes in 10% steps from one material to the other. Sumitomo Coal Mining Co. used a plasma spark technique to produce a FGM plate that changes from 100% stainless steel to 100% zirconia in a five-stage gradient. The precursor powders are pressed between two electrodes, and the applied current causes sparking between individual grains. The particles are joined where spark paths develop, and the resulting electrical resistance causes further sintering.

OUTLOOK

Zircon is a difficult commodity to supply in that there are so many different consumer markets that depend on it for their raw material supply. Zircon supply is directly related to and dependent on the demand and ensuing supply of titanium minerals for metal and pigment (white) production. Within the confines of one mining business, it is relatively simple to match production with the needs of a specific set of customers, even in their

dissociated markets. Expanded to the global marketplace and its independent producers, coordinated production would be difficult to achieve even if demand for the myriad sectors of consumers could be predicted with certainty. With zircon being so codependent on the supply and demand sides and all the variables each side raises now and then, it is no wonder that zircon has seen the wild swings of the 1970's and 1980's. There have been three significant shortage events in that period: the early 1970's, the early 1980's, and again in the late 1980's. If the 7- to 10-year cycle continues, another bust can be expected near the end of the present decade after a slow and steady rebound. Unexpected heavy demand in one of the large consuming industries could certainly bring it sooner. For example, a surge in infrastructure spending would boost demand for steel and other metallurgical refractories. Likewise, if manufacturing companies increased investment in modern plant and capital equipment, alumina-zirconia abrasives and foundries would demand more zircon. However unlikely, new chemical plants and nuclear powerplants would increase demand for zirconium metal.
