# The regulation of Iroquois factors *Irx3* and *Irx5* in the developing ovary and in the impact of *Irx3* overexpression during gonad development

By Megan L. Koth

A dissertation submitted in partial fulfillment of the requirements for the degree of

Doctor of Philosophy (Molecular and Cellular Pharmacology)

at the UNIVERSITY OF WISCONSIN-MADISON 2019

Date of final oral examination: 08/05/2019

The dissertation is approved by the following members of the Final Oral Committee: Joan S. Jorgensen, Associate Professor, Comparative Biosciences Linda Schuler, Professor, Department of Comparative Biosciences John P. Svaren, Professor, Department of Comparative Biosciences Jyoti J. Watters, Professor, Department of Comparative Biosciences Deane F. Mosher, Professor, Department of Biomolecular Chemistry

#### Acknowledgements

I am thoroughly indebted to my thesis advisor, Dr. Joan S Jorgensen, for the continuous support, advice, and mentorship throughout my graduate career. Dr. Jorgensen sees her students as a top priority in her life, and I couldn't imagine being in a more encouraging learning environment. I truly consider this lab my family, and I am so thankful that I had the opportunity to thrive here. Any future student would be lucky to work with Dr. Jorgensen and the talented scientists under her supervision. Dr. Jorgensen consistently encouraged me to become an independent thinker, to be critical of my own work, and to get out of my comfort zone. These are some of the reasons why my development as a young scientist have been successful, and I look forward to carrying these attributes into future endeavors.

I would also like to thank my graduate program, Molecular and Cellular Pharmacology, Dr. Anjon Audhya, and Kristin Cooper, for their endless support and encouragement. They gave me the opportunity to TA a new graduate class for Pharmacology students, which proved to be a challenge, albeit extremely rewarding.

My committee members Dr. Linda Schuler, Dr. John Svaren, Dr. Jyoti Watters, and Dr. Deane Mosher have also provided helpful insight and advice throughout my scientific progression, which has been an integral part of my personal and career development. Thank you for the tough discussions, critical questions, and guidance.

I was also lucky to have an amazing community of labs surrounding me with help around every corner. I would like to personally thank Debra Rugowski from the Schuler lab for technical support and many discussions, both science and non-science related. To the members of the Arendt lab, thank you for sharing reagents and plenty of food in the hallway! And a big thank you to Mike Huelsmeyer, who never said no to equipment use, and who never failed to make me laugh.

To the thousands of mice who have sacrificed their lives for the betterment of mankind and our scientific understanding of gonad development and human disease, thank you.

Finally, I would like to thank my family. My husband Brian has been my rock over the past 6 years, allowing this rollercoaster called graduate school to take over my life. Thank you for being there for me when I needed you the most, and I'm looking forward to bringing a child into this world with you and Stella by my side. To my parents, who were always interested in hearing how my research was going, thank you for humoring me when I explained my experiments to you. I am incredibly fortunate to have you all in my life, cheering me on from the sidelines.

## Dedication

This dissertation is dedicated to my wonderful husband, Brian, and our soon-to-be daughter, Emma. I wish for you to grow up into a strong, independent, and kind individual.

#### Thesis Abstract

Irx3 and Irx5 are critical transcription factors necessary for ovarian follicle development in the mouse. The knockout of Irx3 and Irx5 results in marked oocyte death, which is a feature common to  $Wnt/\beta$ -catenin knockout ovaries. Canonical  $Wnt/\beta$ catenin are crucial factors involved in ovarian development and this similar phenotype suggests a link between Irx3 and Irx5 and this pathway. Irx3 has been used as a marker for canonical Wnt signaling in several tissues, including the developing ovary; however, the mechanism by which regulation occurs is unclear. I hypothesized that  $\beta$ -catenin binds Wnt-responsive enhancer elements via TCF/LEF family members to stimulate Irx3 and *Irx5* in the developing ovary. DNasel-seg and ATAC-seg data helped identify potential regulatory elements in the somatic cell population of developing gonads, and I discovered two regions within the *IrxB* locus that may function as  $\beta$ -catenin responsive enhancers that stimulate Irx3 and Irx5 in ovarian development. Repressive histone marker H3K27me3 may also play a role in the repression of these enhancers in the testis, suggesting that histone modifications and  $\beta$ -catenin/TCF/LEF are regulating *Irx3* and *Irx5* expression in developing gonads at both the epigenetic and transcriptional levels.

We also have evidence to support that *Irx3* plays a critical role in the germ cell of the ovary. While I showed *Irx3* and *Irx5* are regulated by canonical Wnt/ $\beta$ -catenin signaling in the somatic cells, I hypothesized whether their regulatory mechanism is consistent in the oocyte. With the use of a newly developed germ-cell specific cre *Figla*Cre-EGFP, I was able to eliminate  $\beta$ -catenin in the oocyte of the ovary at an early

postnatal stage. IRX3 expression in the oocyte is not affected by the loss of  $\beta$ -catenin, indicating the regulation of *Irx3* in the oocyte differs from that in the somatic cells. Loss of  $\beta$ -catenin in the oocyte, additionally, does not affect ovarian development or follicle maturation, suggesting loss of  $\beta$ -catenin is not critical for ovarian health.

*Irx3* has a dynamic expression profile in the ovary, where it is expressed in both somatic and germ cells at different points during development. Prior to primordial follicle formation, *Irx3* is confined to the somatic (pre-granulosa) cells of germline nests. After germline nest breakdown and primordial follicle formation, however, *Irx3* is expressed in the oocyte and remains in the oocyte into adulthood. My goal was to stabilize *Irx3* in the somatic cells in the ovary after expression would normally migrate to the germ cell, or to overexpress *Irx3* in the oocyte to explore if *Irx3* overexpression would affect ovarian health or female fertility. I can conclude that overexpression of *Irx3* in either the somatic or germ cells of the ovary does not affect ovarian morphology during development and adulthood and that these females are viable and fertile.

In addition, I also introduced *Irx3* in the testis in both somatic and germ cells where it is normally absent at all stages of development. While somatic cell *Irx3* overexpression did not affect testis histology or male fertility, germ cell *Irx3* overexpression revealed these males were sub-fertile and displayed a sperm agglutination phenotype. *Irx3* overexpression has yet to be connected to male infertility and warrants further investigation into the pathogenesis of this phenotype.

Altogether, I was able to elucidate the regulatory mechanism for *Irx3* and *Irx5* in the somatic cells of the ovary while I also discovered that this mechanism does not translate to the neighboring oocyte. Next, I showed that *Irx3* overexpression in the ovary

does not affect ovarian function, while germ cell overexpression of *Irx3* produces as unique phenotype in male mice. This work expands our understanding and opens new avenues of research for the study of *Irx3* and *Irx5* in gonad development and how the regulation of these factors may contribute to fertility defects in humans.

Chapter 1

Literature Review

Dysregulation of genes involved in development could have a major impact on overall health later in life. Our lab focuses on two Iroquois genes, *Irx3* and *Irx5*, which are active during ovarian development and have an impact on both fetal and adult ovarian and follicle health. My thesis project outlines one of the pathways involved in their regulation, and how overexpression of *Irx3* affects both ovarian and testis development. This literature review will summarize the primary ovarian disease that we believe could be caused by deficient *Irx3* and/or *Irx5* expression, followed by a brief section on early gonad formation. Next, pathways involved in both testis and ovarian differentiation will be outlined, along with a summary of known epigenetic regulation in the gonad. This is then followed by the critical role of  $\beta$ -catenin in the ovary, and why we believe this protein is central to Iroquois factor regulation in the somatic cells of the developing gonad.

#### **Premature Ovarian Insufficiency**

Human infertility is a disorder classified by the failure to become pregnant after at least one year of timed, unprotected intercourse. The number of couples experiencing infertility is on the rise, currently estimated at 50 million couples worldwide (Datta et al., 2016; Mascarenhas, Flaxman, Boerma, Vanderpoel, & Stevens, 2012). Female factors leading to infertility, which account for about one-third of causes, include ovulation disorders, tubal disease, and endometrial pathology (Smith, Pfeifer, & Collins, 2003). In the female, each step leading to healthy and competent oocyte maturation and ovulation is crucial to ensure reproductive success in females. Dysfunction in any stage of this process could lead to premature ovarian insufficiency (POI), previously called

premature ovarian failure. POI is a complex and poorly understood disease and is defined by the loss of ovarian function before the age of 40 and is a common condition that occurs in roughly 1.5% of women worldwide (Luborsky, Meyer, Sowers, Gold, & Santoro, 2003). Abnormal follicle formation or premature depletion of oocytes are recognized as potential causes of POI (Persani, Rossetti, Cacciatore, & Fabre, 2011). Infertility is a primary symptom of the disease, but POI has far-reaching consequences for a woman in later life. Early menopause comes with increased risk of mortality (Cooper & Sandler, 1998; van der Schouw, van der Graaf, Steyerberg, Eijkemans, & Banga, 1996), cancer (Cramer, 1990), cardiovascular disease (Gold et al., 2001; Joakimsen, Bønaa, Stensland-Bugge, & Jacobsen, 2000; Senöz, Direm, Gülekli, & Gökmen, 1996; van der Schouw et al., 1996), and osteoporosis (Cooper & Sandler, 1997; Gökmen, Seçkin, Sener, Ozakşit, & Ekmekçi, 1995; Harlow & Signorello, 2000; Kritz-Silverstein & Barrett-Connor, 1993; Ohta et al., 1996).

POI is generally considered an idiopathic disease because the cause in the majority of cases is unknown (Coulam, Adamson, & Annegers, 1986; Nelson, Covington, & Rebar, 2005). Some underlying reasons for POI, however, have been established and can be grouped as follows: genetic abnormalities, autoimmunity, metabolism disorders, infections, and environmental factors. The most critical causes of POI to this thesis are genetic abnormalities; therefore, this section will expand on this topic.

Genetic abnormalities cause about 10.8% of POI cases (Lakhal et al., 2010). The most common chromosomal abnormality is Turner syndrome, which occurs when one or part of one X chromosome is missing in the female. Women with Turner syndrome

have dysgenic gonads that consist of fibrous tissue and primary amenorrhea, which illustrates the importance of two functional X chromosomes in ovarian health (Cordts, Christofolini, Dos Santos, Bianco, & Barbosa, 2011; Hjerrild, Mortensen, & Gravholt, 2008; Lakhal et al., 2010). The next most common genetic abnormality is the mutation of *Fmr1* on the X chromosome, which could lead to Fragile X syndrome. The severity of the disease depends on the number of CGG repetitions in the untranslated region of the X chromosome: 55-199 repetitions result in females with an increased risk of developing POI (Conway, 2010; Wittenberger et al., 2007). A full mutation, which results in greater than 200 repetitions, completely inactivate *Fmr1* by methylation, resulting in Fragile X syndrome (Monaghan, Lyon, Spector, & Genomics, 2013). Other commonly mutated genes that could lead to POI include *Bmp15* and *Gdf9*. Both are essential signaling factors that originate in the oocyte and impact folliculogenesis (Otsuka, McTavish, & Shimasaki, 2011; Spicer et al., 2008). Less common genes associated with POI include Xist, Foxo4, Fshr, Foxl2, Cyp17A1, Cyp19A1, and Star (not a complete list) (Goswami & Conway, 2005; Lakhal et al., 2010). Most of these genes can be related to the reproductive hormone axis.

POI is a severe medical problem, and it can significantly affect a woman's life. Because this disease has no common cause and prevention/treatment is nonexistent, it is imperative that all aspects of this disease are studied. We believe that two transcription factors, *Irx3* and *Irx5*, are associated with POI and we aim to show that these genes have a significant impact on ovarian development and follicular health.

#### The Bipotential Gonad

The mammalian gonad is an extraordinary organ that can change its fate depending on the signaling cascades activated early in gestation. Unlike any other organ during development, the cells within the early gonad can differentiate into either a testis or an ovary – two completely distinct systems. While both of these organs have the same functional outcome of reproduction, the male and female reproductive structures are quite different. Therefore, it is imperative that these systems are appropriately established during a critical window early in gonad development to ensure the reproductive strength of the organism.

During embryonic development, the bipotential gonad emerges at about embryonic day (E)10.5 in the mouse on the surface of the mesonephros within the urogenital ridge. Human gonads appear as a pair of longitudinal gonadal ridges in the 4-5<sup>th</sup> week after conception, and the primitive gonad is formed by proliferation of both the epithelium and the compression of the underlying mesenchyme (TW, 2000, 2012). Until E11.5-12.5 in the mouse and the 7<sup>th</sup> week of development in humans, there are no morphological differences in the mesonephros or gonad between XX and XY embryos (Jost, 1972; McLaren, 2000; Swain & Lovell-Badge, 1999).

There are several genes required for the gonad to form during the bipotential state that are not sex-dependent including *Emx2*, *Lhx9*, *Cbx2*, *Nr5a1* (*Sf1*), and *Wt1*. Based on mouse knockout models, mutations or deletions of these genes can result in a gonad that fails to develop beyond the bipotential state. Mice lacking *Emx2* completely lack gonads, kidneys, and genital tracts (Miyamoto, Yoshida, Kuratani, Matsuo, & Aizawa, 1997). While *Lhx9*-null mice also do not form gonads, *Lhx9*<sup>-/-</sup> XY mice develop as XX phenotypically due to the downstream effects of the *Lhx9* deletion (Birk et al., 2000). *Lhx9* regulates expression of *Nr5a1* or *Sf1*, which is a critical transcription factor required for early gonad development (Hatano et al., 1994; Luo, Ikeda, & Parker, 1994; Wilhelm & Englert, 2002).

*Nr5a1* or *Sf1* encodes a transcription factor that is present in both sexes in all somatic cells in the gonad and throughout the adrenal cortex (Ikeda, Shen, Ingraham, & Parker, 1994; Luo et al., 1994; Val, Lefrançois-Martinez, Veyssière, & Martinez, 2003). *Sf1* null mice have a severe phenotype, where both gonads and adrenal glands form, but dissolve into streak gonads by E12.5 (Luo et al., 1994). It is also important to note that *Sf1* plays a critical role in upregulating an important testis-determining factor *Sox9*, the master driver of Sertoli cell differentiation, (Sekido & Lovell-Badge, 2008), which is expanded upon in the male sex determination section.

*Wt1* is vital for gonad formation and subsequently for testis differentiation. One isoform of *Wt1* in cooperation with *Sf1* is responsible for the transcriptional control of *Amh*, an early hormone produced by the testis and is essential for the regression of the female Müllerian ducts (Wilhelm & Englert, 2002). Mice lacking *Wt1* fail to develop both gonads and kidneys, which supports the idea that *Wt1* plays a vital role in early gonad formation (Kreidberg et al., 1993).

The final known gene required for the formation of the bipotential gonad is *Cbx2*. This gene encodes a component of the polycomb complex, which is necessary to maintain the repression of genes throughout development by way of chromatin remodeling or modification of histones (reviewed in (Golbabapour et al., 2013)). *Cbx2*-/- mice had delayed gonad development and eventual male-to-female sex reversal (Katoh-Fukui et al., 1998). A different study revealed *Cbx2* is required to upregulate

multiple testis-determination genes, including *Sf1*, *Wt1*, and *Sry* itself, which explains the male-to-female sex reversal phenotype (Katoh-Fukui et al., 2012). More recently, *Cbx2* was shown to actually stabilize the testis pathway by repressing female genes, specifically Wnt target gene *Lef1* (Garcia-Moreno, Lin, et al., 2019).

#### Male Sex Determination

Sox (*Sry*-related HMG box) genes are critical factors for testis differentiation. The first *Sox* gene identified in the early 1990s was *Sry*, which encodes the sex-determining region of the Y chromosome (Berta et al., 1990; Koopman, Gubbay, Vivian, Goodfellow, & Lovell-Badge, 1991; Koopman, Münsterberg, Capel, Vivian, & Lovell-Badge, 1990; Sinclair et al., 1990). This single gene is responsible for a waterfall cascade of other male-specific factors in the somatic cell lineage. *Sry* null male mice develop ovaries (Lovell-Badge & Robertson, 1990), and conversely, forced Sry expression in XX mice results in testis differentiation and morphogenesis (Koopman et al., 1991). *Sry* is essential for the initiation of testis development in addition to its indispensable role to upregulate its downstream target *Sox9* (Sekido, Bar, Narváez, Penny, & Lovell-Badge, 2004), which is then continuously expressed.

Sox9 is expressed in both XX and XY genital ridges until *Sry* expression initiates at E11.5 in XY gonads, causing the expression of *Sox9* to become male-specific (Hacker, Capel, Goodfellow, & Lovell-Badge, 1995; Kent, Wheatley, Andrews, Sinclair, & Koopman, 1996). *Sox9* positive cells then differentiate into Sertoli cells (Morais da Silva et al., 1996; Sekido et al., 2004); conditional knockout of *Sox9* in Sertoli cells results in a male-to-female sex reversal in mice (Barrionuevo et al., 2006; Chaboissier et al., 2004). Conversely, ectopic overexpression of *Sox9* in ovaries resulted in the development of testes (Bishop et al., 2000; Vidal, Chaboissier, de Rooij, & Schedl, 2001). These phenotypes are similar to those of *Sry* deletion or exogenous overexpression, suggesting that *Sry* establishment of *Sox9* expression is the most crucial step to initiate differentiation of Sertoli cells and the morphological development of the testis.

Several pathways downstream of Sox9 are involved in testis organogenesis. Some of these include: Faf9 (Colvin, Green, Schmahl, Capel, & Ornitz, 2001; Schmahl, Kim, Colvin, Ornitz, & Capel, 2004), Dhh (H. H. Yao, Whoriskey, & Capel, 2002), Pdgfralpha (Brennan, Tilmann, & Capel, 2003), insulin receptors (Nef et al., 2003), and prostaglandins (Malki et al., 2005; Wilhelm et al., 2005). Of these pathways, the best studied is *Fgf*9, and it is the only case where the deletion of this molecule results in Sertoli cell differentiation failure and sex reversal (Colvin et al., 2001; Y. Kim et al., 2006; Schmahl et al., 2004). Conclusions from these studies revealed that Faf9 arranges a regulatory network in conjunction with Sry and Sox9 during early Sertoli cell differentiation. Without Fgf9, Sox9 expression is depleted despite the natural expression of Sry and the initial drive of Sox9. Without appropriate levels of SOX9 achieved at the right time, the testis fails to differentiate and fails to form testis cords, suggesting that Sry requires Fgf9 to successfully promote the male pathway. The Sertoli cells in these mice, however, do not die, but transdifferentiate into female-like somatic cells that express Wnt4 and its downstream markers (DiNapoli, Batchvarov, & Capel, 2006; Y. Kim et al., 2006). Figure 1.1 outlines these important genes for testis development and

their relationship to one another, as well as how they interact with the female pathway, which is discussed in the next section.

#### **Female Sex Determination**

Granulosa cells, the supporting cell lineage in the ovary, are the male equivalent Sertoli cells. Granulosa cells enclose female germ cells (oocytes) and secrete factors critical for oocyte growth and maturation within the follicle, the functional unit of the ovary. Each follicle, composed of a single oocyte surrounded by granulosa and theca cells, grows and matures throughout each cycle, ultimately resulting in ovulation of the oocyte for fertilization. During mouse ovary development, primordial germ cells are first organized into structures called germ cell nests, or germline cysts, where the germ cells will mature into oocytes. These nests are composed of clusters of oocytes surrounded by a layer of pre-granulosa cells, which are later broken down into individual follicles in early postnatal life (Hirshfield, 1991). Formation of the ovary was once considered the "default" gonad development pathway for many years, which only occurred in the absence of *Sry*. Studies show that this is not the case – several female-specific ovarian factors, such as WNT4,  $\beta$ -catenin, RSPO1, and FOXL2 were identified, and ovarian development cannot take place in their absence (C. F. Liu, Liu, & Yao, 2010).

One vital gene involved in ovarian development is *Foxl2*. In contrast to *Wnt4/Rspo1*, this protein is solely expressed in the ovarian somatic cells and is never expressed in the testis. FOXL2 expression arises at E12.5 and continues into adulthood; however, inactivation of *Foxl2* does not disrupt granulosa cell differentiation or the assembly of follicles. (Loffler, Zarkower, & Koopman, 2003; Ottolenghi et al.,

2005). In female mice lacking *Foxl2*, follicle development is not impaired, but the follicles fail to mature past the primary stage and subsequently degenerate (Schmidt et al., 2004; Uda et al., 2004). After birth, granulosa cells begin to express male markers (such as *Sox9* and *Dhh*) and transdifferentiate into Sertoli-like cells (Ottolenghi et al., 2005; Uhlenhaut et al., 2009). *Foxl2*<sup>-/-</sup> ovaries also develop Leydig-like cells, which are the cells responsible for steroid synthesis in the male. These mutant female ovaries were capable of secreting testosterone comparable to wild-type male controls (Uhlenhaut et al., 2009). There is also evidence to support a relationship between FOXL2 and ER $\alpha$  showing they synergistically repress *Sox9* in vitro. This relationship suggests that both proteins work together to prevent Sertoli cell differentiation and maintain the granulosa cell fate (Uhlenhaut et al., 2009). FOXL2 and the *Wnt/Rspo1* pathway appear to work independently of each other, which is demonstrated by the finding that *Foxl2* alteration does not affect *Rspo1* and *Wnt4* expression, or vice versa (Ottolenghi et al., 2007; Tomizuka et al., 2008).

The canonical Wnt signaling pathway has been extensively studied in development and is known to control progenitor cell differentiation and morphogenesis (reviewed in (Logan & Nusse, 2004)). The pathway is activated by the interaction of a WNT ligand, predominantly WNT4 in the ovary, with the Frizzled/LRP5/6 receptor complex at the membrane of the somatic cell surface. Without the binding of this ligand, a "destruction complex" is formed in the cytoplasm of the cell which targets  $\beta$ -catenin for degradation by the proteasome. When Wnt is bound, this "destruction complex" is disrupted, causing stabilization of  $\beta$ -catenin, which allows it to translocate to the nucleus and regulate target gene expression via TCF/LEF (T-cell factor/lymphoid enhancer-

binding factor) transcription factor binding. **Figure 1.2** shows a schematic outlining basic canonical Wnt signaling.

Canonical Wnt signaling is expressed in both XX and XY gonads prior to sex determination but becomes specific to XX gonads after E11.5, where it upregulates in the developing ovary and downregulates in the testis (Vainio, Heikkilä, Kispert, Chin, & McMahon, 1999). Female mice lacking Wnt4 develop partially sex-reversed gonads that contain XY gonad features including testis vasculature and the production of androgens. The ovaries of these mice contain oocytes, but the number is significantly reduced compared to a control ovary (Heikkilä et al., 2005; Vainio et al., 1999). Rspo1 (*Rspondin1*), another female-specific factor, is an activator of the canonical Wnt/ $\beta$ catenin signaling pathway (Kazanskaya et al., 2004; Tomizuka et al., 2008). An Rspo1 null mutation in humans results in complete female-to-male sex reversal, uncovering the role of *Rspo1* as a candidate female sex determining gene in mammals (Parma et al., 2006). Subsequent studies in mice lacking Rspo1 showed a partial female-to-male sex reversal and the presence of ovotestes (Anne Amandine Chassot et al., 2008; Tomizuka et al., 2008). The reduced expression of Wnt4 in Rspo1-null ovaries indicates that RSPO1 is necessary for *Wnt4* and  $\beta$ -catenin expression, but once activated, WNT4 can synergize with RSPO1 to further activate  $\beta$ -catenin activity (Anne Amandine Chassot et al., 2008). The current understanding is that WNT4 is a critical factor that promotes ovarian differentiation in conjunction with RSPO1 by activating a part of the ovarian genetic cascade while also antagonizing the testis pathway and differentiation in mice (Anne Amandine Chassot et al., 2008; Jameson, Lin, & Capel, 2012; Y. Kim et al., 2006; Vainio et al., 1999). Fox/2/Wnt4 and Fox/2/Rspo1 double knockout mice have a

more severe ovarian phenotype compared to their single mutant counterparts, suggesting that both pathways are essential for proper ovarian differentiation (Anne Amandine Chassot et al., 2008).

The downstream mediator of canonical *Wnt/Rspo1* signaling,  $\beta$ -catenin, has been shown to play a critical role in ovarian development as well. The somatic cellspecific knockout of  $\beta$ -catenin using *Sf1*Cre results in ovaries with molecular and morphological defects, such as the formation of the testis-specific coelomic vessel, ablation of oocytes before birth, and the presence of androgen-producing adrenal-like cells (C.-F. Liu, Bingham, Parker, & Yao, 2009). This phenotype is similar to both the *Rspo1* and *Wnt4* knockout ovaries, further connecting its role as a downstream mediator in this common pathway. Conversely, the expression of stabilized, constitutively active  $\beta$ -catenin in XY gonads is sufficient to cause male-to-female sex reversal, indicating  $\beta$ -catenin itself has pro-ovarian and anti-testis activity (Maatouk et al., 2008). **Figure 1.3** outlines key phenotypes in mouse knockout models of this pathway.

Multiple factors are hypothesized to be regulated by  $\beta$ -catenin mediated transcription in the developing ovary, but few direct targets have been identified. *Irx3* and *Irx5* double knockout ovaries show a similar phenotype to *Wnt4*<sup>-/-</sup>, *Rspo1*<sup>-/-</sup>, and somatic  $\beta$ -catenin cKO mice, suggesting there may be a link between this critical ovarian pathway and *Irx3* and *Irx5* expression. **Chapter 2** and **Chapter 3** explore this connection in both the somatic and germ cell compartments of the ovary.

#### **Mutual Antagonism**

The bipotential gonad can differentiate into a testis or an ovary depending on the signaling cues within the supporting cell population. These cells then push a particular fate forward and guide other cells, including germ cells, towards the same sex-specific result. One might think this is irreversible, but some studies suggest this is not the case. Multiple factors have been shown to both promote sex determination and counteract the factors supporting the opposite sex. The absence of primary sex determination genes results in the ectopic expression of factors specific to the opposite sex. For example, Sox9 or Faf9 (or its receptor Fafr2) deletions in the male cause partial or complete male to female sex reversal and upregulation of female-specific factors (Bagheri-Fam et al., 2008; Chaboissier et al., 2004; Colvin et al., 2001; Y. Kim et al., 2006; Siggers et al., 2014). This antagonism is also demonstrated in the female, where the loss of Rspo1/Wnt4/Ctnnb1 individually or in combination results in the increased expression of male factors Sox9 and Fqf9 and partial female to male sex reversal (A. A. Chassot, Gillot, & Chaboissier, 2014; Y. Kim et al., 2006). Figure 1.1 outlines some of the known antagonistic pathways present during gonad differentiation.

#### Epigenetic landscape within the gonad

Somatic cells contain approximately 2 meters of DNA (Bloom & Joglekar, 2010), which is highly compacted into tightly regulated structures called nucleosomes. This octameric protein complex contains two of each core histone (H2A, H2B, H3, and H4) (Bentley, Lewit-Bentley, Finch, Podjarny, & Roth, 1984; Kornberg & Thomas, 1974; Luger, Mäder, Richmond, Sargent, & Richmond, 1997) with 145-147bp of DNA wrapped around the exterior of the structure. Generally, nucleosomes impede DNA transcription (Lee, Hayes, Pruss, & Wolffe, 1993; Wasylyk & Chambon, 1979) via physical obstruction or bending of DNA. However, post-translational modifications of histones play an enormous role that can influence compaction and accessibility of DNA, which can then impact gene expression. The most common post-translational modifications - acetylation, methylation, and phosphorylation - occur on the N-terminal tail region of histones, which is accessible on its surface (Luger et al., 1997). Histone tail modifications can serve to recruit additional factors by precise recognition of modified histones by way of protein domains, which are specialized for these purposes (Jenuwein & Allis, 2001).

In past years, it has come to light that epigenetics plays a significant role in the dynamic gene expression regulation in many tissues and systems. The gonad is no exception – there is increasing evidence for the role of epigenetics in regulating essential sex determination and differentiation factors (Garcia-Moreno, Futtner, et al., 2019; Garcia-Moreno, Lin, et al., 2019; Garcia-Moreno, Plebanek, & Capel, 2018; Gonen et al., 2018). The accessibility of both enhancer and promoter regions is a fundamental mechanism of gene regulation, and it involves DNA conformation, chromatin modifications, and DNA methylation. Modern techniques such as DNAselseq, ATAC-seq, Native ChIP-seq, ChIP-seq, and single-cell transcriptomics are being utilized to tease out the complicated processes that underlie sex determination and differentiation.

Although the exact mechanisms that drive the precise spatiotemporal expression of *Sry* are not clear, recent studies have started to elucidate some critical cellular pathways involved (Hiramatsu et al., 2009). Histone and DNA methylation status at two regions upstream of *Sry* have been shown to coincide with *Sry* expression (Gierl, Gruhn, von Seggern, Maltry, & Niehrs, 2012; Nishino et al., 2011; Nishino, Hattori, Tanaka, & Shiota, 2004). Both areas exhibit CpG hypermethylation before sex determination and *Sry* expression. Both regions are hypomethylated in the gonad at the time of sex determination but remain hypermethylated in other tissues (Gierl et al., 2012; Nishino et al., 2004). Additionally, histone methylation has been shown to play a role in *Sry* expression. H3K9me2 marks around the *Sry* promoter require histone demethylase JMJD1A for proper *Sry* expression in the testis. Disruption of *Jmjd1a* results in the accumulation of H3K9me2, leading to lower *Sry* expression (Kuroki et al., 2013). Permissive histone markers H3K4me3 and H3ac enrichment have also been reported in the *Sry* promoter to facilitate *Sry* expression (Gierl et al., 2012).

The testis-specific enhancer TESCO was discovered to influence the expression of *Sox9* during testis determination (Sekido & Lovell-Badge, 2008). The deletion of this enhancer resulted in a 50% reduction of *Sox9* expression but did not elicit sex reversal in XY mice (Gonen, Quinn, O'Neill, Koopman, & Lovell-Badge, 2017). Recently, our collaborators combined ATAC-seq with ChIP-seq to screen for additional *Sox9* enhancers and found a 557bp element located 565kb upstream of *Sox9* that, when deleted, resulted in complete male-to-female sex reversal (Gonen et al., 2018). (Chapter 2 will present more information on these datasets).

Because the supporting cell population in both XY and XX gonads arise from a common precursor, questions arise about how transcription factors and epigenetics intertwine to control cell fate decision. One protein, CBX2, has recently come to light as

a potential major player to influence cell fate in the gonad. CBX2 is a member of the polycomb repressive complex 1 (PRC1), which binds to H3K27me3 to maintain chromatin compaction status and to repress gene expression (Lau et al., 2017). *Cbx2* was mentioned earlier as an essential gene for the bipotential gonad and this gene, when disrupted, results in ovary development in XY mice (Katoh-Fukui et al., 2012; Katoh-Fukui et al., 1998). It was initially thought that *Cbx2* acted as a pro-testis factor by indirect positive regulation of *Sry* (Garcia-Moreno et al., 2018; Katoh-Fukui et al., 2012), but it turns out that this is not the case. Recent studies suggest that instead, *Cbx2* blocks the upregulation of female-determining genes, therefore stabilizing the male fate (Garcia-Moreno, Lin, et al., 2019). This study confirmed CBX2 enrichment at the *Lef1* promoter, a female-specific Wnt target gene, blocking its transcription. In testes lacking *Cbx2, Lef1* is upregulated, promoting the female pathways that actively antagonize male factors, allowing for somatic differentiation into pregranulosa cells (Garcia-Moreno, Lin, et al., 2019).

Our knowledge about the epigenetic influence on gonad development and sex differentiation is still minimal, and these genome-wide sequencing studies will play an enormous role in many important discoveries in the years to come. Until recently, most of our understanding of sex determination and differentiation was limited to targeted knockout genes. These data, alongside chromatin status screens and transcription factor binding maps, will be the foundation to uncover the vital regulatory networks that control this complicated process and will lead this field into uncharted territories.

Because the regulation of *Irx3* and *Irx5* varies between species and tissues, one of our goals was to elucidate regulatory regions within the *IrxB* locus using the available

epigenetic datasets and histone markers as a starting point. We used histone markers such as H3K27ac and H3K27me3 to identify active and repressive regions, respectively, within cell populations of the gonad during development. We hypothesize that histone modifications, in coordination with canonical *Wnt/Rspo1/β-catenin* signaling in the ovary, lead to increased *Irx3* and *Irx5* expression, meanwhile absence of βcatenin and the presence of repressive histones in the testis results in the lack of *Irx3* and *Irx5* expression. **Chapter 2** explores these connections, and how both epigenetics and β-catenin play sex-specific roles in *Irx3* and *Irx5* regulation.

#### β-catenin and its multiple roles in the cell

β-catenin, a multifaceted and evolutionary conserved protein, has numerous functions in the cell. Specifically, β-catenin is an integral component of cadherin-based adherens junctions, but also is the critical nuclear effector of canonical Wnt signaling (**Figure 1.2**). During development, β-catenin contributes to the establishment of the body axis while additionally orchestrating the development of many tissues and organs. In the adult, β-catenin plays roles in tissue homeostasis, cell renewal, and regeneration.

In the 1980s, the Kemler group isolated  $\beta$ -catenin together with two other proteins (now known as  $\alpha$ -catenin and  $\gamma$ -catenin) as proteins associated with Ecadherin, which is a critical molecule in calcium-dependent cell adhesion. The name 'catenin' comes from the Latin word 'Catena,' which means chain. This name reflects their linking of E-cadherin to cytoskeletal structures (Ozawa, Baribault, & Kemler, 1989).  $\beta$ -catenin's structure is the reason it can mediate both adhesive and signaling roles independently – the protein (781aa residues in human) consists of 12 imperfect Armadillo repeats that are flanked by N- and C-terminal domains. A conserved Helix-C is located proximal to the C-terminal domain, next to the last armadillo repeat (Xing et al., 2008). The terminal domains are structurally flexible, where the central region forms a relatively rigid scaffold. This rigid scaffold is where  $\beta$ -catenin can interact to its binding partners on the membrane, in the cytoplasm, and the nucleus (Huber, Nelson, & Weis, 1997). Both biochemical and crystal structure analysis showed that many binding partners of  $\beta$ -catenin share overlapping binding sites within this region, which means that these partners cannot bind simultaneously (Eklof Spink, Fridman, & Weis, 2001; Graham, Weaver, Mao, Kimelman, & Xu, 2000; Huber & Weis, 2001; Poy, Lepourcelet, Shivdasani, & Eck, 2001).

In the absence of Wnt signaling, most  $\beta$ -catenin is at the cytoplasmic side of the membrane as a component of the cadherin complex. Cadherins are single-pass transmembrane glycoproteins that link  $\beta$ -catenin through their cytoplasmic tails.  $\beta$ -catenin can interact with both E-cadherins and N-cadherins, but the most extensively studied are the  $\beta$ -catenin and E-cadherin interactions. The interaction between  $\beta$ -catenin and E-cadherin is constitutive; newly synthesized E-cadherin links with  $\beta$ -catenin while still in the endoplasmic reticulum, and then both proteins move together to the membrane. Interference between the  $\beta$ -catenin/E-cadherin interaction results in the degradation of E-cadherin due to the exposure of a PEST sequence on E-cadherin usually shielded by  $\beta$ -catenin. This motif is recognized by a ubiquitin ligase, marking E-cadherin for degradation (Hinck, Näthke, Papkoff, & Nelson, 1994).

Cadherin-catenin junctions are highly dynamic complexes, and loss of cell adhesion via cadherins can promote the release of  $\beta$ -catenin and its signaling activity. Conversely, cadherins can act as a trap for free  $\beta$ -catenin as well (reviewed in (Heuberger & Birchmeier, 2010)). Proteases can also cleave the intracellular domain of cadherins, affecting the integrity of adherins junctions and  $\beta$ -catenin activity (Maretzky et al., 2005; Reiss et al., 2005). Both somatic and germ cell-specific knockouts of Ecadherin in the gonad result in germ cell death, suggesting that *Cdh1* is necessary for germ cell survival (Piprek, Kolasa, Podkowa, Kloc, & Kubiak, 2019). This study did not investigate the effect of *Cdh1* loss on  $\beta$ -catenin activity, which would be an important question for future studies.

Free β-catenin (not bound by E-cadherin) in the cytoplasm is short-lived in the absence of Wnt signaling. Axin almost immediately recognizes β-catenin and APC in its free state, establishing a platform for kinases CK1 $\alpha$  and GSK3 $\beta$  to phosphorylate residues Ser45, Thr41, Ser37, and Ser33 on β-catenin (C. Liu et al., 2002; Roberts et al., 2011; Xing, Clements, Kimelman, & Xu, 2003). Phosphorylated β-catenin can then interact with the E3 ubiquitin ligase machinery and it is ultimately degraded by the 26S proteasome (Hart et al., 1999). Activation of Wnt signaling at the membrane via the Frizzled (FZD) receptor or co-receptors LRP5/6 result in the disassembly of the destruction complex, which blocks the kinase activity by GSK3 $\beta$  on β-catenin. This disassembly is thought to occur based on the recruitment of Dishevelled (DvI) to the ligand-activated FZD receptor, ultimately recruiting Axin and other associated proteins (such as CK1 $\alpha$  and GSK3 $\beta$ ) thereby destabilizing the entire complex (Bilic et al., 2007;

Schwarz-Romond, Metcalfe, & Bienz, 2007).  $\beta$ -catenin then remains unphosphorylated, accumulates in the cytoplasm, and then translocates to the nucleus. Nuclear  $\beta$ -catenin can subsequently associate with TCF/LEF DNA binding family members, converting the TCF/LEF proteins from transcriptional repressors to activators (van Noort & Clevers, 2002). See **Figure 1.2** for a simplified model.

The identification of  $\beta$ -catenin/TCF/LEF binding sites specific to the female during gonad differentiation plays a central role in **Chapter 2**. Our genes of interest, *Irx3* and *Irx5*, show a positive correlation to  $\beta$ -catenin expression in the developing ovary, and we hypothesize that these highly conserved genes are direct targets of this pathway.

#### **Iroquois Genes**

The Iroquois (Iro) genes were first discovered in *Drosophila* when researchers were identifying genes that affected the patterning of external sensory organs (Dambly-Chaudière & Leyns, 1992; Leyns, Gómez-Skarmeta, & Dambly-Chaudière, 1996). The phenotype that arose in *Drosophila* after mutation of *iro* resembled the hairstyle of the Iroquois American Indians (more commonly known as the Mohawk); hence, the name was given to the gene locus. Characterization of these genes in *Drosophila* by Gómez-Skarmeta *et al.* and McNeill *et al.* (Gomez-Skarmeta, Diez del Corral, de la Calle-Mustienes, Ferré-Marcó, & Modolell, 1996; McNeill, Yang, Brodsky, Ungos, & Simon, 1997) led to the identification of homologs in *C. elegans, Xenopus*, zebrafish, mouse, and human (Bao, Bruneau, Seidman, Seidman, & Cepko, 1999; Bellefroid et al., 1998; Bosse et al., 2000; Bosse et al., 1997; Christoffels, Keijser, Houweling, Clout, & Moorman, 2000; Cohen, Cheng, Cheng, & Hui, 2000; Funayama, Sato, Matsumoto,

Ogura, & Takahashi, 1999; Goriely, Diez del Corral, & Storey, 1999; JL, 1998; T. Peters, R. Dildrop, K. Ausmeier, & U. Rüther, 2000; Tan, Korzh, & Gong, 1999). All Iroquois proteins conform to the TALE (Three Amino Acid Loop Extension) structure and contain an Iro box domain, which is a motif with an unknown function, but most likely mediates protein-protein interactions (Bürglin, 1997; J. L. Gómez-Skarmeta & Modolell, 2002; Mukherjee & Bürglin, 2007). *Drosophila* has three Iro genes (*ara, caup, mirror*), and mammals have six Iro genes organized by two clusters (*Irx1-6*). The mammalian Iro genes are clustered in two groups of three with the A cluster (*Irx1, 2, 4*) and the B cluster (*Irx3, 5, 6*) located on chromosomes 5 and 16 in the human and chromosomes 8 and 13 in the mouse (Bosse et al., 2000; Thomas Peters, Renate Dildrop, Katrin Ausmeier, & Ulrich Rüther, 2000). The organization of these genes most likely arose from a duplication event in an ancestral lineage, as the mouse and human organization are strikingly similar.

Most functional studies of the *Iro* gene family have been performed in *Drosophila* and have provided important insight for vertebrate research. One of the first systems studied in connection with the Iroquois complex (Iro-C) was *Drosophila* eye development. One group analyzed the loss of *mirr* in the dorsal region of the eye (McNeill et al., 1997), which induced ectopic barriers at the border between *mirr* positive and negative cells. Following this study, multiple groups demonstrated that the misexpression of any genes within Iro-C in the eye disc led to a loss-of-eye phenotype (Cavodeassi, Diez Del Corral, Campuzano, & Domínguez, 1999; Cho & Choi, 1998; Domínguez & de Celis, 1998). Similarly, Iro-C helps confer identity and patterning of tissues at the Iro-C expression and non-expression boundary in the *Drosophila* dorsal mesothorax (Diez del Corral, Aroca, G mez-Skarmeta, Cavodeassi, & Modolell, 1999). Overall, the *Drosophila* studies conclude that the Iro-C genes play a role in the dorsoventral organization in multiple tissues throughout the body.

In early *Xenopus* development, *Xiro1* and *Xiro2* are essential for neural plate development. Injection of mRNA that encodes wild-type or mutated Xiro proteins show abnormal neural crest development in the mutant samples, and overexpression of *Xiro1* and *Xiro2* results in an enlarged neural plate and a reduction in neural crests (Bellefroid et al., 1998; J. Gómez-Skarmeta, de La Calle-Mustienes, & Modolell, 2001; JL, 1998). One of the key findings in early neural fate development is the regulation of *Xiro1* by Wnt signaling and its role in the repression of *Bmp-4*. Overexpression of *Xiro1* reduces *Bmp-4* and, conversely, the presence of dominant negative *Xiro1* results in ectopic *Bmp-4* expression (J. Gómez-Skarmeta et al., 2001).

Iro genes are also necessary for heart patterning and function. Mice with a disruption of *Irx4* develop a normal heart but exhibit abnormal ventricular gene expression, and these mice eventually develop cardiomyopathy as adults (Bruneau et al., 2001). *Irx* genes are essential for some postnatal cardiac function in mice, such as cardiac repolarization (*Irx5*) and rapid ventricular conduction (*Irx3*) (Costantini et al., 2005; Zhang, Kim, Rosen, Smyth, & Sakuma, 2011). Additionally, *Irx3* has been shown to ensure proper expression of gap junction proteins *Gja5* and *Gja1* in the postnatal ventricular conduction system (VCS); mice lacking *Irx3* in these tissues develop morphological defects in the VCS (K. H. Kim et al., 2016; Zhang et al., 2011).

The control of *Iro* gene expression is an elusive journey – the emerging conclusion is that although some signaling pathways commonly control these genes,

22

the details of this regulation varies widely between tissues. In the *Drosophila* eye, Iro genes are activated by Wg (Wingless) and Hh (Hedgehog) signaling (Cavodeassi et al., 1999), while the JAK/STAT pathway has been shown to positively regulate *mirr* (Zeidler, Perrimon, & Strutt, 1999). The EGFR pathway has also been implicated in activating Iro-C in the wing (Wang, Simcox, & Campbell, 2000). In early vertebrate development, both Wnt and BMP-4 have been involved (J. Gómez-Skarmeta et al., 2001), but many questions about the control of the postnatal expression of the Irx genes remain unanswered. Some groups have claimed postnatal expression relies on Hh signaling (*Xenopus*, Chick) or FGF factors in the brain (*Xenopus*), but these claims require further investigation (Bellefroid et al., 1998; Briscoe, Pierani, Jessell, & Ericson, 2000; JL, 1998).

#### Irx3 and Irx5 role in Ovarian Development

Our laboratory discovered that *Irx3*, an *IrxB* cluster member, is specifically expressed in the ovary (and not the testis) during gonad development using an Affymetrix GeneChip. *Irx3* expression is abundant in the ovary during development and early adulthood (Jorgensen & Gao, 2005). This expression pattern is similar for *Irx5*, another *IrxB* cluster member, which is also ovary-specific (B. Kim, Kim, Sakuma, et al., 2011).

The first mouse model we explored was the *Fused Toes* (*Ft*) mouse. This mouse lacked the *IrxB* cluster (*Irx3, 5, 6*) and three *Ft* genes (*Ftm, Fts, Fto*). *Ft* mutant ovaries exhibit fewer germ cells caused by a progressive decrease in germ cell proliferation (B. Kim, Kim, Sakuma, et al., 2011). These mutant ovaries also show improper follicle

development and have few surviving immature follicles, ultimately leading to the conclusion that the disruption of these genes stunt follicle maturation in *Ft* mutant ovaries (B. Kim, Kim, Cooke, Rüther, & Jorgensen, 2011).

The *Ft* mutant mice established that *IrxB* and or *Ft* loci were critical for ovary development. Next, we obtained mutant mouse models that allowed us to focus on *Irx3* and *Irx5*. Ovaries lacking both *Irx3* and *Irx5* had abnormal granulosa cell morphology within the follicle and disrupted granulosa/oocyte interactions (Fu et al., 2018). Another mouse with a complex genotype that included global knockout of *Irx5*, a single allele knockout of *Irx3* ( $\Delta$ ), and a single floxed allele of *Irx3* (*Irx3/5* Hypomorph mouse), failed to respond to hormonal signals dedicated for ovulation. These ovaries had fewer oocytes retrieved in IVF, supported by the presence of fewer corpora lutea (CL), which are present at a 1:1 ratio of ovulated oocytes (Fu et al., 2018).

Finally, individual knockouts of either *Irx3* (*Irx3<sup>LacZ/LacZ</sup>*) or *Irx5* (*Irx5<sup>EGFP/EGFP</sup>*) showed that both strains were sub-fertile, but in different ways. *Irx3* knockout mice gave birth to fewer pups throughout the breeding period but *Irx5* knockout mice did not produce fewer pups until 4 months into the 6-month long breeding study. These data led us to conclude that while both factors are essential for optimal fertility, they potentially have different roles in the ovary (Fu et al., 2018), which may be explained by their differential expression patterns. Both *Irx3* and *Irx5* are expressed solely in the somatic, pre-granulosa cells within germline nests during development, but their expression transitions to the germ cell (while remaining on in the somatic compartment) during primordial follicle formation. Once primordial follicles form and then initiate follicle

maturation, *Irx3* is confined to the germ cell, while *Irx5* reverts back into the granulosa cells before diminishing completely (Fu et al., 2018).

Because *Irx3* and *Irx5* are expressed in both cell types during distinct time frames, we explored both somatic (**Chapter 2**) and germ cell (**Chapter 3**) connections between *Irx3*, *Irx5*, and the canonical *Wnt/Rspo1/\beta-catenin* signaling pathway. In addition, the overexpression of *Irx3* in both cell types is examined in **Chapter 4** with intriguing results.

In summary, a delicate balance between signaling pathways and epigenetic markers coordinate sex differentiation and regulation in the ovary, and we sought to explore this coordination in connection to *Irx3* and *Irx5* expression in the ovary, along with the effects of *Irx3* overexpression in both sexes. While we have come a long way with this project, there are future avenues for this study that could answer some critical questions pertaining to the important roles of *Irx3* and *Irx5* may be linked to the pathogenesis of POI in humans (**Chapter 5**).

# Figure 1.1

## Factors underlying sex determination in the gonad

Gonad development in the mouse begins at a bipotential state and can differentiate into either a testis or an ovary depending on the activation of certain genes/pathways. Mutual antagonism between many of these factors ensure the proper formation of either a testis or an ovary. Red lines indicate antagonism, green lines indicate a positive feedback loop.

### Figure 1.2:

Canonical Wnt/Rspo1 signaling leads to  $\beta$ -catenin induced transcription

Left panel: Without a WNT or RSPO1 ligand present at the membrane at the Frizzled (FZD) or LRP5/6 receptors, the destruction complex forms, leading to  $\beta$ -catenin degradation by the 26S proteasome, keeping Wnt target genes in an "off" state. Right panel: If a WNT or RSPO1 ligand binds to its membrane receptor(s), the destruction complex does not form, allowing  $\beta$ -catenin to accumulate, translocate to the nucleus, bind to its DNA binding partners TCF/LEF family members, and turn on Wnt target genes (ovary examples: *Fst, Irx3, Irx5*).

					28
Gene- Altered	Loss or Gain	Ovary Phenotype	Testis Phenotype	Sex reversal?	Reference
Wnt4	Knockout	Testis vasculature, Leydig cell markers are shown, depletion of oocytes	Possible abnormal Sertoli cell differentiation (conflicting evidence)	Partial	(Jeays-Ward, Dandonneau, & Swain, 2004; Vainio et al., 1999; H. H. C. Yao et al., 2004)
Rspo1	Knockout	Testis vasculature, seminiferous tubules, Sertoli and Leydig cells present, loss of oocytes, meiosis impaired	None reported	Partial	(AA. Chassot et al., 2011; Anne Amandine Chassot et al., 2008; Tomizuka et al., 2008)
Ctnnb1	Somatic Loss	Coelomic vessel formation, Leydig cell markers are shown, loss of germ cells	None reported	Partial	(CF. Liu et al., 2009; Manuylov, Smagulova, Leach, & Tevosian, 2008)
Ctnnb1	Somatic Gain	Hemorrhagic areas present, previously described in another model. Infertile.	No cord formation resemble ovary lacking oocytes, disruption of Sertoli cell lineage. Infertile.	Full	(Boerboom et al., 2005; Maatouk et al., 2008)

## Figure 1.3:

Phenotypes of Canonical Wnt/Rspo1/ $\beta$ -catenin manipulation in mouse gonads.

Previous literature reported effects of the indicated manipulation.

#### Abstract

Members of the Iroquois B (IrxB) homeodomain cluster genes, specifically Irx3 and Irx5, are critical for heart, limb, and bone development. Recently, we reported their importance for follicle health and oocyte survival within the developing ovary. Within developing gonads, Irx3 and Irx5 are expressed shortly after sex determination in the ovary but are absent in the fetal testis. Mutually antagonistic molecular signals ensure ovary vs testis differentiation with canonical Wnt/β-catenin signals at the forefront for promoting the ovary pathway in XX gonads. Notably, few direct downstream targets have been identified within the ovary. Here, we report that the canonical Wnt/ $\beta$ -catenin signaling pathway directly stimulates *Irx3* and *Irx5* transcription in the developing ovary. Using in silico analysis of ATAC- and ChIP-Seq databases in conjunction with gonad explant transfection assays, we identified TCF/LEF binding sequences within two distal enhancers of the *IrxB* locus that promote  $\beta$ -catenin-responsive ovary expression. Meanwhile, Irx3 and Irx5 transcription is suppressed within the developing testis by the presence of H3K27me3 on these same two enhancer sequences. In summary, our results have uncovered two enhancer sequences that resolve sexually dimorphic regulation of *Irx3* and *Irx5* that are also direct targets of  $\beta$ -catenin transcriptional control. Together, they mediate oocyte and follicle survival to promote ovarian health.

#### Introduction

Early in development, the bipotential mammalian gonad can transform into a testis or an ovary depending on the activation or repression of signaling cascades in the somatic cell lineage (reviewed in (Svingen & Koopman, 2013)). In the ovary, the canonical Wnt4/Rspo1/β-catenin pathway plays a crucial role for proper differentiation and development (reviewed in (Nicol & Yao, 2014)). In XX mouse embryos, knockouts of Wnt4 (Jeays-Ward, Dandonneau, & Swain, 2004; Vainio, Heikkilä, Kispert, Chin, & McMahon, 1999), Rspo1 (A. A. Chassot et al., 2008; Tomizuka et al., 2008) or somatic cell loss of the downstream mediator,  $\beta$ -catenin, (Liu, Bingham, Parker, & Yao, 2009; Manuylov, Smagulova, Leach, & Tevosian, 2008) results in a partial ovary to testis sex reversal and subsequent loss of 90% of the germ cell population by birth. Conversely, stabilization of  $\beta$ -catenin in the somatic cell population of the XY gonad leads to maleto-female sex reversal, suggesting that  $\beta$ -catenin is a crucial regulator of the sex identity of the somatic cell lineage (Danielle M. Maatouk et al., 2008). Multiple ovarian factors are thought to be regulated by  $\beta$ -catenin and its cognate DNA binding partners TCF/LEF, but a direct relationship in the ovary has yet to be elucidated.

Previously, we reported that two Iroquois homeobox transcription factors *Irx3* and *Irx5* are expressed in the ovary beginning shortly after sex differentiation. Each exhibits a dynamic profile during the course of germline nest establishment and breakdown through primordial follicle formation suggesting they play important roles in ovarian development (Fu et al., 2018; B. Kim et al., 2011). Iroquois factors are highly conserved factors that are known for their roles in patterning and embryogenesis, along with

organization of the spinal cord, limb, bone, and heart (Bruneau et al., 2001; Diez del Corral, Aroca, G mez-Skarmeta, Cavodeassi, & Modolell, 1999; J. Gómez-Skarmeta, de La Calle-Mustienes, & Modolell, 2001; J. L. Gómez-Skarmeta & Modolell, 2002; Lovrics et al., 2014). Developmental regulation of these factors within these systems is context-specific as a number of signaling pathways have been described. Recently, we showed that null mutation of both *Irx3* and *Irx5* resulted in improper somatic-germ cell connections within follicles, which culminated in oocyte death (Fu et al., 2018). Notably, it was previously reported that the *Wnt4* knockout mouse also exhibited physical gaps between germ and somatic cells within follicles (Vainio et al., 1999), suggesting that Wnt and Iroquois factors may lie in the same pathway. *Irx3* and *Irx5* expression have been attributed to the canonical Wnt signaling pathway in other tissues including the developing mouse ovary (F. Naillat et al., 2010; Naillat et al., 2015), but a direct link to β-catenin/TCF/LEF transcriptional regulation has not been made.

Based on results from our and other studies, we hypothesized that *Irx3* and *Irx5* are direct transcriptional targets of the canonical Wnt/ $\beta$ -catenin pathway in the developing ovary. We detected no sex-specific regulatory activity within the proximal promoter regions using *ex vivo* gonad transfection assays. Instead, we uncovered two distant regulatory sequences within the *IrxB* locus that promote sexually dimorphic expression during critical stages of gonad differentiation. Herein, we report that active histone marks work together with  $\beta$ -catenin/TCF/LEF to bind and activate at least two enhancer regions within the *IrxB* locus to stimulate *Irx3* and *Irx5* transcription in the ovary. Meanwhile, these same sites were enriched for repressor H3K27me3 chromatin marks

that actively repressed their transcription in developing testes. Together, these findings increase our perspective of the complex networks that are in place to ensure appropriate sex differentiation of gonads that include cooperation between epigenetic marks and transcription factors on promoter and distant regulatory sequences. In addition, this report uncovers mechanisms by which bipotential regulation can be achieved on the *IrxB* locus. These data provide a foundation for new discoveries of mechanisms by which canonical Wnt and other regulatory pathways work together to promote IRX3 and IRX5 function in a spatiotemporal manner within the developing ovary and during organogenesis of other systems including the heart, limb, bone and spinal cord.

#### Results

#### β-catenin activity correlates with *Irx3* and *Irx5* expression

Wnt4/Rspo1/ $\beta$ -catenin regulated transcription plays an essential role in ovarian development in somatic cells during sex differentiation. Our lab previously reported that *Irx3* and *Irx5* expression increased upon the onset of sex differentiation in the ovary (Fu et al., 2018) and these factors have been linked to canonical Wnt/ $\beta$ -catenin signaling in other tissues (Janssens, Denayer, Deroo, Van Roy, & Vleminckx, 2010; F. Naillat et al., 2010; Naillat et al., 2015). Therefore, we hypothesized that canonical  $\beta$ -catenin regulates *Irx3* and *Irx5* in the somatic cells of the ovary at this time. To test this hypothesis, *ex vivo* and *in vivo* approaches were used to manipulate  $\beta$ -catenin activity to cause loss and gain-of-function in the developing ovary and testis, respectively. Embryonic day 11.5 (E11.5) wild-type ovaries were cultured with two different dosages

of iCRT14, a small molecule that inhibits the interaction between  $\beta$ -catenin and TCF/LEF family members to block  $\beta$ -catenin mediated gene transcription (M. Yan, Li, & An, 2017). As expected, treatment did not change the expression of *Rps29*, a ribosomal protein used as a negative control but inhibited β-catenin-responsive transcription in a dose-responsive manner. The 50μM dose decreased expression of known β-catenin target genes Axin2 (0.23 fold) and Fst (0.13 fold) and caused a significant decrease in Irx3 (0.27 fold) and Irx5 (0.24 fold) transcripts (Figure 2-1A). Next, we evaluated Irx3 and *Irx5* transcript accumulation in embryonic ovaries lacking somatic cell  $\beta$ -catenin activity that were generated by crossing Sf1Cre to Ctnnb1<sup>F/F</sup> mice (**Supplementary** Figure 2-1). *Rps29* transcripts from E14.5 control (*Sf1Cre*; *Ctnnb1<sup>F/+</sup>*) and mutant (*Sf1Cre; Ctnnb1<sup>F/F</sup>*) ovaries were not changed while *Axin2* and *Fst* were significantly decreased in mutant ovaries (0.24 and 0.04 fold, respectively). In support of the ex vivo culture findings, Irx3 and Irx5 transcripts were also significantly decreased (0.35 and 0.40-fold, respectively) in the mutant ovaries compared to the controls (Figure 2-1B). Together, ex vivo and in vivo results showed that the loss of  $\beta$ -catenin and its transcriptional activity in the developing ovary significantly diminished Irx3 and Irx5 expression.

Canonical Wnt/ $\beta$ -catenin is actively repressed in the developing testis (Y. Kim et al., 2006; Uhlenhaut et al., 2009). Indeed, it has been shown that stabilization of  $\beta$ -catenin within the somatic cell population was sufficient to cause male-to-female sex reversal (Danielle M. Maatouk et al., 2008). Therefore, we evaluated whether  $\beta$ -catenin

stabilization in the developing testis influenced *Irx3* and *Irx5* expression. Wild-type E11.5 testes were cultured *ex vivo* for 24 hours with Lithium Chloride (LiCl) to stabilize  $\beta$ -catenin. Results from treated testes showed no change for *Rps29* and significantly increased expression of positive controls *Axin2* (4 fold) and *Fst* (10 fold). *Irx3* and *Irx5* transcripts also increased 9- and 5-fold, respectively, compared to vehicle control (**Figure 2-1C**). Previously it was reported that stabilized  $\beta$ -catenin activity in somatic cells of developing testes from *Sf1Cre*;*Ctnnb1*<sup>Δex3/+</sup> (Harada et al., 1999) embryos caused sex reversal (Danielle M. Maatouk et al., 2008). Transcripts from control (No Cre;*Ctnnb1*<sup>Δex3/+</sup>) and mutant (*Sf1Cre*;*Ctnnb1*<sup>Δex3/+</sup>) testes (**Supplementary Figure 2-1**) at E14.5 displayed no significant change in *Rps29* transcript levels but exhibited significantly increased expression of *Axin2* (11 fold), *Fst* (7 fold), *Irx3* (16 fold), and *Irx5* (20 fold) (**Figure 1D**) *Bmp2* was also used to test for Wnt/ $\beta$ -catenin specificity due to its role as a pro-ovarian gene that is not regulated by Wnt signaling.

Later in ovarian development, upon germline nest breakdown, *Irx3* expression expands to include both somatic cells and oocytes (Fu et al., 2018).  $\beta$ -catenin is also present in oocytes at this stage as shown by our immunohistochemistry results from ovaries at E14.5 and P7 and supported by previous reports (**Supplementary Figures 2-1, 2-2**) (Bothun & Woods, 2019; A.-A. Chassot et al., 2011; Jameson et al., 2012; Kumar et al., 2016; Usongo, Rizk, & Farookhi, 2012; H. Yan et al., 2019). To test whether  $\beta$ -catenin activity regulates expression of *Irx3* within oocytes during the stage of nest breakdown and primordial follicle formation, we targeted loss of *Ctnnb1* in oocytes using *Figla*Cre (Lin, Jimenez-Movilla, & Dean, 2014) and evaluated ovaries at P0 and P7 . Germ-cell specific loss of  $\beta$ -catenin using *Figla*Cre was confirmed (**Supplementary Figure 2-2A**); however, immunohistochemistry analysis indicated no obvious change in IRX3 within oocytes of mutant compared to control mice (**Supplementary Figure 2-2B**). Altogether these data suggest that canonical  $\beta$ -catenin transcriptional activity promotes *Irx3* and *Irx5* expression within somatic cells of the germline nest but does not regulate their transcription within oocytes upon their appearance during germline nest breakdown.

#### β-catenin responsive enhancer sites are present within the *IrxB* locus

Irx3 and Irx5 are on opposing strands of DNA located 550kb apart within the IrxB cluster on chromosome 8 in the mouse (Cavodeassi, Modolell, & Gómez-Skarmeta, 2001; Peters, Dildrop, Ausmeier, & Rüther, 2000). Given their proximity, we set out to identify accessible regions of chromatin within the IrxB locus. Previously, we performed DNaseland ATAC-seq on male and female somatic cell populations sorted from embryonic gonads at E10.5 (pre-sex differentiation) and E13.5 (post-sex differentiation) (Garcia-Moreno, Futtner, et al., 2019; D. M. Maatouk et al., 2017). These datasets were used to interrogate chromosome 8 spanning 600kb on either side of the Irx3 transcription start site (tss) to search for areas of open chromatin that also included the consensus motif for  $\beta$ -catenin binding partners TCF/LEF (TCAAAG) (van de Wetering et al., 1997). Those sites that were used for further evaluation included those that were either resolved (R) by- or derived *de novo* (D) by E13.5 in the ovary (Garcia-Moreno, Futtner, et al., 2019). Five sites of interest were identified and named based on their distances from the Irx3 tss: +205kb, +86kb, -305kb, and -580kb (see boxed peaks in Figure 2-**2A**). The site at -305kb contained two separate TCF/LEF binding motifs, labeled 'A' and

'B'; all others harbored a single consensus element. A map detailing the approximate location of each site relative to *Irx3* and *Irx5* is outlined in **Figure 2-2B**.

To evaluate these open chromatin sites, we harvested ovaries and testes from E13.5-14.5 embryos to perform chromatin immunoprecipitation (ChIP) gPCR using antibodies for H3K27ac to mark active enhancer sites, and TCF7L2 to identify TCF/LEF binding sites relevant to the developing ovary. Of TCF/LEF factors, TCF7L2 was chosen for the following reasons: robust ChIP-seg data are available on the ENCODE database. microarray data indicating TCF7L2 is expressed predominantly in the somatic cells of the gonad (Jameson et al., 2012), and the GUDMAP database showed that TCF7L2 expression was detected in the ovary via in situ hybridization, whereas other TCF/LEF factors were negative (Harding et al., 2011; McMahon et al., 2008). For each replicate, whole gonad ChIP was first validated by showing RNA Polymerase II enrichment at the GAPDH promoter and TCF7L2 presence at a known  $\beta$ -catenin/TCF complex target, the SP5 promoter (Kennedy et al., 2016) in ovaries and testes (Supplementary Figure 2-3). Ovary (XX) ChIP results showed that H3K27ac was significantly enriched at the +86kb (20.1 fold enrichment), and trended towards significant enrichment at the -580kb (11.1 fold enrichment) sites suggesting that they are potential enhancers (**Figure 2-3A**). Only the -305kb (B) site showed a trend for H3K27ac enrichment in the testis (XY) (6.8 fold enrichment) (Figure 2-3B). Next, ChIP PCR indicated that significant enrighment for TCF7L2 was observed on ovarian sites +86kb (2.2 fold enrichment) and -580kb (2.7 fold enrichment) and trended for enrichment at +205kb (2.0 fold enrichment), -305kb (A) (1.7 fold enrichment), and -305kb (B) (3.6 fold enrichment). Unlike the ovary, the only

site that had potential TCF7L2 enrichment in the testis was the +205kb site (6.1 fold enrichment) (**Figure 2-3A, B**). These data suggest that  $\beta$ -catenin/TCF/LEF transcription factors bind and act on enhancer sequences at the +86kb and -580kb sites to regulate *Irx3* and *Irx5* expression within developing ovaries. These results also suggest the potential for sex-specific regulation.

# Constitutively active $\beta$ -catenin defines the +86kb and -580kb sites as Wnt responsive enhancers in the *IrxB* locus

To test  $\beta$ -catenin responsive enhancer activity, each potential regulatory site was cloned into a luciferase reporter vector containing a minimal E1b promoter (Huang, Jia, Yan, Guo, & Li, 2006). In addition, each reporter vector was altered to include a single point mutation of the TCF/LEF binding motif (TCAAAG to CCAAAG), which is the same mutation that differentiates the TOPflash (active) versus FOPflash (inactive)  $\beta$ -catenin reporter plasmids (Korinek et al., 1997) (Supplementary Table 2-1). Reporter plasmids were transfected into HEK293 cells along with a constitutively active  $\beta$ -catenin expression vector, CMV-S37A (Jordan, Shen, Olaso, Ingraham, & Vilain, 2003). Specific β-catenin activity of the CMV-S37A expression vector was confirmed using cotransfection with positive and negative control reporter vectors, TOPflash and FOPflash, respectively (Supplementary Figure 2-4). Among all reporter vectors including +250kb, +86kb, -305kb (A, B), and -580kb, only the +86kb and -580kb plasmids exhibited a significant increase in reporter activity that was specific to the putative TCF/LEF binding site. Of note, the larger plasmid containing wild type -305ABkb sequences, which includes A and B TCF/LEF binding sites, was not responsive to CMV-S37A, and the

double mutation of (A) and (B) had no effect (**Figure 2-4A**). To test whether the +86kb and -580kb DNA enhancers (together equals 209bp) could stimulate promoter activity, both were cloned into the pGL3 basic luciferase reporter in front of 2,080bp of the mouse *Irx3* promoter (+86kb;-580kb;-1634/+446bp m/*rx3* pGL3). Constitutively active CMV-S37A cotransfected with the enhancer plus promoter reporter stimulated a 3 fold increase in activity compared to promoter alone. In addition, single base pair point mutations of the TCF/LEF binding site in each enhancer sequence completely disrupted enhancer activity (**Figure 2-4B**). Together, these data suggest that the +86kb and -580kb enhancer sequences confer  $\beta$ -catenin specific regulatory activity within the context of the *Irx3* promoter.

# +86kb and -580kb enhancers promote β-catenin specific activity in transfected fetal ovaries

Based on ovary-specific expression of *Irx3*, we reasoned that sequences within the *Irx3* promoter would confer ovary-specific expression. To test this hypothesis, three different sized segments of the mouse *Irx3* promoter (-351/+446bp, -603/+446bp, and - 1634/+446bp) were cloned into a luciferase reporter plasmid and transfected into ovaries and testes from E13.5 embryos. While reporter activity increased along with longer promoter sequences, none of the promoters exhibited a significant difference when testis and ovary reporter activities were compared (**Figure 2-5A**). Next, we tested whether  $\beta$ -catenin specific activity within the +86kb and -580kb enhancer sequences would promote ovary specific expression. Both enhancers and their mutated counterparts were cloned in front of the most active promoter (-1634/+446bp)

mIrx3pGL3) reporter vector and transfected into E14.5 gonads. While the enhancer plus m*Irx3* promoter was equally expressed in both ovary and testes, only ovary expression was disrupted upon mutation of the TCF/LEF binding sites (60% decrease from wild type enhancers) (**Figure 2-5B**). Based on these results we conclude that the +86kb and -580kb enhancer sequences promote  $\beta$ -catenin responsive activity only within the ovary.

## +86kb and -580kb regions in the male are enriched for H3K27me3, which results in sex-specific repression of the enhancer activity

Plasmid vectors containing the enhancer sequences linked to the m*Irx3* promoter did not confer ovary versus testis specific reporter activity as expected; however, one limitation to this analysis is that the reporter vectors lack epigenetic decorations that may have a profound impact on enhancer and/or promoter activity. Thus, we hypothesized that repressor histones suppress the +86kb and -580kb enhancer sequences within the developing testis. To test this hypothesis, we mined H3K27me3 ChIP-Seq data (Garcia-Moreno, Lin, et al., 2019) to identify sequences enriched for H3K27me3 using the same somatic cell populations described previously for ATAC-Seq (**Figure 2-2**) (Garcia-Moreno, Futtner, et al., 2019). Results show that H3K27me3 marks are enriched in both the +86kb and -580kb sites in the testis but are completely absent in the ovary (see boxed regions within **Figure 2-6A**). Next, to test whether the H3K27me3 marks actively repress *Irx3* and *Irx5* expression in the testes, wild-type gonads were harvested at E11.5 and cultured for 48 hours with 500nM Tazemetostat (TAZ), a potent EZH2 inhibitor that has been shown to diminish H3K27me3 presence in ovary chromatin during development (Prokopuk, Hogg, & Western, 2018). To validate TAZ activity in developing gonads, we compared *Rps29* and *p21* transcripts between treated versus control cultures. In silico analysis of ovary and testis sequences showed that H3K27me3 was absent at the *Rps29* locus, but present at the *p21* locus, as has been reported in other cell types (Supplementary Figure 2-5) (Garcia-Moreno, Lin, et al., 2019; Knutson et al., 2014). Results showed no change in *Rps29* transcripts in both gonads subject toTAZ treatment. As expected, transcripts of p21 increased in treated gonads in both sexes, but the increase was more robust in treated ovaries (XX 4-fold versus XY 2.5-fold) (Figure 2-6B). In contrast, TAZ treatment appeared to have a relatively greater impact on Irx3 and Irx5 transcript levels in cultured testes versus ovaries. Irx3 and Irx5 increased to only 25-30% of the positive control value in ovaries (Irx3 1.8-fold and Irx5 1.6-fold increase) but approached 100% of p21 values in treated testes (2.4-fold increase for both transcripts) suggesting release of epigenetic repression in testes. Taken together, our data uncovers two specific enhancers within the *IrxB* locus that confer ovary versus testis specific promoter activity. In the ovary, canonical  $\beta$ -catenin activity stimulates the +86kb and -580kb enhancers while expression is silenced in the testis due to the combined effects of histone methylation repression and the lack of functional  $\beta$ -catenin activity.

#### Discussion

Canonical Wnt/ $\beta$ -catenin signaling has been reported to promote *Irx3* and *Irx5* expression in the ovary (Florence Naillat et al., 2010; Naillat et al., 2015) and other tissues such as the brain (Braun, Etheridge, Bernard, Robertson, & Roelink, 2003), lung

(Bell et al., 2008), neural axis (Janssens et al., 2010), kidney (Holmguist Mengelbier et al., 2019), and in colon cancer (Hovanes et al., 2001), but evidence for direct transacting regulation via DNA binding partners has not been elucidated. Here we used in vitro, ex vivo, and in vivo approaches to provide a direct link between canonical Wnt/βcatenin signaling and Irx3 and Irx5 expression within the somatic cell population of the developing ovary. In addition, we previously showed that both Iroquois factors emerge in germ cells in late stages of ovarian development (Fu et al., 2018), but here we report that their regulation in this cell type is independent of  $\beta$ -catenin. Specific to Irx3 and Irx5 expression within the somatic cell population, we uncovered two enhancer sequences that, although distant from the transcription start site, provided the focus for regulation within the ovary and testis. Our data indicate that chromatin enhancer marks work in conjunction with β-catenin/TCF/LEF at these sites to stimulate the *IrxB* locus in the ovary, while the absence of activated  $\beta$ -catenin in somatic cells along with repressive histone marks enriched at these same sites functionally antagonize expression of Irx3 and Irx5 in the testis. Together, these findings highlight interactions between signaling pathways and epigenetic marks that regulate Irx3 and Irx5 to ensure appropriate expression based on time, sex, and cellular environments within developing gonads.

It has long been established that the fate of the developing gonad depends on a cadre of active transcription factors and epigenetic marks within the somatic cell population during the sex differentiation window (Garcia-Moreno, Futtner, et al., 2019; Garcia-Moreno, Plebanek, & Capel, 2018; Hiramatsu et al., 2009; Katoh-Fukui et al., 2012; Morais da Silva et al., 1996).  $\beta$ -catenin interacts with its DNA binding partners
(TCF/LEF) in response to canonical Wnt/Rspo1 signals within somatic cells to promote ovary formation while antagonizing testis-promoting factors (A. A. Chassot et al., 2008; Liu et al., 2009; Danielle M. Maatouk et al., 2008). Our previous study showed that the onset of *Irx3* and *Irx5* expression in the ovary is just after sex differentiation and is localized to the somatic cell population that surround germline nests and will eventually be marked by FOXL2, a granulosa cell marker (Fu et al., 2018). This profile indicated that both factors were good candidates for direct regulation by activated  $\beta$ -catenin at this time. Indeed, our transcript analyses of ovaries and testes subjected to pharmacological treatments in hanging drop culture or obtained from gain- and loss-of-function genetic mouse models supported the association of *Irx3* and *Irx5* expression with stabilized  $\beta$ -catenin.

As the ovary continues development, the germline nests break down and primordial follicles assemble to form the ovarian reserve.  $\beta$ -catenin expression has been documented in both somatic and germ cells at this time (A.-A. Chassot et al., 2011; Liu et al., 2009). *Irx3* expression is maintained within somatic cells as germline nests began to breakdown, but we were surprised to find that it is also present within oocytes beginning at the time of nest breakdown and lasting until follicles reached the primary stage (Fu et al., 2018). Once the follicle matures to the primary stage, *Irx3* transitions exclusively to the germ cell where it remains, even in mature follicles within the adult ovary (Fu et al., 2018). To test whether  $\beta$ -catenin also controlled *Irx3* expression within the oocyte during this critical transition, we crossed *Ctnnb1<sup>flox/flox</sup>* to *Figla*Cre mouse lines (Lin et al., 2014). We verified germ cell-specific elimination of  $\beta$ -catenin but

observed no impact on IRX3 expression, suggesting that *Irx3* is regulated by a separate pathway in the oocyte. Besides canonical Wnt/ $\beta$ -catenin signaling, *Irx3* has also been shown to be controlled by other pathways including TGF $\beta$  (Cavodeassi et al., 2001; JL, 1998), SHH (Briscoe, Pierani, Jessell, & Ericson, 2000; Kobayashi et al., 2002), FGF (Kobayashi et al., 2002), and Retinoic acid (Sirbu, Gresh, Barra, & Duester, 2005). Currently, little is known about signals that impact the oocyte during germline nest breakdown, follicle formation, and early maturation. These data highlight new directions of research that need exploration including the intriguing expression profiles of *Irx3* and *Irx5* within the oocyte at a critical phase of ovary development.

We examined ~1200kb of chromosome 8, which included the *IrxB* and *Fto* loci, for female-specific open chromatin sites that could also mediate canonical  $\beta$ -catenin regulation within somatic cells after sex differentiation. Altogether, our ATAC- (D. M. Maatouk et al., 2017) and DNAse1-Seq (Garcia-Moreno, Futtner, et al., 2019) data, along with results from ENCODE ChIP-Seq derived TCF/LEF enrichment in human cell lines (Consortium, 2012) illuminated five putative sites that met these criteria. Notably, none were identified within the proximal promoters of either *Irx3* or *Irx5*. Open chromatin sites were evaluated in the context of sex-specific somatic cells before and after sex determination, which allowed us to envision nucleosome depleted regions that became ovary specific over time. Two sites, +205kb and +86kb were shown to be nucleosome depleted in somatic cells of both sexes before sex determination but resolved into sites specific to ovarian somatic cells after sex determination. The other three sites at -305Akb, -305Bkb, and -580kb represented nucleosome depleted regions

that arised de novo only in cells from differentiated ovaries. All five regions had one transcription factor binding site in common, TCF7L2. One limitation to this study is that only perfect matches to the TCF/LEF binding domains were explored. HMG box transcription factors, such as TCF/LEF, can also bind to DNA motifs that do not match the perfect consensus sequence; therefore, all potential binding regions were not explored. In addition, the nucleosome depleted regions also harbor a variety of other putative binding sites according to the JASPAR database (Appendix 2) (Khan et al., 2018). These *in silico* analyses did not distinguish any common suite of transcription factor binding sites within either the resolved or *de novo* open chromatin regions. In particular, the two sites that we identified as the most promising  $\beta$ -catenin-responsive enhancers in the ovary, +86kb and -580kb, were characterized as resolved and de novo sites, respectively. Notably, besides TCF7L2, the +86kb site harbors sequences that also bind CTCF, p300, and YY1, factors that are important for facilitating higher order chromatin structures (Chan & La Thangue, 2001; Deng, Cao, Wan, & Sui, 2010; Ghirlando & Felsenfeld, 2016). These findings, in combination with the significant distance between enhancer sites and our results that show that 20-40% of Irx3 and Irx5 transcripts remain after elimination of  $\beta$ -catenin suggest that chromatin encompassing the IrxB locus loops and undergoes extensive remodeling in response to sex-specific signals and developmental time. As noted above, this activity may also incorporate alternative time-sensitive signals that are currently under intense investigation.

We used ChIP-PCR followed by transient transfection assays to identify which of the five nucleosome depleted sites qualified as putative TCF-bound enhancer sequences

that were also responsive to  $\beta$ -catenin activity. Of the five sites, both +86kb and -580kb regions achieved these criteria. Together, they significantly elevated reporter activity when cloned in front of ~2,000bp of the mouse *Irx3* promoter and a single base pair mutation specific to  $\beta$ -catenin/TCF binding in each site completely abrogated this effect. Our next goal was to determine the relevance of these sequences in promoting ovary-specific expression of *Irx3* and *Irx5*. To that end, we used our previously described microinjection and electroporation technique to transfect reporter plasmids into embryonic gonads (Gao et al., 2011) focusing on the mouse *Irx3* promoter and added both +86kb and -580kb enhancers into a luciferase reporter. *Ex vivo* gonad transfection analysis failed to detect any sex-specific reporter activity. Point mutation of each  $\beta$ -catenin/TCF binding site, however, turned out to be critical to uncover ovary-specific regulation.

At first, we were surprised that the enhancer/m/rx3 promoter reporters were equally active in ovaries and testes. We noted however, that in general, reporter plasmids are inherently devoid of epigenetic information. Enrichment of the active enhancer mark, H3K27Ac, was detected at the +86kb site in ovaries, with a trend towards positive enrichment at the -580kb site, while neither of these sites were enriched in testes. Meanwhile, our ChIP-Seq data showed substantial coverage by the repressor mark, H3K27me3 (Ringrose & Paro, 2007; Schuettengruber, Chourrout, Vervoort, Leblanc, & Cavalli, 2007) on both sites only in testes (Garcia-Moreno, Lin, et al., 2019). To test the relevance of these marks, we treated gonads *ex vivo* with Tazemetostat, a

pharmacological inhibitor of EZH2 mediated methyl transferase onto H3K27 (Knutson et al., 2014). Although we observed individual variability between gonads, we found that TAZ effectively increased the positive control, p21, transcripts in both ovaries and testes. The impact on *Irx3* and *Irx5* expression, however, appeared more profound in testis compared to ovary samples relative to p21 responses in each. It is possible that Tazemetostat treatment may cause release of another factor that could then stimulate *Iroquois* transcripts in testes; however, the results reported here are in the context of testis culture that lack aggressive epigenetic or transcription factor activation of other ovary-specific factors. Thus, taken together, we conclude that both +86kb and -560kb open sites are subject to changing epigenetic landscapes. In newly differentiated ovarian somatic cells, active  $\beta$ -catenin/TCF complexes accumulate on the *IrxB* locus to stimulate *Irx3* and *Irx5* transcription. In contrast, somatic cells that are destined for the testis phenotype lack  $\beta$ -catenin and instead, recruit epigenetic decorations consistent with transcriptional repression.

The results of this study highlight the importance of transcription factor binding and local epigenetic landscape in illuminating cell and sex-defining fates during gonadogenesis. Previous studies have focused on epigenetic events at the proximal promoter, demonstrating *Cbx2* binding at female specific-gene promoters to repress transcription of female factors during male sex differentiation. (Garcia-Moreno, Lin, et al., 2019). Our study highlights a similar mechanism, where repressive histone mark H3K27me3 and EZH2 activity represses transcriptional activity in the testis, but in this example, at female-specific enhancers, not promoters. Distant enhancer sites have long been

implicated in gene control in the gonad and new technologies are improving our capacity to identify and validate their importance (Gonen et al., 2018; Gonen, Quinn, O'Neill, Koopman, & Lovell-Badge, 2017; Sekido & Lovell-Badge, 2008). Here, we describe two distal enhancer sites on the *IrxB* locus that are actively repressed in developing testes while at the same time, are engaged with active chromatin marks and  $\beta$ -catenin/TCF to stimulate *Irx3* and *Irx5* expression within the developing ovary. Thus, *Irx3* and *Irx5* are bonafide downstream targets of Wnt/Rspo1/ $\beta$ -catenin that together, are critical mediators of ovary development and oocyte survival. These findings allow us to begin to unravel the means by which specific cell environments control *Irx3* and *Irx5* expression within the fetal ovary. We suggest that these same principles could be applied to the developing brain, spinal cord, lung, kidney, or to abnormal cellular activity in Iroquois-positive cancers.

# **Methods & Materials**

## Animals

Mouse strains included CD1 outbred mice (CrI:CD1(ICR), Charles River, MA), *Sf1*Cre mice that were originally obtained from the Keith Parker Lab (Bingham, Verma-Kurvari, Parada, & Parker, 2006), *Ctnnb1* conditional loss-of-function (LOF) mice (B6.129-*Ctnnb1*<sup>tm2Kem</sup>/KnwJ, Jackson Labs), and *Ctnnb1* conditional gain-of-function (GOF) mice ( $\beta$ -cat<sup>fl.ex3</sup>) obtained from Dr. Makoto Mark Taketo, Kyoto University, Kyoto, Japan (Harada et al., 1999). Timed mating was identified by the presence of a vaginal plug, which was designated as embryonic day 0.5 (E0.5). Animals were dissected at the appropriate time and genomic DNA was isolated from tails or ear notches and subjected to PCR using gene specific primers: Sf1Cre: 5'-

GAGTGAACGAACCTGGTCGAAATCAGTGCG-3' and 5'-GCATTACCGGTCGATGCAACGAGTGATGAG-3'; *Ctnnb1* wild-type and floxed (LOF) allele 5'-AAGGTAGAGTG ATGAAAGTTGTT-3' and 5'-CACCATTGTCCTCTGTCTATTC -3'; *Ctnnb1* wild-type and β-cat<sup>fl.ex3</sup> (GOF) allele 5'-GCTGCGTGGACAATGGCTACTCAA-3' and 5'-GCCATGTCCAACTCCATCAGGTCA-3'. In the case where sex could not be determined visually, PCR for SRY was performed: 5'-TGCAGCTCTACTCCAGTCTTG-3' and

5'-GATCTTGATTTTTAGTGTTC-3'.

Animal housing and all procedures described were reviewed and approved by the Institutional Animal Care and Use Committee at the University of Wisconsin-Madison and were performed in accordance with the National Institute of Health Guiding Principles for the Care and Use of Laboratory Animals. Mice were housed in disposable, ventilated cages (Innovive, San Diego, CA). Rooms were maintained at 22 ±2 degrees Celsius and 30–70% humidity on a 12 hour light/dark cycle.

# Organ culture using the droplet method

Gonad cultures were performed using a modified version of previously described protocols (Danielle M. Maatouk et al., 2008; Martineau, Nordqvist, Tilmann, Lovell-Badge, & Capel, 1997). Briefly, E11.5 gonad/mesonephros complexes were cultured at 37°C with 5%CO<sub>2</sub>/95% air in ~20µl droplet of culture media (DMEM F-12 (Fisher, SH3002301)) supplemented with 10% fetal bovine serum (Fisher, SH3091003) and 1%

Penicillin-Streptomycin (Fisher, ICN1670249). Sex of the gonads was determined by genotyping PCR for SRY (see above). Gonad/mesonephros complexes were placed in round droplets of media on an inverted lid of a 100mm Petri dish within a humidified chamber. Gonads (XX and XY) were cultured in a droplet supplemented with either vehicle control DMSO, the indicated concentrations of iCRT14 (XX gonads, Sigma SML0203), or LiCl (XY gonads, Fisher L121-100) for 24 hours, rinsed with PBS and then harvested for RNA extraction and qPCR analysis. Tazemetostat (EPZ-6438) (Selleckchem, S7128) treated gonads were cultured for 48 hours (media change at 24 hours) before harvest.

#### RNA Extraction and qPCR

RNA was extracted using Trizol (Invitrogen, ca#: 15596026) according to the manufacturer's instructions and quantified using a NanoDrop 2000. 500ng RNA from each sample was used for First-Strand cDNA synthesis by SuperScriptII-RT (Invitrogen, AM9515). cDNA was diluted 1:5 and then 2  $\mu$ I was added to 5  $\mu$ I SYBR green PCR mixture (Applied Biosystems), 2.4  $\mu$ I water, and 1.25 pmol primer mix. PCR reactions were carried out using the ABI Prism 7000 Sequence Detection System (Applied Biosystems). RNA transcripts were quantified using the  $\Delta\Delta$ Ct method (Livak & Schmittgen, 2001). Briefly, to control for overall gene expression in each time point, the average cycle threshold (aveCt) for 36B4 was subtracted from the aveCt value for each gene to generate  $\Delta$ Ct. Next,  $\Delta$ Ct for each gene was compared to  $\Delta$ Ct of that same gene for the mutant genotype (e.g.  $\Delta$ Ct Irx3<sub>female control</sub>- $\Delta$ Ct Irx3<sub>female mutant</sub>), to generate  $\Delta$ Ct.

Finally, fold change was calculated as 2 to the  $-\Delta\Delta Ct$  power ( $2^{-\Delta\Delta Ct}$ ). Primers are listed in **Supplementary Table 2-2**.

## DNase-I seq, ATAC-seq cluster analysis, and ChIP-seq

DNAse-I, ATAC-seq, and H3K27me3 data were mined from these studies: (Garcia-Moreno, Futtner, et al., 2019; Garcia-Moreno, Lin, et al., 2019; D. M. Maatouk et al., 2017). These data were analyzed for open chromatin regions within 600kb on either side of the *Irx3* transcription start site (tss) of chromosome 8 in the mouse. Open chromatin region sequences that were specific to the female after sex determination were explored for TCF/LEF binding motifs using the JASPAR database (jaspar.genereg.net). The sequences containing the highest scores for binding potential were chosen for further investigation.

#### Chromatin Immunoprecipitation

E13.5-E14.5 CD1 ovaries and testes without mesonephros were harvested, snap frozen, and stored at -80°C. 100-150 pairs of snap-frozen gonads were thawed and fixed in 1% formaldehyde for 15 min at room temperature with gentle shaking. The reaction was quenched with 160 µL of 1.25 M glycine for 5 min at room temp with gentle shaking. Samples were washed 2x with PBS and cOmplete<sup>™</sup> protease inhibitor (CPI) tablets (Roche, Basel, Switzerland; catalog #04693116001) then resuspended in 400 µL RIPA lysis buffer + CPI tablets. Samples were homogenized with a pestle, then chromatin shearing was performed by lightly sonicating via probe-based sonication to fully lyse cells and the nuclear envelope followed by 1 minute incubation at 37°C using

1000 gel units of Micrococcal Nuclease (MNase) (New England Biolabs; catalog #M0247S). A separate 5µL sample was incubated with Proteinase K to validate efficient shearing of DNA (between 300 bp-900 bp). The MNase reaction was stopped with 1.25 µmol EGTA. Debris was removed by centrifugation at 15,000 g for 10 m at 4 °C and then 100 µL of each lysate was diluted in 200 µL IP buffer (PBS + 0.05% Triton X-100) and incubated overnight with 2 µg of antibody. After overnight antibody incubation, 25 µL of Dynabeads protein G magnetic beads (Life Technologies; catalog #10004D) was added and mixed for 2 hours at 4 °C with gentle rocking. Samples were washed sequentially with 500 µL Low Salt, 500 µL High Salt, and 500 µL TE Buffers, then resuspended in Digestion Buffer (50 mM Tris, 10 mM EDTA, 0.5% SDS, pH 8.0) + Proteinase K for 2 hours at 62 °C. DNA was isolated via ethanol precipitation. qPCR analysis was performed to quantify relative amounts of DNA enrichment; immunoprecipitated (IP) samples were normalized to input and IgG. Antibodies used: Anti-phospo RNA PollI (Ser2), clone 3 (Millipore MABE954), Normal Mouse IgG (Sigma, M8695), TCF4 (C4H811) (Cell Signaling Technology, #2569S), and Histone H3K27Ac (Active Motif, Cat#39133).

# Plasmid Constructs

Luciferase reporters were generated from mouse genomic sequences of the enhancers at +205kb, +86kb, -305kb, and -580kb from the *Irx3* tss specific to the region containing the TCF/LEF binding motif via PCR with the addition of the KpnI and XhoI restriction enzyme sequences (**Supplementary Table 2-1**). Each sequence was digested and inserted into the pGL3 basic vector containing a minimal E1b promoter (Huang et al., 2006) digested at the KpnI and XhoI sites. The QuikChangeII site-directed mutagenesis kit was used to make a single base pair mutation for each TCF/LEF binding site as directed in the manufacturer's protocol (Stratagene) (**Supplementary Table 2-1**). The mouse *Irx3* promoter construct was generated from mouse genomic sequence using primers specific to 1634bp upstream and 446bp downstream of the *Irx3* tss and placed into the pGL3 basic vector. The +86kb and -580kb sequences were inserted in front of the mouse *Irx3* promoter using the NEBuilder HiFi DNA Assembly Cloning Kit according the manufacturer's instructions (New England BioLabs, E5520S). Each reporter construct was sequenced for accuracy after initial construction and proper mutation following mutagenesis (Sanger sequencing, UW Madison Biotech Center).

Plasmids containing promoter regions of *Irx3* were constructed via the Ensembl *Irx3* gene sequence and primer design software (Primer Designer version 1.01). PCR primers targeted the promoter region 5' of the *Irx3* tss. Genomic DNA was amplified, and inserts were blunt-end ligated into the pST-blue Accepter vector (Novagen). Sequencing was then performed (Keck Center, University of Illinois); the insert sequence was compared to the archived DNA sequence (NT\_078586.1) and validated for accuracy.

#### Cell culture and Transient Transfection

80,000 HEK293 cells were plated in 24 well plates (Thermo Scientific, catalog #12565163) for transfection assays. Plasmids were prepped using column based mini or midi prep kits (Qiagen, cat#27104, cat#12143) and quantified using a NanoDrop

2000. Cells were transfected using Lipofectamine 2000 (Invitrogen, cat#11668019) with plasmid DNA diluted in OPTI-MEM media (Fisher, cat#31985070) according to the manufacturer's instructions. Luciferase reporter vectors were transfected at 0.8µg/well along with 50ng/well co-expression vector CMV-EGFP (Addgene #11153) or CMV-S37A-β-catenin (Jordan et al., 2003) (kindly provided by Dr. Vincent Harley, Hudson Institute for Medical Research, Monash University, Melbourne, Australia) for normalization or treatment, respectively. The lipofectamine 2000 mixture was incubated with the cells for 16-18 hours followed by a media change. After 24 hours, the cells were lysed using 1X Passive lysis buffer and read using the Dual Luciferase Reporter Assay (Promega, E1910). Treatment groups were plated in triplicate and experiments were repeated at least three times. Luciferase values from the treatment group were normalized to the non-treatment group and also normalized to the empty vector control.

# Gonad Injection and Electroporation

Transient transfection assays in urogenital ridge explant cultures were based on previously reported methods of the explant culture system (Jorgensen & Gao, 2005). The sex of the gonad tissue was determined by characteristic findings of a coelomic vessel and testicular cords in the male and the lack of these in the female. Urogenital ridges were harvested from embryos at E14.5 and injected with approximately  $0.5\mu$ L of a DNA cocktail containing 4 µg/µl pGL3, wild type +86kb/-580kb/mIrx3 promoter pGL3, or mutated +86kb/-580kb/mIrx3 promoter pGL3 plus 2 µg/µl SV40-Renilla luciferase in Dulbecco phosphate-buffered saline (PBS; Sigma D8537). An additional aliquot of 25 µl of sterile PBS was placed on the gonad for electroporation. Immediately thereafter, five square electrical pulses of 65 V, 50 msec each at 100-msec intervals, were delivered through platinum electrodes from an electroporator. After electroporation, urogenital ridges were placed back into the culture for 24 hours. Explant cultures were maintained at 37°C with 5% CO<sub>2</sub>/95% air in 50 µl of Dulbecco minimal Eagle medium (DMEM) supplemented with 10% FBS (fetal bovine serum) and 1% Penicillin/Streptomycin. Transfected gonad explants were harvested in 50µl passive lysis buffer, snap frozen, subjected to three freeze-thaw cycles, and then processed for dual luciferase assays. Data were calculated by taking the ratio of luciferase to renilla expression with at least 3 biological replicates for each injected plasmid.

#### Statistics

Statistics between groups were carried out using a two-tailed t-test assuming unequal variances. Results were considered statistically significant if p-values were  $\leq$  0.05. One-way ANOVA Post-hoc Tukey was performed where appropriate.

# Acknowledgements

Special thanks to all members of the Jorgensen lab for ideas and support throughout this work. We are extremely grateful for the technical support from Dr. Camila Lopez-Anido and Dr. John Svaren in our. ChIP experiments. Also, thank you to Janelle Ryan and Dr. Vincent Harley for the CMV-S37A active  $\beta$ -catenin plasmid. We have an immense amount of gratitude to the cohort of undergraduates that helped with immunofluorescence, genotyping, and sectioning, especially Linda Wang, Ann Turcotte, and Rebekah Schroeder. In addition, thanks to the University of Wisconsin Biotron for the exemplary mouse husbandry help.

Dedicated to Danielle M. Maatouk, a wonderful colleague, scientist, and friend.

# Funding Support

This work was supported by the National Institutes of Health: R21HD48911, R01HD075079, and R01HD090660 to JSJ; R01HD090660-Reentry Supplement to AK; T32GM008688 to MLK; T32GM008061 to SAGM. In addition, this research was also supported in part by the Intramural Research Program of the National Institutes of Health at the National Institute of Environmental Health Sciences (NIH-ZIAES102965 to H.H-C.Y.).

Chapter 3

## Loss of $\beta$ -catenin in the oocyte does not impact *Irx3* expression or ovarian development

Koth, ML and Jorgensen, JS

Department of Comparative Biosciences, School of Veterinary Medicine, University of

Wisconsin – Madison, Madison, Wisconsin, USA

#### Abstract

β-catenin is critical for proper ovarian development and lies downstream of canonical Wnt/Rspo1 signaling during development. The somatic cell expression of β-catenin has been extensively studied, and its primary roles are to repress male-specific factors and to promote the female lineage. The role of β-catenin, however, in the germ cell has been harder to define based on the tools available. Using the newly developed *Figla*Cre-EGFP mouse line, we asked if knocking out β-catenin in the early oocyte would affect oocyte development, follicle formation, and ovarian morphology. We previously confirmed that β-catenin regulates *Irx3* in the somatic cell compartment. Therefore, we hypothesized that β-catenin regulates *Irx3* within the oocyte as well. Results indicate oocyte expression of β-catenin is not essential for ovarian function, oocyte health, follicle growth, or *Irx3* expression.

#### Introduction

β-catenin plays an integral role in ovarian development, which is clear based on the evidence presented in Chapter 1. This role is established in the somatic cell population of the ovary, with the conditional knockout exhibiting male-specific features (Liu, Bingham, Parker, & Yao, 2009; Manuylov, Smagulova, Leach, & Tevosian, 2008). Additionally, somatic cell stabilization of β-catenin in the testis overrides the male pathway and instead, promotes a male-to-female sex reversal (Maatouk et al., 2008). While the importance of β-catenin in the somatic cell compartment of the ovary is evident, the role of β-catenin in the oocyte remains elusive.

β-catenin is expressed in the oocyte as early as E12.5 and is transcriptionally active due to the detection of β-galactosidase in oocytes of  $Axin2^{+/LacZ}$  reporter mice (A.-A. Chassot et al., 2011; A. A. Chassot et al., 2008). Furthermore, *Rspo1* is necessary for the expression of β-catenin in the oocyte due to the lack of nuclear β-catenin staining in *Rspo1*-/- oocytes (A.-A. Chassot et al., 2011). Meiosis is affected in *Rspo1*-/- oocytes, where early meiotic marker *Stra8* and entry into meiosis is impaired. This ovarian phenotype occurs prior to detectable Sertoli cell differentiation, a feature of this mouse model, indicating that β-catenin expression in the germ cells promotes oocytes toward an XX fate and entry into meiosis (A.-A. Chassot et al., 2011). Moreover, overexpression of β-catenin in oocytes using *Ddx4*Cre showed a sub-fertile phenotype due to defects in ectoderm differentiation and abnormal fetal development, but no defects in ovarian function, oocyte number, ovulation ability, or embryonic development (Kumar et al., 2016).

 $\beta$ -catenin directly regulates transcription factors Irx3 and Irx5 in the somatic cells of the ovary (Chapter 2). Because Irx3 and Irx5 are expressed in the oocyte starting shortly after birth (Fu et al., 2018) and  $\beta$ -catenin is detected in the oocyte starting E12.5 (A.-A. Chassot et al., 2011; A. A. Chassot et al., 2008), we hypothesize the regulatory mechanism is consistent with the somatic cell compartment. Iroquois genes have a wide array of pathways associated with their regulation, which includes Wnt, Hedgehog, JAK/STAT, EGFR, and FGF (Briscoe, Pierani, Jessell, & Ericson, 2000; Cavodeassi, Diez Del Corral, Campuzano, & Domínguez, 1999; Gómez-Skarmeta, de La Calle-Mustienes, & Modolell, 2001; JL, 1998; Wang, Simcox, & Campbell, 2000; Zeidler, Perrimon, & Strutt, 1999). Therefore, we aimed to generate an oocyte-specific conditional knockout of β-catenin using the newly developed *FiglaCre*-EGFP to elucidate the importance of  $\beta$ -catenin in the developing oocyte and whether *Irx3* expression is regulated by  $\beta$ -catenin in the oocyte. We also hypothesized knocking out β-catenin in the early oocyte would affect follicle formation, meiosis, or proliferation in the ovary during early stages of development.

Multiple labs, including our own, have attempted to generate a knockout mouse that targets  $\beta$ -catenin loss specific to oocytes within the developing ovary. Attempts to eliminate  $\beta$ -catenin in oocytes at early embryonic stages using *TNAP*Cre or *Ddx4*Cre studies have either failed due to embryonic lethality (*TNAP*Cre (A.-A. Chassot et al., 2011)) or have remained unpublished, most likely due to the same issues (*Ddx4*Cre). One study was successful in knocking out  $\beta$ -catenin in oocytes using *Zp3*Cre, but this cre is not expressed until early postnatal development in growing oocytes (de Vries et al., 2000; Takezawa et al., 2011). In *Zp3*Cre  $\beta$ -catenin conditional knockout females, oocytes from control and mutant mice were super-ovulated and sperm-oocyte adhesion was examined *in vitro*, revealing a sperm-oocyte adhesion defect (Takezawa et al., 2011). While this study reported valuable information regarding the importance of  $\beta$ -catenin at the oocyte membrane, this group did not examine ovaries and the lack of phenotype could be due to cre recombinase activity turning on after follicle formation and after the onset of meiosis, when *Irx3* is first detected in the oocyte. Although their results suggest  $\beta$ -catenin deficient oocytes do not affect ovarian development in females, our study would be the first to directly observe this conditional knockout and its effects on ovarian and follicle development.

The conditional knockout of  $\beta$ -catenin in the oocyte utilizing *Figla*Cre-EGFP was successful, however, mutant mice exhibited ovaries indistinguishable from controls. Our factor of interest, *Irx3*, was not affected in the knockout mouse, indicating that a pathway other than  $\beta$ -catenin is responsible for its expression in the oocyte. Mutant oocytes were able to enter into meiosis properly and follicle development was not impaired. Further, while the ovarian somatic cell knockout of  $\beta$ -catenin exhibits germ cell death around birth, the germ cell knockout of  $\beta$ -catenin did not display any major phenotype.

Three major conclusions can be drawn from this study: First, our results suggest that oocyte activity of  $\beta$ -catenin is not necessary for ovary development and follicle maturation, which is a similar conclusion drawn in a previous study using a cre expressed at a later stage. Second, the outcome of Cre-Lox recombination is highly

dependent on the flox lines used. To our knowledge, *Figla*Cre-EGFP has been bred to three different flox lines: *mTomato/mEGFP*, *TdTomato*, and *Ctnnb1<sup>flox</sup>*. The original *Figla*Cre-EGFP study highlighted cre activity starting at E14.5 using *mTomato/mEGFP* mice. Dr. Humphrey Yao's lab presented evidence of *Figla*cre-EGFP activity beginning in early postnatal gonads using *TdTomato* mice, and we also did not see cre activity until early postnatal ovaries using *Ctnnb1<sup>flox</sup>* mice. Finally, important and useful new information gives us reason to conclude that *Irx3* is not regulated by β-catenin in the oocyte as we hypothesized. Even though we show critical evidence that *Irx3* is directly regulated by β-catenin in the somatic cells of the ovary, the oocyte expression of *Irx3* is independent of β-catenin.

#### Results

# Conclusion 1: $\beta$ -catenin in the oocyte is not required for proper ovarian development or follicle maturation

It is well established that  $\beta$ -catenin is necessary in the ovarian somatic cell and, therefore, ovary development, starting in the bipotential gonad (Chapter 1). Besides somatic cell expression,  $\beta$ -catenin is detected within germ cells of the ovary starting as early as E12.5 (A.-A. Chassot et al., 2011; A. A. Chassot et al., 2008). Elimination of  $\beta$ -catenin in the oocyte starting at post-natal, primary follicle stage had no impact on female fertility (Takezawa et al., 2011). Therefore, our goal was to evaluate whether loss of  $\beta$ -catenin in the oocyte at an earlier time point within the fetal ovary would have an impact on ovarian development.

#### Ovarian and follicle development is unaffected in mutant females

Histological analysis of ovaries in early postnatal (P0, P3, P7, P21) and preweaning stages confirms proper ovarian development in both control (No Cre;  $Ctnnb1^{t/f}$ ) and mutant (*Figla*Cre-EGFP;  $Ctnnb1^{t/f}$ ) mice. Follicles at all stages were present, indicating proper follicle maturation in mutant ovaries (**Figure 3-1**). Overall, the loss of  $\beta$ -catenin in the oocyte does not seem to affect ovarian development and follicle formation and maturation in the ovary (n=2-3 of each genotype and age).

#### Germ cells initiate meiosis in the early mutant ovary

β-catenin expression in the oocyte is important for proper entry into meiosis (A.-A. Chassot et al., 2011), therefore we used SCP3, which encodes synaptonemal complex protein 3 functions within a complex that forms between homologous chromosomes during prophase of meiosis (Yuan et al., 2002) to detect oocytes undergoing meiosis in E16.5 ovaries. Our results showed that there was no difference in staining between control (No Cre; *Ctnnb1<sup>F/F</sup>*) and mutant (*Figla*Cre; *Ctnnb1<sup>F/F</sup>*) ovaries. Most germ cells stained positive for SCP3 in both genotypes, indicating that mutant oocytes initiated meiosis similar to controls (n=2 ovaries for each genotype and age) (**Figure 3-2**).

#### Germ cells remain abundant at birth

Massive germ cell death curing early ovarian development is a shared phenotype in *Wnt4* null (Vainio, Heikkilä, Kispert, Chin, & McMahon, 1999), *Rspo1*<sup>-/-</sup> (Tomizuka et

al., 2008), and  $\beta$ -catenin somatic cKO mice (Liu et al., 2009). We hypothesized that  $\beta$ catenin depletion in the oocyte would also result in germ cell death. Ovary sections were stained with a germ cell-specific marker, Tra98, at P0 in control (No Cre; *Ctnnb1<sup>F/F</sup>*) and mutant (*Figla*Cre; *Ctnnb1<sup>F/F</sup>*) ovaries. Quantification indicated that germ cell numbers were comparable between mutant and control ovaries (n=2-3 ovaries per genotype) (**Figure 3-3**).

#### The proliferation of somatic cells is unaltered

β-catenin is implicated in many cell types as a proliferative marker and is shown to regulate Wnt4 expression in the ovary, a paracrine signal that affects downstream events, such as proliferation (Hernandez Gifford, 2015; Liu et al., 2009; Liu, Parker, & Yao, 2010). This function of Wnt4 leads to the question of whether loss of β-catenin in the oocyte could affect proliferation in other ovarian cell types. Postnatal day 7 (P7) ovaries were examined for proliferation differences using Ki67 (**Figure 3-4A**). Average Ki67 positive granulosa cells per follicle were quantified, and there was no significant difference between control and mutant animals (n=8 follicles of similar size/stage, 2-3 animals per genotype) (**Figure 3-4B**).

#### Follicle number is not affected in adult mutant females

Although our restuls indicate that early ovarian development is comparable between control and mutant mice up to preweaning age, we hypothesized that the loss of  $\beta$ -catenin in the oocyte might have an effect on germ/somatic cell contacts in larger follicles, which could potentially trigger follicle death. To quantify follicles in adult mice, eight-week-old control and mutant females were collected for histological analysis. Follicle types were quantified and presented as the percentage of total follicles counted. No significant difference was seen at any follicle stage between the control and mutant ovaries: Primordial (29.0% vs 22.1%), primary (10.2% vs 9.4%), secondary (4.9% vs 4.0%), preantral (14.8% vs 19.9%), antral (7.4% vs 7.7%), small atretic (25.2% vs 29.7%) and large atretic (8.5% vs 7.3%). Based on these results, we conclude that follicle formation and growth are independent of  $\beta$ -catenin expression in the oocyte. (**Figure 3-5**)

#### Conclusion 2: Flox lines respond to Cre activity differently

#### Loss of $\beta$ -catenin using FiglaCre-EGFP confirmed via immunohistochemistry

According to the original publication of the *Figla*Cre-EGFP mouse (Lin, Jimenez-Movilla, & Dean, 2014), cre recombinase activity was observed beginning at E14.5 (shown by EGFP expression) and in newborn ovaries and testes of *mTomato/mEGFP* reporter lines. *Figla*Cre-EGFP was also bred to the *TdTomato* line, and EGFP expression was not detected in embryonic gonad tissue but was observed in early postnatal gonads starting at P1, courtesy of Dr. Paula Brown and Dr. Humphrey Yao (NIEHS) (**Supplementary Figure 3-1**). In our study, *Figla*Cre-EGFP were bred to *Ctnnb1<sup>flox</sup>* mice in two generations to generate mutant samples (see methods). We did not observe differences in β-catenin expression in oocytes of mutant mice (*Figla*Cre-EGFP; *Ctnnb1<sup>flox/flox</sup>*) until postnatal day 3 (**Figure 3-1**). The most notable effect on βcatenin was observed by postnatal day 7, with oocytes of all stages harboring β-catenin in control but were absent in the mutant ovaries (**Figure 3-1**). Our data are similar to *Figla*Cre-EGFP x *TdTomato* reporter, indicating that the timing of *Figla*Cre onset is occurring at a later stage than anticipated. This may explain why our phenotype is similar to the *Zp3*Cre knockout of  $\beta$ -catenin, as *Zp3*Cre is not efficient until after follicle formation in early postnatal oocytes.

#### Conclusion 3: Irx3 is not regulated by $\beta$ -catenin in the oocyte

#### Irx3 expression in oocyte is unaffected

Even though we did not detect any defect in ovarian development or follicle maturation using *Figla*Cre-EGFP x *Ctnnb1<sup>flox</sup>* females, we were still determined to assess its role in regulating *Irx3*. We have demonstrated that  $\beta$ -catenin controls the expression of *Irx3* (and *Irx5*) in the somatic cells of the ovary (Chapter 2), therefore it was hypothesized that  $\beta$ -catenin controls the expression of these genes in the oocytes as well. Immunohistochemistry using an antibody for IRX3 indicate that IRX3 is expressed at similar levels within oocytes of control (No Cre; *Ctnnb1<sup>F/F</sup>*) and mutant (*Figla*Cre; *Ctnnb1<sup>F/F</sup>*) ovaries at P7, despite the absence of  $\beta$ -catenin in the oocyte (**Figure 3-7**). These results suggest that IRX3 expression in the oocyte is independent of  $\beta$ -catenin activity, and further investigation is necessary to uncover the regulatory mechanism of *Irx3* and *Irx5* in the oocyte.

#### Discussion

β-catenin is critical for proper ovarian development, and has been shown to play roles in both the somatic and germ cell compartments during gestation (A.-A. Chassot et al., 2011; Liu et al., 2009). The role of β-catenin in the oocyte during development has remained elusive due to the lack of efficient cre mouse models, therefore we aimed to generate an oocyte-specific knockout of β-catenin utilizing the newly developed *Figla*Cre-EGFP (Lin et al., 2014). In addition, we previously determined that β-catenin is responsible for *Irx3* regulation in the somatic cells of the ovary (Chapter 2) and therefore hypothesized that loss of β-catenin in the oocyte would result in loss of *Irx3* expression in the oocyte. Altogether, this study provided additional insight into the role of β-catenin in the germ cell and gave us key information regarding the regulation of *Irx3* in a critical ovarian cell type.

We generated three conclusions from this study:  $\beta$ -catenin in the oocyte is not required for proper ovarian development or follicle maturation, flox lines respond to *Figla*Cre-EGFP activity differently, and *Irx3* is not regulated by  $\beta$ -catenin in the oocyte. First, we found that *Figla*Cre-EGFP; *Ctnnb1*<sup>flox/flox</sup> ovaries had a normal phenotype and female mice were fertile. Germ cell numbers, proliferation rate, and follicle counts were comparable between our control and mutant ovaries, indicating mutant ovaries did not exhibit any major defects.  $\beta$ -catenin is crucial for the entry of meiosis in oocytes (A.-A. Chassot et al., 2011), but oocytes in our mutant mice were able to initiate meiosis comparable to control oocytes. We discovered that in contrast to previous reports using *Figla*Cre-EGFP mice,  $\beta$ -catenin was not eliminated until after birth, around P3. For

example, meiosis initiates during ovarian development and would likely be affected if the cre initiated excision of β-catenin by E14.5, but based on our expression data, *Figla*Cre-EGFP is not expressed until after this process has already initiated. We were able to mimic the phenotype reported in a previous study using *Zp3*Cre that knocked out β-catenin in the oocyte. *Zp3*Cre is active in growing oocytes, generally starting at about the secondary follicle stage. The authors used IVF to study the sperm-oocyte adhesion defects in these oocytes lacking β-catenin, and they reported similar numbers of oocytes were collected from control and mutant animals, suggesting no ovarian defects in mutant females (Takezawa et al., 2011). Ovarian development was not examined in the *Zp3*Cre; *Ctnnb1<sup>flox/flox</sup>* mutant mice, and we were able to confirm that there are no defects in ovarian development or follicle maturation when β-catenin is knocked out in the oocyte.

Next, the outcome of *Figla*Cre depends on the applied flox line. In the original study, *Figla*Cre-EGFP activity was reported at E14.5 utilizing the EGFP tag (Lin et al., 2014). *mTomato/mEGFP*, an additional reporter line used in this study, reported *Figla*Cre-EGFP activity in newborn gonads of both sexes. It was not clear if the authors examined the reporter strain at an earlier time point, yet it would be an important finding to disclose in the study. Our collaborators Dr. Humphrey Yao and Dr. Pamela Brown performed an expression test using *TdTomato* and did not see *Figla*Cre-EGFP activity via EGFP staining until early postnatal life. Our results emulated the results from the Yao lab, showing no obvious loss of  $\beta$ -catenin in the oocyte in the *Figla*Cre-EGFP; *Ctnnb1*<sup>f/f</sup> oocytes until postnatal age points.

Finally, we were able to conclude that  $\beta$ -catenin does not regulate *Irx3* in the oocyte. IRX3 is expressed in the somatic cells of the ovary during development, and is expressed solely in the oocyte around birth in the mouse (Fu et al., 2018). Our previous work has shown that *Irx3* is directly regulated by the canonical Wnt/Rspo1/ $\beta$ -catenin signaling pathway in the somatic cells of the ovary early in development (Chapter 2) and we hypothesized that this pathway may also be responsible for the expression of *Irx3* in the oocyte. Our results show that IRX3 expression in the oocyte is not affected by oocyte-specific knockout of  $\beta$ -catenin. Thus, regulation of Iroquois factors may be linked to other pathways documented, including Hedgehog (Cavodeassi et al., 1999), JAK/STAT (Zeidler et al., 1999), EGFR (Wang et al., 2000), and TGF $\beta$  factors (Cavodeassi, Modolell, & Gómez-Skarmeta, 2001). This important finding requires further examination, as we have reason to believe that IRX3 expression in the oocyte has a large impact on oocyte and follicle health.

Previous reports showed that overexpression of  $\beta$ -catenin in oocytes using *Ddx4*Cre had no impact on oocytes or ovarian function (Kumar et al., 2016). In spite of this finding, mutant females bred to males with known fertility never resulted in pups. The authors showed that  $\beta$ -catenin overexpression in oocytes caused defects in the development of embryonic germ layers, which lead to fetal death (Kumar et al., 2016). We tried to recapitulate this phenotype using *Figla*Cre-EGFP with no success – pups from the F2 generation (*Figla*Cre-EGFP; *Ctnnb1*<sup>GOF/+</sup> X *Ctnnb1*<sup>GOF/GOF</sup>) were all heterozygous. Further analysis revealed these mutant pups died *in utero*, most likely due to a combination of a leaky cre and a very robust  $\beta$ -catenin gain-of-function model. Analysis of *Figla*Cre-EGFP; *Ctnnb1<sup>GOF/+</sup>* mice revealed no distinct phenotype, as they were viable and fertile, indicating the defect most likely occurred during the F2 breeding.

In conclusion, the loss of  $\beta$ -catenin in the oocyte starting at a postnatal stage did not have a significant effect on oocyte and follicle development, maturation, or morphology. Our phenotype was similar to that reported with *Zp3*Cre, which initiated cre-excision at approximately the same time although previous reports indicated robust *Figla*Cre expression by E14.5 in the female (Lin et al., 2014). The *Figla*Cre-EGFP; *Ctnnb1*<sup>flox/flox</sup> mutant mouse model did not eliminate *Irx3* expression in the oocyte, suggesting that Iroquois factors have a different regulatory mechanism in their expression than in the somatic cell compartment, a critical finding that requires further investigation. To date, there is no model to knock out  $\beta$ -catenin in the oocyte at an early gestational age, indicating a need for this critical resource; perhaps or a novel technique in gene manipulation, such as cell-specific CrisprCas9, would help to reveal the role of  $\beta$ -catenin in the early oocyte.

#### Methods

#### Animals

Mouse strains included *Ctnnb1* floxed conditional loss-of-function (LOF) mice (B6.129-*Ctnnb1*<sup>tm2Kem</sup>/KnwJ, Jackson Labs) and *Figla*Cre-EGFP (FVB/N-Tg(Figla-EGFPicre)ZP3Dean/Mmjax) obtained from Dr. Jurrien Dean at NIH/NIDDK. Timed mating was identified by the presence of a vaginal plug, which was designated as embryonic day 0.5 (E0.5). Animals were dissected at the appropriate time, and genomic DNA was isolated from tails or ear notches and subjected to PCR using gene-specific primers: *Ctnnb1* wild-type and floxed (LOF) allele 5'-AAGGTAGAGTG ATGAAAGTTGTT-3' and 5'-CACCATTGTCCTCTGTCTATTC -3'; *Figla*Cre iCRE F: 5' -CCAGCTCAACATGCTGCACA-3' and iCRE R: 5' - GCCACACCAGACACAGAGAT – 3'.

Animal housing and all procedures described were reviewed and approved by the Institutional Animal Care and Use Committee at the University of Wisconsin-Madison and were performed in accordance with the National Institute of Health Guiding Principles for the Care and Use of Laboratory Animals. Mice were housed in disposable, ventilated cages (Innovive, San Diego, CA). Rooms were maintained at 22 ±2 degrees Celsius and 30–70% humidity on a 12 hour light/dark cycle.

*Figla*Cre-EGFP mice were bred in two generations to generate mutant samples as outlined below.

#### Histology

Ovaries were harvested at the age indicated, fixed in 4% PFA overnight and embedded in paraffin. Paraffin blocks were sectioned at 8µm thickness and stained with hematoxylin and eosin (H&E) for histological analysis.

#### Immunofluorescence

Mouse ovaries were harvested at the age indicated, fixed in 4% paraformaldehyde overnight at 4°C, and washed in PBS. Samples were dehydrated through an ethanol gradient, cleared in xylene, and embedded in paraffin. Blocks were sectioned at 8µm thickness. After paraffin clearing, rehydration gradient, antigen retrieval, and blocking, primary antibodies were applied to paraffin sections at 4°C overnight (**Supplementary Table 1**). Secondary antibodies were then incubated at room temperature for 1 hour. DAPI in PBS solution was used as a nuclear counterstain. Images were collected on a Leica SP8 confocal microscope and a Keyence BZ-X700 microscope.

#### Cell Counting

Blinded to genotype, Ki67 positive granulosa cells of similar-staged follicles were counted using ImageJ. N=8 follicles, 2-3 animals per genotype.

#### Follicle Quantification

Ovaries were sectioned entirely through. Every 10<sup>th</sup> section was stained for H&E and used to quantify the numbers for each follicle type. All counting was completed blinded to the ovary genotype.

### Chapter 4

### *Irx3* Overexpression in the Developing Ovary and Testis

Manuscript in preparation

Wisconsin – Madison, Madison, Wisconsin, USA

#### Abstract

*Irx3* is expressed in the mouse ovary after sex differentiation and plays an important role in follicle health and female fertility while *Irx3* is not expressed in the testis. A novel *Irx3* overexpression mouse model was used to overexpress *Irx3* in the somatic or germ cells of ovaries and to introduce *Irx3* in testes where expression is normally absent. *Sf1*Cre was used to drive overexpression in somatic cells of the gonad, while *Figla*Cre-EGFP drove germ-cell specific cre recombinase. Our results suggest *Irx3* overexpression in either granulosa cells or oocytes had no impact on ovarian morphology or female fertility. *Irx3* overexpression in the somatic cells of the testes did not affect testis histology or male fertility. In contrast, *Irx3* overexpression in the germ cells of the testis resulted in sub-fertility and a sperm agglutination phenotype. These results suggest that introduction of *Irx3* expression in sperm may be detrimental to sperm health and could give us insight into a potential contributing factor to male infertility.

#### Introduction

*Irx3* and *Irx5*, two transcription factors expressed in the ovary, but not the testis during gonad development, are important for follicle integrity, ovarian health, and fertility (A. Fu et al., 2018; B. Kim, Kim, Cooke, Rüther, & Jorgensen, 2011). Both *Irx3* and *Irx5* are expressed in the somatic cells (pre-granulosa cells) prior to birth, but their expression expands to the germ cell just before germline nest breakdown around E17.5 to postnatal day zero (P0). After follicles have formed, *Irx3* expression transitions to oocyte only, while *Irx5* expression reverts back into the somatic cells for a brief period of time before its expression diminishes (A. Fu et al., 2018). The dynamic expression profile of these genes leads us to question whether overexpression of *Irx3* in the ovary or introduction of *Irx3* in the testis would have any effect on gonad development or fertility.

The gonad consists of two major cell types: somatic and germ. Ovaries consist of both theca and granulosa somatic cells and germ cells called oocytes. Testes are composed of Sertoli, Leydig, and interstitial somatic cells and germ cells called sperm. *Irx3* is not expressed in any testis cell type, while ovarian somatic and germ cells have a dynamic expression pattern of *Irx3*. The expression profile of *Irx3* in ovaries led us to hypothesize whether extending the expression of *Irx3* in the somatic cells of the ovary or increasing *Irx3* in the oocyte would have any effect on ovarian development or fertility. Moreover, we questioned if introduction of *Irx3* in either somatic or germ cells of the testis would have any effect in the male. Utilizing a conditional *Irx3* overexpression mouse model, we were able to overexpress *Irx3* in somatic cells using *Sf1*Cre and germ cells with a newly developed line, *Figla*Cre-EGFP. These mouse models gave us insight

into the role and function of *Irx3* in both ovaries and testes, and how abnormal expression due to genetic defects may have long-term effects on gonad health and fertility later in life.

After histological analysis and breeding studies, we can conclude that *Irx3* overexpression in the somatic or germ cells of the ovary had no impact on ovarian histology and function. *Sf1*Cre driven overexpression of *Irx3* in the somatic cells of the testis did not affect testis morphology or male fertility. *Irx3* overexpression in sperm, however, were sub-fertile; these males were able to generate litters and pups, but litters were inconsistent and fewer pups were produced in total throughout the breeding period. Through sperm analysis, we discovered an intriguing phenotype that suggests *Irx3* overexpression in sperm causes sperm agglutination. Sperm agglutination is commonly seen in men, and *Irx3* has yet to be connected with this phenotype.

#### Results

#### Irx3 overexpression mouse model and confirmation of overexpression

*Irx3* sequences were inserted downstream of a stop cassette flanked by LoxP sites targeted into the *Rosa26* locus, enabling tissue (cre) specific overexpression of *Irx3*. Cre recombinase excises the stop codon which will allow expression of HA-*Irx3* and EGFP within cre expressing cells (Hui C.C., unpublished). Cre recombinase was targeted to the somatic cells of the gonad with *Sf1*Cre (Bingham, Verma-Kurvari, Parada, & Parker, 2006) or *Figla*Cre-EGFP (Lin, Jimenez-Movilla, & Dean, 2014) to overexpress *Irx3* in ovaries or testes. **Figure 4-1A** shows a diagram of the *Irx3* overexpression mouse model used in these studies.

For clarity, the following nomenclature will be used to classify each mouse model:

- Ovary C-*Irx3*: Control female (No Cre; *Irx3<sup>GOF/GOF</sup>*). This genotype is the control for both somatic and germ cell overexpression within each breeding line.
- Ovary S-Irx3: Somatic cell Irx3 overexpression female (Sf1Cre; Irx3<sup>GOF/GOF</sup>)
- Ovary G-Irx3: Germ cell Irx3 overexpression female (FiglaCre-EGFP; Irx3<sup>GOF/GOF</sup>)
- Testis C-*Irx3*: Control male (No Cre; *Irx3<sup>GOF/GOF</sup>*). This genotype is the control for both somatic and germ cell overexpression within each breeding line.
- Testis S-Irx3: Somatic cell Irx3 overexpression male (Sf1Cre; Irx3<sup>GOF/GOF</sup>)
- Testis G-Irx3: Germ cell Irx3 overexpression male (FiglaCre-EGFP; Irx3<sup>GOF/GOF</sup>)

Methods to confirm overexpression of *Irx3* in the somatic cells of both ovaries and testes included evaluation of *Irx3* transcripts and immunohistochemistry for EGFPreporter detection. qPCR was performed using E15.5 gonads. *Irx3* is specific to somatic cells in the ovary at this gestational age and is near its peak expression level. **Ovary**: transcripts from Ovary C-*Irx3* and Ovary S-*Irx3* at E15.5 showed no change in negative control *Rps29* as expected. *Irx3* expression was significantly higher in Ovary S-*Irx3* (2.2 fold over Ovary C-*Irx3*, p=0.016), and *Irx5* was unchanged (**Figure 4-1B**). **Testis**: *Rps29* was unchanged between Testis C-*Irx3* and Testis S-*Irx3*, while *Irx3* was significantly higher in Testis S-*Irx3* (29.5 fold over Testis C-*Irx3*, p=0.0001). It is important to note that because *Irx3* is expressed at extremely low levels in the Testis C-*Irx3*, the relative fold change in the Testis S-*Irx3* is high. When the Testis S-*Irx3* values were normalized to the Ovary C-*Irx3*, the fold change is equivalent to the Ovary S-*Irx3*, at about 2.4-fold. *Irx5* was unchanged in the Testis S-*Irx3* compared to Testis C-*Irx3*. Preliminary results from P0 Testis C-*Irx3* and Testis G-*Irx3* indicate *Irx3* is expressed about 14-fold higher in the Testis G-*Irx3* (**Figure 4-1C**). Ovary G-*Irx3* expression in the somatic cells at P0.

Sf1Cre drives expression to somatic cells, and it is important to confirm that *Irx3* or EGFP expression is confined to this cell type. Quantitative PCR suggested elevated *Irx3* transcripts in developing ovaries and testes but does not produce localization information. To establish cell specificity, we evaluated gonads by immunohistochemistry (IHC) and *in-situ* hybridization (ISH). To confirm overexpression of *Irx3* specifically to somatic cells, we took advantage of the reporter that was incorporated in the targeted knock-in in gonads from *Sf1Cre* positive animals. IHC was performed using an antibody for EGFP, which is tagged to *Irx3* in the overexpression mouse model. P0 testes show EGFP expression of *Irx3* in the correct cell type (**Figure 4-2A**). Previously, we reported that *Irx3* is expressed in the both the somatic and germ cell compartments at postnatal day 0 (P0) (A. Fu et al., 2018). Shortly thereafter, *Irx3* expression transitions in the somatic cells and is confined to the oocyte. Therefore, P21 ovaries from Ovary C-*Irx3* 

and Ovary S-*Irx3* were subjected to both ISH for *Irx3* and IHC for EGFP for somatic overexpression analysis. Ovary S-*Irx3* ovaries showed increased *Irx3* mRNA and EGFP expression in the somatic cells of the P21 ovaries compared to Ovary C-*Irx3* (**Figure 4-2B**).

To confirm *Irx3* overexpression did not affect classic sex-specific markers, additional sex-specific controls *Foxl2* (ovary) and *Sox9* (testis) transcripts were analyzed by qPCR. *Foxl2* showed no change between Ovary C-*Irx3* and Ovary S-*Irx3* ovaries. *Sox9* was unchanged between Testis C-*Irx3* and Testis S-*Irx3* testes (**Supplementary Figure 4-1**). Overall, *Irx3* transcripts were elevated in the overexpression models analyzed, and EGFP expression is confined to the correct cell type in the somatic cell models.

#### Irx3 overexpression in the ovary does not affect ovarian function or female fertility

*Sf1Cre* was bred to *Irx3<sup>GOF/GOF</sup>* females to generate *Irx3* overexpression confined to the somatic cells of the ovary. Although *Irx3* is endogenously expressed in the somatic cells until the primordial follicle stage, we hypothesized that stabilizing *Irx3* after it is normally absent in the somatic cells could have an effect on follicle health and maturation. Ovary C-*Irx3* and Ovary S-*Irx3* ovaries were harvested from embryonic (E) 16.5, postnatal (P) day 0, P21, and adult mice to follow ovarian development and follicle maturation over time. Of most interest was to observe any defects in later follicle stages, when *Irx3* is normally turned off. Healthy follicles of all stages were present in both Ovary C-*Irx3* and Ovary S-*Irx3* ovaries, indicating there were no defects during follicle formation or development. (**Figure 4-3A**). Next, Ovary S-*Irx3* mice and Ovary C-*Irx3* 

controls were set up with wild-type CD1 males for 6 months to assess fertility. Litter dates and pup numbers were recorded throughout the breeding period. No significant difference was seen at any point in the study between Ovary C-*Irx3* and Ovary S-*Irx3* (**Figure 4-3B**).

Likewise, *Figla*Cre-EGFP was bred to *Irx3*<sup>GOF/GOF</sup> female mice to overexpress *Irx3* in the germ cell. *Irx3* is endogenously expressed in the oocyte beginning at the primordial follicle stage. Stabilized expression of other endogenously expressed genes, such as  $\beta$ -catenin, can disrupt normal ovarian function (Maatouk et al., 2008). Therefore, we questioned whether stabilization of *Irx3* could have an effect on oocyte health, follicle maturation, or female fertility. Ovary C-*Irx3* and Ovary G-*Irx3* ovaries from P0, P7, and P21 were processed for H&E analysis, and no visible defects were seen in follicle development or maturation. (**Figure 4-4A**). Next, to assess fertility, Ovary C-*Irx3* and Ovary G-*Irx3* mice were bred to male wild-type CD1 mice for 5 months and litter dates and pup numbers were recorded. Total pup number accumulation over time was comparable between Ovary C-*Irx3* and Ovary G-*Irx3* mice, indicating no fertility defects (**Figure 4-4B**).

Irx3 overexpression in the somatic cells of the testis does not affect testis function or male fertility

*Irx3* is not expressed at any point during testis development; therefore, we hypothesized that aberrant *Irx3* overexpression may cause defects in testis development and/or male fertility. Testes were collected during gestation and into adulthood to analyze testis cord formation and development at E16.5, P0, P21, and

adult in Testis C-*Irx3* and Testis S-*Irx3* mice. Histological analysis shows normal testis cords and seminiferous tubules in Testis S-*Irx3* mice that were comparable to controls throughout development and into adulthood, indicating proper testis formation and development (**Figure 4-5A**). As with studies in female mice, Testis S-*Irx3* males along with Testis C-*Irx3* controls were paired with wild-type CD1 females for a 6-month breeding study. Results showed no difference in litter sizes over time between control and Testis S-*Irx3* mice (**Figure 4-5B**). Overall, *Irx3* overexpression in the somatic cells of the testis had no effect on testis histology and had no effect on male fertility.

# Irx3 overexpression in the germ cells of male mice results in a sub-fertile phenotype and sperm agglutination

To assess the effects of *Irx3* overexpression in sperm, we bred *Figla*Cre-EGFP to *Irx3*<sup>GOF/GOF</sup> mice. Testes were collected at P0, P7, P21, and adult in Testis C-*Irx3* and Testis G-*Irx3* mice and processed for histological analysis. Sections from testes from each time point were stained with H&E. Results show no obvious defects in Testis G-*Irx3* samples when compared to controls (**Figure 4-6A**). Although there was no obvious defect based on histology, a breeding study was required to assess testis function in these mice. Testis C-*Irx3* and Testis G-*Irx3* males were set up with wild-type CD1 females for 4 months. Testis C-*Irx3* males, on average, produced litters of 11 to 18 pups every 23 days. In contrast, Testis G-*Irx3* males failed to produce litters on a regular basis of consistent size. One Testis G-*Irx3* mouse produced litters, but the litter sizes contained fewer pups than the average control litter size (15 vs 5.4 pups). Two other Testis G-*Irx3* males in the study produced one litter within 1-2 months, but then failed to

produce any litters thereafter. Finally, one other Testis G-*Irx3* male has never produced a litter. Overall, Testis G-*Irx3* males showed a phenotype consistent with sub- or complete infertility when *Irx3* was overexpressed in the germ cells of the testis (**Figure 4-6B**).

The results of the breeding study were surprising given that no obvious morphological defect was observed. Thus, we hypothesized that sperm concentration and/or motility were decreased in Testis G-Irx3 males. Following the breeding study, Testis C-Irx3 and Testis G-Irx3 males were euthanized and their epididiymides were aseptically dissected. Mature sperm were released from the epididymides and after brief incubation at 37°C, loaded onto a sperm-counting chamber slide and analyzed using a computer assisted sperm analyzer to assess motility and concentration. Testis C-Irx3 sperm were normal with high sperm counts and high motility rates. The Testis G-Irx3 mouse that produced consistent litters of fewer pups showed normal sperm concentration and motility, but displayed numerous clumps of sperm moving around within the sample. The two Testis G-Irx3 males that produced one litter and then none thereafter showed variable sperm concentration (though nothing of concern) and high motility, but also displayed sperm agglutination throughout the sample. The sperm from the Testis G-Irx3 male that has produced zero litters will be analyzed after the conclusion of his breeding period. A table displaying sperm counts, motility rate, and phenotype displayed as well as images of a representative sperm analysis image is presented in Figure 4-7A, B. In conclusion, Testis G-Irx3 males exhibit an intriguing phenotype of sperm agglutination that warrants further investigation and the need to fine-tune testicular histological analysis.

#### Discussion

To disrupt the endogenous expression profile of *Irx3* in the ovary or to introduce *Irx3* expression in the testis, we overexpressed *Irx3* in either the somatic or germ cells of both ovaries and testes. We can conclude that *Irx3* overexpression in the ovary in either somatic or germ cells has no impact on ovarian histology or fertility, and *Irx3* overexpression in the somatic cells of the testis does not affect testis histology or fertility. In the Testis G-*Irx3* model, testis morphology was not histologically different from controls; however, Testis G-*Irx3* mice exhibited a sub-fertile phenotype and sperm agglutination was detected using sperm analysis. Sperm agglutination is not widely seen in mice and warrants further investigation for this project.

In the ovary, *Irx3* expression turns off in the somatic cell compartment after primordial follicle formation. We questioned whether stabilizing *Irx3* expression in the granulosa cells would have an effect on follicle maturation or ovarian function. We did not see any defect in the Ovary S-*Irx3* model, and we reflected on the qPCR transcript levels of *Irx3* compared to Ovary C-*Irx3* mice. Ovary S-*Irx3* mice displayed a 2.2-fold increase in *Irx3* transcripts compared to the control, which may not be sufficient to drive a phenotype in these females, suggesting endogenous *Irx3* expression may be at a point of saturation and overexpression had no effect. This may also be the case in the germ cell compartment, where a slight increase of *Irx3* expression may have no biological consequences *in vivo*.

*Irx3* is not expressed in the testis at any point during development; therefore, we hypothesized that aberrant expression of *Irx3* would disrupt testicular development and fertility. The somatic cell overexpression of *Irx3* showed no indication of irregular

testicular cord development, and the breeding study confirmed that these male mice were as fertile as control littermates. In contrast, germ cell overexpression of *Irx3* showed no obvious signs of abnormal testes or sperm by H&E analysis, but the breeding study exposed a significant fertility defect. Some, but not all Testis G-*Irx3* mice were able to produce litters that were inconsistent in timing and litter size. Sperm analysis determined that Testis G-*Irx3* males had normal sperm counts; however, there was significant evidence of sperm agglutination.

Sperm agglutination is defined as sperm adhering to each other without the presence of other cells or debris (Ulrik Kvist, 2002). This phenomenon was first documented in the early 1900s and seen as a relatively uncommon condition (WILSON, 1956). More recent studies show that sperm autoimmunity, the leading cause of sperm agglutination, is thought to be caused by the presence of antibodies against spermatozoa (Friberg, 1980; Friberg & Tilly-Friberg, 1977; Ulrik Kvist, 2002; WILSON, 1956) and is responsible for about 7% of human male infertility (Shlomi Barak, 2016). Sperm are normally protected from sperm antigens by tight junctions of Sertoli cells, which form the blood-testis barrier (Vasan, 2011). We previously showed that Connexin 43 (GJA1) expression is decreased in our Irx3/5 double knockout ovaries (A. Fu et al., 2018), and *Irx3* was also shown to modulate the transcription of both Cx43 and Cx40 in the heart (K. H. Kim et al., 2016). These data suggest that the presence of Irx3 within germ cells impacts tight or gap junctions. We plan to analyze tight junctions and the testis-blood barrier of Male G-Irx3 mice. Defects in the testis-blood barrier has been shown to elicit an immune response that leads to the formation of anti-sperm antibodies (ASAs). ASAs are shown to create clumps of moving sperm in semen samples, which

hinder the passage of sperm through cervical mucus, zonal binding, and passage through the cervix (Mortimer, 1994). One group investigated cognate antigens of agglutinating ASAs and identified 8 potential ASA candidates (Koide, Wang, & Kamada, 2000). Sperm agglutination factors, interestingly, have been proposed as potential contraceptive agents for men (Aggarwal & Prabha, 2006; Naz & Chauhan, 2001). Most agglutination cases in humans can be treated by reproductive assistance and sperm washing, but treatment with proteolytic enzymes has also been proposed to treat this condition (Pattinson, Mortimer, Curtis, Leader, & Taylor, 1990).

Available research suggests that a sperm agglutination phenotype is generally seen in mice that have antibodies against spermatozoon-specific proteins (J. Fu et al., 2012) or if there was any sort of trauma to the genital area by either infection or disease (Kalaydjiev, Dimitrova, Mitov, Dikov, & Nakov, 2007; Shetty, Bronson, & Herr, 2008). The agglutination phenotype seen in the Testis G-*Irx3* sperm is intriguing due to the lack of evidence connecting *Irx3* to sperm agglutination and could be caused by the presence of ASAs. An ELISA assay for ASAs is commercially available and would give us the opportunity to detect ASAs in the serum of Testis G-*Irx3* males. This would give us insight whether ASAs were playing a role in the agglutination phenotype or if there are additional factors involved. Furthermore, we plan to perform RNA-seq on Testis G-*Irx3* sperm to identify genes that are up- or down-regulated in mutant sperm, and whether those genes tie into an auto-immunity pathway.

In conclusion, we successfully overexpressed *Irx3* in distinct cell populations within both ovaries and testes using a novel *Irx3* overexpression mouse line. No significant differences were seen in morphology or fertility between control and mutant

ovaries of either overexpression model, indicating that an increase of *Irx3* expression has no effect on ovarian development or overall health. Next, *Irx3* overexpression in the somatic cells of the developing testis, where *Irx3* is normally absent, had no effect on testis morphology or fertility in males. In contrast, *Irx3* overexpression in sperm had no obvious morphology defects during testis development, but resulted in male sub-fertility, potentially caused by a sperm agglutination phenotype in mutant sperm. In order to build on this study, we need to determine how *Irx3* overexpression in the sperm results in a sperm agglutination phenotype, which could lead to a novel pathogenesis in male infertility.

#### Methods

#### Animals

Mouse strains included ROSA26-Stop<sup>flox</sup>/Irx3-IRES-EGFP mice (referenced as *Irx3<sup>GOF</sup>*), generated and provided by Dr. Chi-Chung Hui, University of Toronto, with *Irx3* sequences inserted behind the Rosa26 promoter within the Rosa locus with a floxed stop codon (**Figure 4-1A**), *Sf1*Cre, originally obtained from the Keith Parker Lab (Bingham et al., 2006), and *Figla*Cre-EGFP (FVB/N-Tg(Figla-EGFPicre)ZP3Dean/Mmjax) obtained from Dr. Jurrien Dean at NIH/NIDDK. Genotyping was carried out using primers Q (Irx3 GOF F): 5'-AAAGTCGCTCTGAGTTGTTAT-3', R (Irx3 GOF Mut R): 5'-GGAGCGGGAGAAATGGATATG-3', S (Irx3 GOF WT R): 5'-GCGAAGAGTTTGTCCTCAACC-3'; *Sf1*Cre: 5'-GAGTGAACGAACCTGGTCGAAATCAGTGCG-3' and 5'-GCATTACCGGTCGATGCAACGAGTGATGAG-3'; *Figla*Cre iCRE F: 5' - CCAGCTCAACATGCTGCACA-3' and iCRE R: 5' - GCCACACCAGACACAGAGAT – 3'. Timed mating was identified by the presence of a vaginal plug, which was designated as embryonic day 0.5 (E0.5).

Animal housing and all procedures described were reviewed and approved by the Institutional Animal Care and Use Committee at the University of Wisconsin-Madison and were performed in accordance with the National Institute of Health Guiding Principles for the Care and Use of Laboratory Animals. Mice were housed in disposable, ventilated cages (Innovive, San Diego, CA). Rooms were maintained at 22 ±2 degrees Celsius and 30–70% humidity on a 12-hour light/dark cycle.

#### Histology

Ovaries and testes were harvested at the age point indicated, fixed in 4% PFA overnight, and embedded in paraffin. Blocks were sectioned at 8µm thickness and then stained with hematoxylin and eosin (H&E) for histological analysis.

#### Immunohistochemistry

Mouse ovaries and testes were harvested at the age indicated, fixed in 4% paraformaldehyde overnight at 4°C, and washed in PBS and embedded in paraffin. Blocks were sectioned at 8µm thickness. Biotin anti GFP (Abcam, ab6658, 1:50 dilution) was applied to paraffin sections at 4°C overnight. 2° (Alexa Fluor 488-conjugate IgG fraction monoclonal mouse anti-biotin, Jackson ImmunoResearch, #200-542-211, 1:100 dilution) was then incubated at room temperature for 1 hour. DAPI in PBS solution was used as a nuclear counterstain. Images were collected on a Keyence BZ-X700 microscope. Images were processed with ImageJ and/or the Keyence BZ-X700 analyzer software.

#### Section In-situ hybridiziation

Full methods can be found in (Wilhelm et al., 2007). Briefly, sections were deparaffinized and rehydrated with an ethanol gradient and incubated with 5µg/ml Proteinase K for 20 minutes at room temperature. Sections were then re-fixed with fresh 4% PFA and acetylated, and prehybridized with hybridization solution for 2 hours at room temperature. Hybridization (hybridization solution + 0.05µg/ml probe) was performed overnight at 60°C in a hybridization oven. Slides were washed and then incubated with blocking solution for 2 hours in a humidified chamber. Anti-DIG (1:1000) was applied overnight at 4°C. Unbound antibodies were removed with washing and slides were equilibrated and incubated in color solution (3.5µl of 5-bromo-4chloro-3-indolyl phosphate (Roche Applied Science) per mL of NTM buffer until staining was satisfactory (usually overnight at 4°C). Sequences for *Irx3* probes can be found in (Jorgensen & Gao, 2005).

#### RNA Extraction and qPCR

RNA was extracted using Trizol (Invitrogen, ca#: 15596026) according to the manufacturer's instructions and quantified using a NanoDrop 2000. 500ng RNA from each sample was used for First-Strand cDNA synthesis by SuperScriptII-RT (Invitrogen, AM9515). cDNA was diluted 1:5 and then 2 µl was added to 5 µl SYBR green PCR

mixture (Applied Biosytems), 2.4 µl water, and 1.25 pmol primer mix. PCR reactions were carried out using the ABI Prism 7000 Sequence Detection System (Applied Biosystems). RNA transcripts were quantified using the  $\Delta\Delta$ Ct method (Livak & Schmittgen, 2001). Briefly, to control for overall gene expression in each time point, the average cycle threshold (aveCt) for 36B4 was subtracted from the aveCt value for each gene to generate  $\Delta$ Ct. Next,  $\Delta$ Ct for each gene was compared to  $\Delta$ Ct of that same gene for the mutant genotype (e.g.  $\Delta$ Ct Irx3<sub>female control</sub>- $\Delta$ Ct Irx3<sub>female mutant</sub>), to generate  $\Delta\Delta$ Ct. Finally, fold change was calculated as 2 to the - $\Delta\Delta$ Ct power (2<sup>- $\Delta\Delta$ Ct</sup>).

#### Breeding Study

Male and female control and mutant mice from all lines (S-*Irx3* and G-*Irx3*) were set up with wild type (CD1) mice of the opposite sex to breed for the times indicated. Litter sizes and birth dates were monitored and recorded throughout the breeding period.

#### Sperm Analysis

Male mice were sacrificed and cauda epididymides were aseptically dissected. Fat and blood were removed and then the cauda epididymides were transferred to 0.8ul HTF+PVA (poly-vinyl-alcohol) at 37°C. Five to six incisions were made in the epididymides using a micro scissors to release the sperm. After a ten-minute swim-up, a 10ul aliquot was diluted in 90ul HTF+PVA. After 1 minute, sperm was loaded into the computer assisted sperm analyzer (Hamilton Thorne) and analyzed to assess motility and sperm concentration.

Chapter 5

**Concluding Remarks and Future Directions** 

#### Summary

The gonad is an extraordinary organ and its development is a fascinating process. Iroquois homeobox transcription factors *Irx3* and *Irx5* play important roles in ovarian health and development in both somatic and germ cells (Fu et al., 2018; Jorgensen & Gao, 2005; Kim, Kim, Cooke, Rüther, & Jorgensen, 2011). The regulation of these factors is largely unexplored, and one of my research objectives was to determine if the canonical Wnt/Rspo1/ $\beta$ -catenin signaling pathway regulated *Irx3* and *Irx5* in either cell type. A further objective was to explore a novel mouse model to determine how the overexpression of *Irx3* affected development of ovaries and testes as well as fertility in mice.

In Chapter 2, I explored the hypothesis that  $\beta$ -catenin was responsible for the transcriptional regulation of *Irx3* and *Irx5* in the somatic cells of the developing ovary. I was able to utilize conditional mouse models to knock out, or stabilize,  $\beta$ -catenin in the somatic cells of the ovary and testis, respectively. I determined that  $\beta$ -catenin expression positively correlates with both *Irx3* and *Irx5* transcripts. Additionally, I applied both DNAseI-seq and ATAC-seq datasets to identify possible regulatory regions of interest that contained  $\beta$ -catenin/TCF/LEF binding elements. Through ChIP-qPCR, transient transfection, and transient gonad transfection, I was able to identify two novel enhancer regions within the *IrxB* locus that responded to  $\beta$ -catenin stimulation and had ovarian-specific loss of activity after mutation of the TCF/LEF consensus motif. Further, we mined an H3K27me3 dataset to find enrichment of this repressive factor in the testis at these same enhancer regions. In our study, inhibition of H3K27me3 in testis cultures significantly upregulated *Irx3* and *Irx5* transcripts supporting this epigenetic repression.

The evidence provided in this chapter led us to conclude that  $\beta$ -catenin is directly regulating *Irx3* and *Irx5* in the somatic cells of the ovary via two enhancers on the *IrxB* locus.

To continue studying the effects of  $\beta$ -catenin in the developing ovary, I shifted to germ cell expression of β-catenin and how its loss could affect Irx3 expression in Chapter 3. Other groups (Chassot et al., 2011) have attempted to conditionally knock out  $\beta$ -catenin in the oocyte early in development, but have failed to do so due to embryonic lethality and/or inefficient cre mouse models. Others have successfully knocked out  $\beta$ -catenin in the oocyte, but only in the post-natal ovary, long after follicles have formed. These conditional  $\beta$ -catenin knockout mice were fertile. Thus, we used a newly developed germ cell-specific cre, FiglaCre, that was reported to be functional during ovarian development. With this cre line, I was able to knock out  $\beta$ -catenin in the oocyte, but cre activity was detected at a much later time than anticipated. Similar to the previous report with Zp3Cre, our FiglaCre; Ctnnb1<sup>flox/flox</sup> females had no effect on the ovary as a whole, with no defects in meiosis, germ cell number, or follicle development. An important discovery, however, was that the loss of  $\beta$ -catenin in the oocyte had no impact on oocyte expression of *Irx3*. This finding is important because it differentiates Iroquois regulation within neighboring cell types in the ovary.

*Irx3* is expressed in the somatic cells of the ovary until primordial follicle formation, but then is solely expressed in the oocyte thereafter. We questioned if *Irx3* overexpression in the somatic cells after primordial follicle formation or *Irx3* overexpression in the germ cells would affect the dynamics of follicle formation or
fertility in females. Furthermore, *Irx3* is never expressed in the testis, and we suspected that its presence could affect testis development and/or fertility. In Chapter 4, with the use of a novel *Irx3* overexpression mouse line, I was able to overexpress *Irx3* in both the somatic (*Sf1Cre*) and the germ (*FiglaCre*-EGFP) cells of both the ovary and testis. *Irx3* overexpression had no effect on ovarian development in either the somatic or the germ cells, displaying normal follicle development and fertility that matched control females in both lines. I also explored *Irx3* overexpression in both the somatic and the germ cells of the developing testis. We found that somatic cell overexpression of *Irx3* had no effect on male fertility. Morphologically, mutant testes look comparable to controls, but mutant male mice did not produce consistent litters and had fewer pups in total compared to control males. We also detected a sperm agglutination phenotype during sperm analysis of these mutant males, which may be a contributing factor to their reduced fertility.

Overall, these data provide insight into the complicated process of gonad development and the role of *Irx3* and *Irx5* therein. This research provides a better understanding of these factors and how they promote overall ovarian health in mice, as well as suggesting multiple directions for future projects. A model is outlined for Chapter 2 (**Figure 5-1**) and a phenotype table is provided for Chapter 4 (**Table 5-1**).

#### **Future Directions**

My research offers a better understanding of the regulation our factors of interest, *Irx3* and *Irx5*, in the developing ovary and how the overexpression of *Irx3* affects gonad development, yet additional questions and potential avenues of inquiry remain. These questions could be answered by experiments proposed below, which could lead to additional projects for our lab. Key conclusions for continued experimentation and future research in this area provide valuable information about ovarian development and overall women's health.

#### Canonical Wnt signaling and *lrx3/5* in the somatic cell

Based on our general conclusion that canonical Wnt signaling regulates *Irx3* and *Irx5* in the somatic cell population of the ovary, I think it would be interesting to treat pregnant dams with a commonly used drug that can inhibit Wnt signaling to see if this would have any effect on ovarian development. NSAIDs (Nonsteroidal anti-inflammatory drugs) have anti-canonical Wnt signaling effects (Castellone, Teramoto, Williams, Druey, & Gutkind, 2005), and their use is therefore generally contraindicated in pregnancy, especially in the first trimester, due to concerns about pregnancy loss and congenital defects (Mayo Clinic). While some women are aware of their pregnancy early in gestation, it is common for others to remain unaware of their pregnancy for multiple weeks, especially if they do not have a regular menstrual cycle. Therefore, many unknowingly pregnant women may be taking regular doses of NSAIDs during a critical window of fetal development. Aspirin, a widely used NSAID, inhibits  $\beta$ -catenin transcriptional activity via inhibition of protein phosphatase A2 (PP2A) (Bos et al., 2006;

Dihlmann, Siermann, & von Knebel Doeberitz, 2001; Ratcliffe, Itoh, & Sokol, 2000). Aspirin has also been shown to reduce  $\beta$ -catenin levels in APC<sup>min</sup> mice *in vivo* (Mahmoud et al., 1998). Because this drug can inhibit  $\beta$ -catenin transcription, we hypothesize that Aspirin use during ovarian development may have a negative effect on ovarian health and could possibly contribute to fertility issues in female pups exposed to NSAID activity. Data from this study could, for the first time, provide a link between Aspirin usage during pregnancy to defects in the developing ovary that may manifest in reproductive disorders, such as POI, in female offspring.

Because we demonstrated TCF/LEF responsive elements in the ovary (Chapter 2), an additional experiment would explore the effects of TCF/LEF knockouts in ovarian development. TCF7L2 and LEF1 knockout mice are commercially available through Jackson Laboratories; it would be interesting to examine the effects of these knockouts on the ovary as a whole, and also how the knockout would affect *Irx3* and *Irx5* expression. We could also use these mice for either ATAC-seq or ChIP-seq for H3K27ac to see if enhancer regions are affected by these knockouts. We could also perform RNA-seq to identify other target genes of this pathway.

Furthermore, I have also considered performing ChIP-seq for TCF/LEF factors in the wild-type ovary to identify direct target genes other than *Irx3* and *Irx5*. This would be performed both pre- and post-sex determination and binding profiles would be compared, giving insight into the spatio-temporal effects of these transcription factors on female-specific gene regulation.

Finally, we discovered two novel enhancer elements at +86kb and -580kb in the *IrxB* locus; it would be fascinating to knock out one or both of these sequences in a

mouse either using CrisprCas9 technology or with the addition of LoxP sites flanking each region. One limitation to the CrisprCas9 technique is that it would result in a global knockout and could affect regulation in other tissues. The conditional knockout of these regions may be a better choice, as we could study the effect of this conditional knockout specifically in the somatic cells of the ovary and the testis.

#### *Irx3* and *Irx5* expression in the oocyte

Because *Irx3* is not affected when  $\beta$ -catenin is eliminated in the oocyte, this of course leads us to question what is regulating the Iroquois factors in the germ cell. As mentioned in both Chapter 1 and Chapter 3, Iroquois factors have been connected to multiple pathways, such as Wnt and Hedgehog (Briscoe, Pierani, Jessell, & Ericson, 2000; Cavodeassi, Diez Del Corral, Campuzano, & Domínguez, 1999; Kobayashi et al., 2002), JAK/STAT (Zeidler, Perrimon, & Strutt, 1999), FGF (Kobayashi et al., 2002), EGFR (Wang, Simcox, & Campbell, 2000), BMP-4 (Gómez-Skarmeta, de La Calle-Mustienes, & Modolell, 2001), and TGF $\beta$  (Cavodeassi, Modolell, & Gómez-Skarmeta, 2001; JL, 1998). Many of these pathways would be good starting points when investigating oocyte regulation, but I found a different gene which has yet to be connected to Iroquois regulation and I hypothesize may be involved in the expression of *Irx3* and *Irx5* in the oocyte.

*Nobox* is an oocyte-specific homeobox gene that is expressed in oocytes (Suzumori, Yan, Matzuk, & Rajkovic, 2002), at about the same time as *Irx3* and *Irx5* expression is detected (Fu et al., 2018). Transcripts of oocyte genes *Mos*, *Oct4*, *Rfp14*, *Fgf8*, *Zar1*, *Dnmtlo*, *Gdf9*, *Bmp15*, and *H100* are downregulated in *Nobox*<sup>-/-</sup> ovaries

(Rajkovic, Pangas, Ballow, Suzumori, & Matzuk, 2004), suggesting that *Nobox* is important for either the direct or the indirect regulation of these genes crucial for postnatal oocyte development. *Nobox* has been implicated in POI in mice, where a null mutation results in the loss of germ cells by 6 weeks of age (Rajkovic et al., 2004), and 6.2% of human POI cases contain mutations in the *Nobox* gene (Bouilly, Bachelot, Broutin, Touraine, & Binart, 2011; Qin et al., 2007). Furthermore, it was reported that *Nobox* deficient mice have defects in somatic cell invasion and germ cell nest breakdown (Lechowska et al., 2011). This is particularly interesting because preliminary data from our lab shows a potential germ cell nest breakdown defect when *Irx3* is conditionally knocked out in the oocyte. Moreover, a cis-acting NOBOX DNA binding element (TAATTG) (Choi & Rajkovic, 2006) is present 1.3kb from the *Irx3* tss. It would be interesting to examine *Nobox* deficient ovaries to determine if *Irx3* and/or *Irx5* expression are affected in the germ cell, giving us insight into how our factors of interest are regulated in another ovarian cell type.

# Could *Irx3* overexpression rescue germ cell loss in the somatic $\beta$ -catenin conditional knockout model?

The somatic cell conditional knockout of  $\beta$ -catenin in mice results in massive germ cell death around birth (Liu, Bingham, Parker, & Yao, 2009). A leading group in this field demonstrated that canonical WNT4/ $\beta$ -catenin is responsible for germ cell survival via inhibition of Activin  $\beta$ B (*Inhbb*) (Liu, Parker, & Yao, 2010). Results from another graduate student in our lab, Anqi Fu, indicate that *Inhbb* mRNA levels are elevated in *Irx3/Irx5* double knock-out ovaries, suggesting that *Inhbb* may be

downstream from *Irx3* and/or *Irx5* (*manuscript in preparation*). One of our original goals was to induce *Irx3* via the overexpression model used in Chapter 4 in the context of the somatic cell conditional knockout of  $\beta$ -catenin (see Chapter 2) to determine if this resulted in increased germ cell survival. Moreover, we would explore whether *Inhbb* levels decreased in this rescue, further solidifying the conclusion that *Irx3* and *Irx5* lie downstream of  $\beta$ -catenin and upstream of *Inhbb*. Before introducing the *Irx3* overexpression line into the  $\beta$ -catenin cKO, we thought it was necessary to characterize the *Irx3* overexpression alone to isolate any phenotypes seen in this line (Chapter 4). We attempted to initiate this rescue project, but unfortunately, due to a nonspecific genotyping issue in the *Ctnnb1*<sup>*F/F*</sup> line, we were unable to complete this study. Because this issue was introduced prior to our receipt of the mice, a new line from Jackson Laboratory would be required in order to complete this experiment.

Overall, multiple avenues have emerged from the conclusions drawn from the studies documented in Chapters 2-4. This will provide our lab with additional exciting experiments to pursue in years to come and expand our knowledge of the complicated processes of gonad development and gene regulation. We look forward to the continued exploration of *Irx3* and *Irx5* in gonad development and how their expression is connected with fertility later in life, which could lead to preventative treatments for POI in humans in the future.

В

**Figure 5-1**: *Model for Irx3 and Irx5 regulation in the somatic cells of the gonad* (**A**) Histones (blue) are modified by H3K27ac (green) at +86kb and -580kb sites in the ovary and DNA (orange) is able to open. TCF/LEF and  $\beta$ -catenin factors can bind at these sites, increasing *Irx3* and *Irx5* expression. (**B**) Histones (blue) are modified by H3K27me3 (red) at +86kb and -580kb sites in the testis, leaving histones and DNA tightly compacted, leaving *Irx3* and *Irx5* in a repressed state. This mechanism does not appear to translate to the oocyte population in the ovary.

Sex	Cell type	Histology defect?	Fertility defect?
Female	Somatic	No	No
Female	Germ	No	No
Male	Somatic	No	No
Male	Germ	No	Yes

#### **Table 5-1:** Irx3 Overexpression in the gonad results

*Irx3* overexpression in the gonad did not have any effects in the female (either somatic or germ cell models) or in the somatic cells of the testis. In contrast, *Irx3* overexpression in the germ cells of the male (sperm) resulted in sub-fertility. We are currently investigating the mechanism behind this fertility issue.
