¹ Cloth includes low-modulus fibers; motor brushes include machined shapes, crucibles include vessels.

tant refractory use for graphite in steel-making is in carbon magnesite brick, where large amounts of crystalline flake are now used.

Graphite is used in brake and clutch linings. More graphite is being used as users change over from asbestos. The graphite lubricates, transfers the heat of friction away from the part, and leads to a lower rate of wear. Graphite is more commonly used in heavier-duty nonautomobile linings. Low-quality crystalline flake and amorphous graphite are suitable for foundry facing use.

The graphite is mixed with a small amount of clay, suspended in an adhesive material, and applied as a thin coating to mold surfaces to provide for clean and easy mold release of the metal castings.

Graphite is important as a lubricant and as an ingredient in special packings. When used as a lubricant, it can be a dry powder or mixed with oil or water. It is used with materials that must withstand extreme conditions, such as very high temperatures. Material for this use must be free of

abrasive-type impurities.

Some interchange of the various types and grades of natural graphite and between manufactured and natural graphite takes place, but the degree is difficult to determine. Manufactured graphite does not compete with natural graphite in most uses because of its greater cost. Manufactured graphite is not substitutable for natural flake graphite in clay-bonded graphite crucibles, although some crucibles are machined from manufactured graphite for special uses. Calcined coke and other

carbons are satisfactory substitutes for graphite for certain foundry core and mold washes and are used when they can compete in terms of price and supply. Other carbons with high purity can be used in batteries.

PRICES

Natural graphite prices are often ne-

gotiated between the buyer and seller and are based on purity and other criteria. Therefore, published price quotations such as those in Industrial Minerals are given as a range of prices. Another source of information for graphite prices is the average customs value per ton of the different imported classes. These mainly represent shipments of unprocessed graphite. A third source for natural graphite prices is the amount paid per ton at the point of

consumption.

The price for crystalline graphite at the point of consumption—mostly crystalline flake, some crystalline dust, and a little lump graphite—rose by 27% to \$1,540 per ton. The price for amorphous graphite (including small amounts of amorphous-synthetic graphite mixtures) rose by 5% to \$707 per ton.

FOREIGN TRADE

The United States changed its tariff classification to the Harmonized Code on January 1, 1989. This has rendered the 1988 and 1989 import and export statistics to be somewhat noncomparable. The statistics for imports of artificial graphite are completely noncomparable; actual activity is believed to be fairly similar in both years.

Total exports of natural graphite decreased slightly. Exports of graphite electrodes totaled 97,307 tons valued at \$142.6 million, of which 32,966 tons (\$20.3 million) went to Canada, 11,474 tons (\$15.0 million) to Brazil, 11,161 tons (\$22.4 million) to Japan, 7,051 tons (\$15.6 million) to Venezuela, 3,542 tons (\$9.2 million) to the Federal Republic of Germany, and the balance to other destinations.

Imports of natural graphite increased 16% from those of 1988. Imports of natural graphite from Canada, China, the Republic of Korea, and Madagascar rose substantially.

WORLD REVIEW

The current year has been interesting and murky, as we watched two major developments being played out. At yearend 1988, the Chinese announced some major price increases in crystalline flake coupled with a cutback in exports of 40,000 to 50,000 tons. They stated that this resulted from a drought which affected the water supply for beneficiation and transportation, greater internal consumption, and the closure of economically marginal mines. The higher prices continued to be posted throughout the year. A high Bureau official was told earlier by the Chinese

that industrial mineral prices at the October 1989 Canton Fair would be "very competitive." In spite of this supposed cutback, the actual Chinese graphite exports to major markets changed little from 1988. No drop off was observed towards the end of the year. The demand by actual consumers such as the steel industry held up well, and it was probably even stronger than 1988. Against this

backdrop, a number of Canadian would-be graphite producers struggled to come on-stream to fill this perceived gap. New capacity came on-stream in Norway and Mexico which also offset the shortfall in production.

Australia

Gwalia Minerals NL entered into a joint venture with a London-based

merchant banker to perform a feasibility study of the Munglinup graphite prospect. The prospect is 80 kilometers east of Ravensthorpe, Western Australia. Earlier diamond drilling showed graphite continuity over a strike length in excess of 600 meters. Total resources were stated to be 1.6 million tons averaging 18% carbon. Pilot plant testwork is also underway. If the feasibility study

is positive, the option on the property will be exercised.

Graphite Mines of Australia, a subsidiary of Solution Mining, announced that it would reopen its Uley Mine near Port Lincoln, South Australia. It will have an output of 2,500 tons per year of product. The firm plans to gradually double the mine's production and export about 75% of the product. It plans to spend around \$3.8 million.

Brazil

Nacional de Grafite Ltda. is planning to increase its product capacity at Pedra Azul by building a new plant on the same site. The present capacity of 28,500 tons of product per year will increase by 18,000 tons per year in mid-1991 and by an additional 18,000 tons per year by 1992.

Canada

Stratmin Inc. was the only Canadian producer of graphite in 1989. It brought its second mine on-stream and was considering expanding its mill capacity to 30,000 tons per year of concentrate. Cal Graphite Corp. and Exploration Graphcor Inc. may come on-stream in 1990. Exploration Graphcor holds three deposits near those of Stratmin and is hoping to have a production capacity of 11,000 tons.

Societe d' Exploration Miniere Mazarin Inc. estimates that its heavily-drilled deposit near Fermont has over 8.5 million tons of an unusually rich ore averaging 17% graphite. This would be a 67 years supply at the proposed productive capacity of 20,000 tons per year. The deposit has good road access and is close to the iron ore towns of Labrador and Quebec. The firm tried to negotiate a partnership with Cassiar Mining Ltd., but was unsuccessful. The project cost was estimated to be \$32 million.

Mexico

For \$5.7 million, the Mexican Government sold all of Grafito de Mexico SA, its crystalline flake graphite operation. The buyer was Minerals No-Metalicos Mexicanos SA, a member of the Jose Valdes group. The capacity doubling now underway should be finished this year. The firm is planning to

add an acid and pressure leaching stage that will allow it to make a 99.6% carbon final product.

Sri Lanka

Guerillas attacked the Kolongaha graphite mine towards the end of the year. They set fires that destroyed some vehicles and machinery, doing about \$500,000 in damage.

CURRENT RESEARCH

The Bureau of Mines examined substitutes for the crystalline flake graphite used in dolomite-carbon refractories, and the use of graphite fiber in particular. Test samples were evaluated for modulus of rupture, deformation under load, and air-slag-metal resistance. Graphite

² In addition to the countries listed, Canada produced graphite during the period covered by this table, but output is unreported.

³ Does not include the following quantities sold directly without beneficiation, in metric tons: 1985—16,425; 1986—19,074; 1987—10,505; 1988—20,000 (estimated); and 1989—20,000 (estimated).

⁴ Data are for fiscal year beginning Apr. 1 of that stated.

⁵ Reported figure.

⁶ Indian marketable production is 10%–20% of mine production.

fiber at the 1.5% level was added to sample dolomite-carbon brick. The resulting physical properties were generally comparable to those obtained with natural flake graphite, but were below those obtained with 10% flake graphite additions. Therefore, graphite fiber was shown to be an unsatisfactory substitute for flake graphite.¹

The U.S. Air Force sponsored a major conference on the occupational health aspects of advanced composite materials use in the aerospace industry in Dayton, OH in February.

OUTLOOK

Projected demand for crystalline

flake graphite totaled 23,000 tons for 1995 and 25,000 tons for 2000. Demand for other graphite, mostly amorphous, totaled 12,000 tons for 1995 and 10,000 tons for 2000. This relatively slow rate reflects the maturity of the market, mostly in refractories, and particularly in carbon-magnesite brick. The supply situation, previously described, is unusually cloudy and appears likely to stay that way for at least several years.

BACKGROUND

Graphite, a soft crystalline form of carbon, has been called plumbago and black lead. It crystallizes in a lamellar hexagonal system, has a gray to black

metallic luster, and is greasy to the feel. It is anisotropic in its physical properties and has a weak plane of cleavage parallel to the lamellae.

The term “amorphous” when applied to graphite is a misnomer. The term “microcrystalline” is more descriptive. The definition of amorphous, as applied to graphite, has been further complicated by longstanding industrial application of the term to very fine particles of crystalline flake graphite which can be sold only for low-value uses such as foundry facings. Fine-grained varieties of lump graphite that are easily reduced to fine particle size by grinding are called amorphous lump, to distinguish them from the tough, platy and acicular varieties, known as crystalline lump, that can be reduced in particle size only with extreme difficulty.

Crystalline flake graphite is well defined in paragraph 214 of the Tariff Act of 1930 as follows:

“The term crystalline flake means graphite, or plumbago, which occurs disseminated as a relatively thin flake throughout its containing rock, decomposed or not, and which may be or has been separated therefrom by ordinary crushing, pulverizing, screening, or mechanical concentration process, such flake being made up of a number of parallel laminae, which may be separated by mechanical means.”

Under the foregoing definition, finely divided particles of crystalline flake graphite would be classified as crystalline graphite. However, the Court of Customs Appeals has reportedly held that commercial designations and not scientific terms must govern classification and when a commercial meaning differs from the technical meaning the commercial designation must govern. Thus, quantities of fine crystalline flake graphite are imported under the other Natural Crude and Refined classification.

Sri Lanka lump graphite is classified as amorphous or crystalline. Each type is divided into a number of grades, depending upon the size (such as lump, ranging from the size of walnuts to that of peas; chip, from that of peas to about that of wheat grains; and dust, finer than 60 mesh), graphitic carbon content, and degree of consolidation.

Amorphous graphite is graded primarily on graphitic carbon content. Commercial ore contains about 75% to

93% carbon, depending on the source.

Crystalline flake graphite from Madagascar is divided into two main grades, "flake" (coarse flake) and "fines" (fine flake). Madagascan crucible flake must have a minimum of 85% graphitic carbon and be essentially all minus 8 plus 60 mesh in particle size. Other crystalline flake graphites are also graded according to graphitic carbon content and particle size.

Natural graphite is marketed in the form of crystalline graphite as flake, lump, chip, and dust and in the form of amorphous graphite in sizes from fine powder to lumps up to the size of walnuts. It is common practice to blend different graphites to obtain a product having certain desired physical and chemical properties. In many instances, the composition of these blends is retained as a trade secret.

GEOLOGY—RESOURCES

The three principal types of natural graphite—lump, amorphous, and crystalline flake—are based on physical characteristics that are the result of major differences in geologic origin and occurrence. A variety of silicate minerals are generally associated with graphite in the ore.

Lump graphite occurs as fissure-filled veins. It is typically massive, ranging in particle size from extremely fine grains (amorphous) to coarse, platy intergrowths of fibrous to acicular aggregates (crystalline). The origin of vein-type graphite deposits is believed to be hydrothermal and/or pneumatolytic.

Amorphous graphite is formed by metamorphism of coalbeds by nearby intrusives. Its purity depends on the purity of the original coalbeds. Amorphous graphite usually is associated with sandstones, shales, slates, and limestones.

Flake graphite commonly occurs disseminated in regionally metamorphosed sedimentary rocks, such as gneisses, schists, and marbles. It is believed that the graphite was formed under the same conditions that caused the metamorphism of the rocks—from carbon deposited with the sediments.

Although the flake graphite deposits of certain countries conform to this description, the commercial deposits

that are exploited are alluvial, lateritic clays that have accumulated at the surface. Graphite, quartz, and other resistant minerals have been freed by kaolinization of the feldspars, lessening the amount of crushing necessary before beneficiation.

World graphite reserves totaled 21.0 million tonnes. Detailed breakouts are given in the 1988 Mineral Yearbook chapter.

TECHNOLOGY

Mining

In Sri Lanka, lump graphite is mined underground from narrow, steeply dipping veins. The ore is mined principally by overhand stoping and filling, using temporary stulls when necessary to support the walls. Hand drilling is used in most stoping to achieve selective mining and to avoid unwanted fines and product contamination. Air drills are used in development headings. The ore is hauled by truck to the sorting and classification yard.

Amorphous graphite beds also are usually mined underground, however, the beds are much thicker than those of amorphous lump and crystalline lump. The ore is drilled, blasted, handloaded into cars, and hauled to the surface by conventional methods.

Flake graphite deposits have been mined by underground and surface methods. Underground deposits are usually unweathered and require drilling and blasting. Most surface mining is confined to the weathered part of the deposit, and normal excavating equipment such as power shovels, bulldozers, and rippers is used with a minimum of drilling and blasting. The ore is usually trucked to the mill.

Milling

Sri Lankan amorphous and crystalline lump graphites are refined by hand cobbing and sorting, and wiping lumps on wet burlap to remove fines. Light hand sorting and cleaning operations are done by women, while the heavier duties are performed by men.

Most amorphous graphite that requires beneficiation is not worth mining. Preparation for most uses requires grinding only, and coarse impurities are removed by screening or air separation

methods.

Flake graphite from disseminated deposits must be concentrated to meet market requirements. Virtually every known concentrating device and combination of separating principles have been tried. The mineral has gained a reputation of being difficult to concentrate, and probably in no other industry has such a large proportion of the mills failed to make commercial recoveries. Graphite actually is one of the easiest minerals to segregate into a rough concentrate, but one of the most difficult to refine.

Graphite floats readily and does not require a collector; hence, froth flotation has become the accepted method for beneficiating disseminated ores. The chief problem lies with depressing the gangue minerals. Relatively pure grains of quartz, mica, and other gangue minerals inadvertently become smeared with the soft, fine graphite, making them floatable and resulting in the necessity for repeated cleaning of the concentrates to attain high-grade products.

ECONOMIC FACTORS

The price structure of graphite is quite complex because of the wide variety of products and the lack of standard market quotations. Prices quoted in trade journals are only a range negotiated between buyer and seller. These quotations are available in Industrial Minerals, Chemical Marketing Reporter, and the Bureau of Mines Minerals Yearbook. However, average declared import values per ton for amorphous and crystalline graphite have been available for years from Bureau of the Census data.

The cost for domestically produced graphite from new mines would be much higher than that for graphite from the major foreign sources, for the same type and purity, chiefly because of high labor costs and the low graphite content of the ore.

Employment and Productivity

Production of marketable natural graphite requires little hand labor, except for the graphite mined in Sri Lanka. Even in areas of low-cost labor, mechanical methods are used to mine

and concentrate flake graphite.

Because of the small size of the domestic natural graphite industry, no publishable employment data are available. Since there is only one small mine and the product is beneficiated and processed to a minimal extent, employment probably does not exceed 50. Much of the imported graphite requires grinding, perhaps further refining, mixing with other grades to meet consumer specifications, bagging, and shipping. The total number of persons engaged in these operations, including marketing, probably does not exceed 500.

Taxes and Tariffs

Graphite producers are granted a 22% depletion allowance for tax purposes on domestic lump and amorphous and 14% on domestic flake and on foreign operations.

Duties on graphite items imported from most favored nations (MFN) are minimal. Graphite from the U.S.S.R. and certain other nations is subject to a higher duty.

TABLE 13
U.S. IMPORT DUTIES

Tariff item	No.	Most favored nation (MFN) Jan. 1, 1990	Non-MFN Jan. 1, 1990
Crystalline flake, (not including flake dust):	2504.10.10	0.7 cents per kilogram	3.6 cents per kilogram.
Other powder	2504.10.50	Free	10% ad valorem.
Other	2504.90.00	Free	Do.

OPERATING FACTORS

Natural graphite is an inert nontoxic substance and environmental requirements are limited to dust control and certain organic vapors arising from ingredients blended with it to manufacture products.

GYPSUM

By Lawrence L. Davis

Mr. Davis, a physical scientist with 34 years of industry and Bureau of Mines experience, has been the commodity specialist for gypsum since 1985. Domestic survey data were prepared by Pamela Shorter, mineral data assistant; and international data tables were prepared by Peter J. Roetzel, international data assistant.

Although demand for gypsum products remained strong in 1989, new public and private housing unit starts, a major indicator of gypsum product demand, decreased 8% to 1.4 million units. The gypsum industry set new record-high levels for crude gypsum mined, calcined gypsum produced, and shipments of pre-fabricated wallboard products.

Sales of gypsum products increased 7% to 27 million short tons, and value decreased 8% to \$1.9 billion. Increased competition caused lower prices for gypsum products. Imports for consumption of crude gypsum decreased 4% to about 9.3 million tons. Total value of gypsum product exports increased 41% to \$60 million.

DOMESTIC DATA COVERAGE

Domestic production data for gypsum are developed by the Bureau of Mines from a survey of U.S. gypsum operations. Of the 120 operations to which the annual survey request was sent, 87 responded, representing 73% of the total crude gypsum production shown in tables 1 and 2. Nonrespondents were estimated from monthly and quarterly canvasses or from previous years data.

PRODUCTION

The United States remained the world's leading producer of gypsum, accounting for 16% of the total world output. Crude gypsum was mined by 36 companies at 65 mines in 21 States. Production increased 8%. Leading producing States, in descending order, were Oklahoma, Iowa, Michigan, Texas,

¹Each mine, calcining plant, or combination mine and plant is counted as one establishment; includes plants that sold byproduct gypsum.

²Does not include value of plasters sold.

California, Nevada, and Indiana. These seven States produced more than 1 million tons each and together accounted for 76% of total domestic production.

Leading companies were USG Corp., 11 mines; National Gypsum Co., 7 mines; Georgia-Pacific Corp., 7 mines; Celotex Corp., 3 mines; and Harrison Gypsum Inc., 2 mines. These 5 companies, operating 30 mines, produced 68% of the total crude gypsum.

Leading individual mines, in descending order of production, were USG's Plaster City Mine, Imperial County, CA; National Gypsum's Tawas Mine, Iosco County, MI; USG's Sweetwater Mine, Nolan County, TX; USG's Shoals Mine, Martin County, IN; USG's Alabaster Mine, Iosco County, MI; USG's Sperry Mine, Des Moines County, IA; National

Gypsum's Sun City Mine, Barber County, KS; Harrison's Cement Mine, Caddo County, OK; Pacific Coast Building Products Inc.'s (PABCO) Las Vegas Mine, Clark County, NV; and H. M. Holloway Inc.'s Lost Hills Mine, Kern County, CA. These 10 mines accounted for 41% of the national total. Average output for the 65 mines increased 6% to 271,000 tons.

Gypsum was calcined by 13 companies at 71 plants in 28 States, principally for the manufacture of gypsum wallboard and plaster. Calcined output increased 4% in tonnage and decreased 9% in value. Leading States, in descending order, were California, Texas, Iowa, Florida, Nevada, and New York. These 6 States, with 29 plants, accounted for 48% of the national output.

Leading companies were USG, 20 plants; National Gypsum, 18 plants; Georgia-Pacific, 10 plants; Domtar, 8 plants; and Celotex, 4 plants. These 5 companies, operating 60 plants, accounted for 83% of the national output.

Leading individual plants were, in descending order of production, USG's Plaster City plant, Imperial County, CA; USG's Jacksonville plant, Duval County, FL; USG's Sweetwater plant, Nolan County, TX; Briar Gypsum Co.'s Briar plant, Howard County, AR; National Gypsum's Tampa plant, Hillsborough County, FL; USG's Baltimore plant, Baltimore County, MD; USG's Shoals plant, Martin County, IN; USG's Sperry plant, Des Moines County, IA; USG's Stony Point plant, Rockland County, NY; and PABCO's Las Vegas Plant, Clark County, NV. These 10 plants accounted for 28% of the national production. Average calcine production for the 71 U.S. plants was 252,000 tons, a 7% increase.

A total of 725,000 tons of byproduct gypsum, valued at \$2.9 million, was used, principally in agriculture, but some for gypsum wallboard manufacturing. Approximately 76% was of nonphosphogypsum origin compared with 67% in 1988.

According to the Gypsum Association, yearend gypsum wallboard plant capacity for producing 1/2-inch regular wallboard decreased slightly to 24.04 billion square feet per year. Total wallboard shipments were 21.9 billion square feet, 91% of capacity.

Improvements to existing plants and construction of new plants continued during the year. Centex-American's new plant in Bernalillo, NM, is expected to be fully operational in 1991.

Domtar continued construction of its \$30 million wallboard plant at Newington, NH. The plant was expected to be operational in 1990, using crude gypsum imported from Domtar's Flat Bay quarry in Newfoundland. Annual capacity of the plant was to be 540 million square feet.

Eagle Gypsum Products was building a new wallboard plant in Eagle County, CO. The plant was expected to be completed in mid-1990. Another new entrant in the gypsum board industry, Highland-American Corp., was constructing a gypsum fiberboard plant in East Providence, RI. The plant was scheduled to begin production in mid-1990 with an annual

capacity of 150 million square feet. National Gypsum was adding a new line to their Rensselaer, NY, plant and were modernizing their Portsmouth, NH, plant. South Florida Gypsum Co. continued construction of a wallboard plant in Miami, FL. The plant, scheduled to begin operating in 1990, will use crude gypsum imported from Spain. USG completed a \$30 million expansion of its wallboard plant at Sperry, IA. The expansion doubled the capacity of the plant.

Weyerhaeuser Co. sold its gypsum mine, calcining plant, and wallboard plant at Nashville, AR, to Boral Ltd., an Australian building and construction materials company. The gypsum complex now operates as Briar Gypsum Co.

Atlantic Gypsum Co. Inc.'s new plant in Port Newark, NJ, opened in late 1988, but was closed for most of 1989.

Western Plains Materials operated three quarries in Oklahoma, mostly for the production of road aggregate. Rock for road construction was also produced by Winn Rock Inc. at its Winnfield Mine in Winn Parish, LA, the only anhydrite mine in the United States. Quad-Honstein Joint Venture's Woodham Mine in Larimer County, CO, and Cox Enterprises Inc.'s Levan Mine in Sanpete County, UT, both idle in 1988, were active during 1989.

CONSUMPTION AND USES

Apparent consumption, defined as production plus net imports plus industry stock changes, of crude gypsum, including byproduct gypsum, increased slightly to 26.8 million tons. Net imports provided 34% of the crude gypsum consumed. Apparent consumption of calcined gypsum increased 6% to 17.8 million tons.

Yearend stocks of crude gypsum at mines and calcining plants were 3.8 million tons. Of this, 53% was at calcining plants in coastal States.

Of the total gypsum products sold or used, 5.5 million tons, about 20%, were uncalcined. Uncalcined gypsum, crushed and screened to specifications, is marketed for use in portland cement manufacture, agriculture, and fillers. The cement industry uses gypsum to retard the setting time of concrete. Finely ground gypsum rock is used in agriculture to neutralize alkaline and saline soils, improve the permeability of argillaceous materials, and provide sulfur and catalytic support for maximum fertilizer utilization and leguminous productivity. Small amounts of very pure gypsum are used as fillers and in glassmaking, papermaking, and pharmaceutical applications.

FIGURE 1
SUPPLY OF CRUDE GYPSUM IN THE UNITED STATES

In 1989, 62% of the uncalcined gypsum products were used in portland cement, and the remainder was used mainly for agricultural purposes.

Of the total calcined gypsum products, most went into prefabricated products. A small percentage was used in industrial and building plasters. Of the prefabricated products, based on surface square feet, 62% was regular wallboard; 28% was fire-resistant type X wallboard; 3% was 5/16-inch mobile home board; and 3% was water- and/or moisture-resistant board. Lath, veneer base, sheathing, predecorated, and other types made up the balance. Of the regular wallboard, 83% was 1/2 inch and 10% was 5/8 inch.

In descending order, the leading sales regions for prefabricated products were the South Atlantic, Pacific, East North-Central, and Middle Atlantic. Together they accounted for 69% of the total.

PRICES

On an average value-per-ton basis, f.o.b. mine or plant, crude gypsum increased 9% to \$7.29, calcined gypsum decreased 12% to \$15.96, and byproduct gypsum decreased to \$4.03, 20% lower than in 1988. Prefabricated products were valued at \$85.96 per ton, plasters at \$128.29 per ton, and uncalcined products at \$13.44 per ton.

According to the Department of Commerce, the average producer price of regular 1/2-inch wallboard was 4% lower in 1989 than in 1988, and type X board was 3% lower.¹

FOREIGN TRADE

Imports for consumption of crude gypsum decreased 4% to 9.3 million tons and represented 34% of apparent consumption. Crude gypsum from Canada and Mexico was used mainly to feed wallboard plants in coastal cities. Imports from Spain, the other major source of imported gypsum, were used mostly for portland cement manufacture. Gypsum wallboard imports, principally from Canada, decreased 44% to 355 million square feet. The sharp decrease is believed to be caused by fewer housing starts in the United States and strengthening of the Canadian dollar against the U.S. dollar.

WORLD REVIEW

Estimated world production of crude gypsum increased slightly to 109 million tons. Total world production figures are probably low because, in some countries, significant production was consumed captive and not reported. Also, production from small deposits in developing countries was intermittent and often unreported. The United States remained the world's largest producer of crude gypsum with 16% of the world total.

Australia

The French company Lafarge-Coppee announced a planned joint venture with Pioneer Concrete to manufacture gypsum wallboard products at plants in Sydney and Melbourne.²

Canada

Louisiana-Pacific Panel Products Ltd., a subsidiary of U.S.-based Louisiana-Pacific Corp., broke ground in early May for a new fiber gypsum board plant in Sydney, Nova Scotia. The \$64.5 million facility will have an annual capacity of 240 million square feet. The company plans to market its products in the northeastern United States.³

Eastern Gypsum Inc. announced plans for construction of a \$40 million gypsum wallboard facility in McAdam, New Brunswick. The plant is scheduled to start production in the summer of 1990.⁴

The Gypsum Association in the United States, of which all Canadian wallboard producers were members, reported that yearend wallboard capacity in Canada was 3.72 billion square feet, about the same as in the previous year.

France

Escogypse SA, a small wallboard producer with a single-line plant at Valenciennes, was in the process of being purchased by Redland Plasterboard Ltd. Redland is a joint venture of Redland PLC of the United Kingdom and CSR Ltd. of Australia.⁵

Italy

BPB Industries PLC of the United Kingdom was planning to build Italy's first wallboard plant. The country was one of the few in Western Europe that relied totally on imported board.

Spain

A German company, G. Siempelkamp GmbH & Co., has been contracted to build a gypsum fiberboard plant at Carboneras, Almeria, for Internacional de Paneles SA. The plant is expected to open in early 1991 with an annual capacity of about 160 million square feet.⁶

OUTLOOK

More than 90% of the gypsum consumed annually in the United States is used in construction, mainly to produce prefabricated wallboard products, with lesser amounts used in the manufacture

of portland cement. Therefore, gypsum demand correlates well with construction activity. Using the macroeconomic indicator, New Construction Activities, annual gypsum use in prefabricated wallboard products is expected to remain about 21 million tons through 1995. Using the same macroeconomic indicator, annual gypsum use in the manufacture of portland cement is expected to reach 4.8 million tons by 1995, an average annual increase of about 3%.

Despite a decline in new housing starts in each of the past 3 years, the gypsum industry has been at record or near-record levels of production. The industry has been able to maintain these high levels by increasing markets in commercial construction, remodeling, and exports. However, increased competition, caused by increased capacity and the slowdown in new housing starts, has driven prices down and lowered profitability. A problem for the immediate future is that several new wallboard plants are supposed to begin operations in 1990. The added capacity will lead to more competition, even lower prices, and lower profits. In the short term, some companies will have difficulties remaining profitable, even though gypsum demand should continue at high levels.

BACKGROUND

Definitions, Grades, and Specifications

Gypsum has a composition of 79% calcium sulfate and 21% water, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, and is used as a commercial and generic term for all calcium sulfate materials. The well-formed transparent crystalline variety is called selenite. The massive variety is called alabaster and can be easily carved. The fibrous, silky variety is called satin spar. Gypsite is a mixture of clay and gypsum crystals.

Anhydrite is calcium sulfate, CaSO_4 , with no water of crystallization. It is a naturally occurring mineral often associated with gypsum. When gypsum is calcined at high temperatures, it is converted to anhydrite.

Commercially calcined gypsum, $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, is a manufactured hemihydrate product produced by partial calcination of gypsum. It is produced by heating gypsum at temperatures to 350° F. Commonly called plaster of paris,

when water is added to form a paste, it quickly sets and hardens to form gypsum again.

Byproduct gypsum is a chemical product of manufacturing processes such as phosphoric acid, hydrofluoric acid, citric acid, and titanium dioxide from ilmenite, consisting essentially of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$. The sludge produced from scrubbers in the desulfurization of stack gas in thermal powerplants is also byproduct gypsum.

Keene's cement is anhydrous gypsum plaster with certain accelerator additives. It is produced by special high-temperature calcining. All of these minerals and materials, including the articles molded from the plaster, are commonly called gypsum or plaster.

Industry Structure

The domestic gypsum industry is large and is dominated by a few large vertically integrated companies that mine and

calcine gypsum and manufacture plaster and wallboard products. These companies also sell crude gypsum for use in cement and agriculture. The large wallboard producers, through foreign subsidiaries, produce most of the crude gypsum that is imported to feed coastal wallboard plants. Plants on the east coast import mostly from Canada's Maritime Provinces, while plants on the west coast import gypsum from Mexico. Crude gypsum from Spain, the other major source of U.S. imports, is used mainly by cement plants.

Gypsum production is worldwide, with at least 80 countries known to produce. Because of its wide distribution and plentiful supply, most of the world's production is consumed domestically. Exceptions include Canada and Mexico, which export significant portions of their production to the United States; Thailand and Australia, which export to much of the Southeast Asia market; and Spain,

which exports to the United States, Scandinavia, and other countries. In the United States and other industrialized nations, the major use of gypsum is in the manufacture of gypsum wallboard products. Most crude gypsum is mined in rural areas and shipped to urban areas for manufacture into wallboard and ultimate consumption. In developing countries, most gypsum is consumed by local cement plants.

Geology-Resources

Gypsum deposits may be found in any geologic era, but they are most common in the Permian. They are frequently found in association with the source rocks for petroleum. Most massive gypsum and anhydrite deposits occur as large, lenticular, stratified bodies that were formed by evaporation of seawater in basins that have one or more restricted openings to the sea. The basins range in diameter from a few miles to many hundreds of miles.

Classic evaporite formation involves the deposition of anhydrite, with later hydration of the anhydrite by meteoric waters to gypsum at depths ranging from 0 to 1,000 feet. The depth of hydration is generally related to topography, structure, and climate, because these factors affect the depth of ground water and surface water penetration.

Domestic and foreign reserves of gypsum are adequate for the foreseeable future. World reserves are conservatively estimated at 2.6 billion tons, of which the United States has 800 million tons. In the United States, gypsum resources are centered near five main areas: the Great Lakes, including the Silurian Basin and the Michigan Basin; the gulf coast embayment of Louisiana, Mississippi, and south Texas; the Permian Basin of New Mexico, Kansas, Oklahoma, and north Texas; several basins in the Rocky Mountain area, including those in Colorado, Montana, New Mexico, Utah, and Wyoming, Utah; and southern California and southern Nevada.

Gypsum reserves and resources are common throughout the world. More than 80 countries produce gypsum, and very few are without any resources.

Technology

Gypsum deposits are explored to determine their physical and chemical properties and to determine a minable thickness and the ratio of gypsum to anhydrite. The

^cEstimated. ^pPreliminary. ^rRevised.

¹Table includes data available through June 27, 1990.

²Includes approximately 55,000 short tons of plaster a year.

³Includes anhydrite.

⁴Reported figure.

⁵Data are for years ending July 7 of that stated. Reported in cubic meters and estimated at 2.2 short tons per cubic yard.

⁶Less than 1/2 unit.

⁷Excludes byproduct gypsum.

depth of hydration is important in mining because the presence of only a few percent anhydrite is sufficient to render gypsum unusable for making plaster. Adequate samples may be obtained from outcrops or drill cores.

Deposits near the surface are developed by stripping the overburden, developing either single- or multiple-bench open pits, and constructing access and transportation routes. Underground ore bodies are developed by sinking shafts or driving adits, with mining development and production by the room-and-pillar system.

Most domestic gypsum is produced from surface mines using standard open pit mining methods. In a typical domestic mine, the gypsum is drilled and blasted as needed, probably every week or two. Broken gypsum rock, loaded with hydraulic shovel or front-end loader, is hauled to the primary crusher by a fleet of three or four 35-ton haultrucks. All material removed from the mines is crude gypsum. All waste is left in the mine.

The processing of crude gypsum depends on the end use. Gypsum for use in cement is crushed to minus 1½ inch plus 3/8 inch. For agricultural or filler use, the gypsum is pulverized to 100 mesh or finer.

To produce plaster and wallboard products, minus 100-mesh gypsum is heated in batch kettles to remove three-quarters of the water of crystallization, converting gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, to the hemihydrate product, $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. A few rotary kilns are also used, in which case a coarse feed with fines removed is calcined. During the commercial calcining process, gypsum is heated to 250° F for about 2 hours, then the temperature rapidly rises to 300° to 350° F, at which time the calcine, called stucco, is dumped into a hot pit. The calcine is then mixed with various additives, including a retarder or accelerator, and manufactured into prefabricated wallboard products and other plaster and cement products.

Plaster is generally reground calcine, modified with retarders or accelerators and containing various binders such as hair, sisal, fiberglass, aggregates, or colored pigments. Retarders, usually glue, starch, or slaughterhouse byproducts, can increase the setting time to as much as 6 hours. Accelerators, such as metal salts, set plaster, or anhydrite, can reduce the setting time to less than 5 minutes. The

plaster is packed in bags and sold under various trade names.

Prefabricated products include lath, veneer base, sheathing, and wallboard. These board products are manufactured by continuous methods on automatic machines that can be adjusted to any of the standard products. A slurry of wet plaster with additives and an accelerator is spread between two moving sheets of paper. Moving through the shaping rolls, the edges are molded and sealed. The green board is run out on a traveling belt until the plaster has set. The board is then cut with a revolving knife into appropriate lengths and slowly passed through a drying kiln.

HELIUM

By William D. Leachman

Mr. Leachman, chemical engineer, Helium Field Operations, has covered helium for 7 years. He also prepared the domestic survey data and the international data.

Grade-A helium (99.995% or better) sales volume in the United States by private industry and the Bureau of Mines was 2,083 million cubic feet (MMcf) in 1989.¹ Grade-A helium exports by private producers were 796 MMcf, for total sales of 2,879 MMcf of U.S. helium. The price of Grade-A helium, f.o.b. plant, was about \$37.50 per thousand cubic feet (Mcf) for both the Bureau and private industry. The Bureau price for bulk liquid helium was \$45.00 per Mcf with additional costs for container services and rent. The liquid helium price for private industry was also about \$45.00 per Mcf with some producers posting surcharges to this price.

DOMESTIC DATA COVERAGE

Domestic production data for helium are developed by the Bureau of Mines from records of its own operations as well as the High Purity Helium Survey, a single, voluntary canvass of private U.S. operations. Of the seven operations to which a survey request was sent, 100% responded, and those data plus data from the Bureau's operations represent 100% of the total production shown in table 2.

LEGISLATION AND GOVERNMENT PROGRAMS

The Government's program for storage of private crude helium in the Government's helium storage facilities at the Cliffside Field near Amarillo, TX, was vital in supplying helium for the private helium market. Excess helium production of private industry ob-

tained from natural gas supplying fuel markets in the winter is stored by the Government under contract. This privately owned crude helium is returned to the owners for purification as needed to provide for private industry demand. Privatization of all the Government's helium program, except the conservation storage operation, is under consideration.

PRODUCTION

In 1989, 12 privately owned domestic helium plants were operated by 9 companies. Seven of these and one Bureau of Mines plant extracted helium from natural gas. Both private and Bureau plants use cryogenic extraction processes. The volume of helium recovered

from natural gas increased 5% in 1989 because most crude helium plants remained operational throughout the year. One plant shut down for about 1 month because of a legal dispute over its feedgas. In addition, Exxon increased the helium production at their Riley Ridge plant by eliminating "bottle-necks." All natural gas processed for helium recovery came from gasfields in Kansas, New Mexico, Oklahoma, Texas, and Wyoming. Pressure-swing adsorption is used for helium purification at four of the private helium plants and at the Bureau's plant. Cryogenic purification is used by the other producers. The Bureau and all seven private plants that produce Grade-A helium also liquefy helium. The plant operators and locations are Air Products and Chemicals Inc., Hansford County, TX; Navajo Refined Helium Co., Shiprock, NM;

Kansas Refined Helium Co., Otis, KS; Exxon Company, U.S.A., Shute Creek, WY; and Union Carbide Corp., Linde Div., Bushton, Elkhart, and Ulysses, KS. Linde's helium plant at Elkhart, KS, was shut down in 1988 after modifications at their Ulysses, KS, plant were completed and it was restarted.

CONSUMPTION AND USES

The major domestic end uses of helium were cryogenics, welding, and pressurizing and purging. Minor uses included synthetic breathing mixtures, chromatography, leak detection, lifting gas, heat transfer, and controlled atmospheres. The Pacific and Gulf Coast States were the principal areas of helium consumption.

Bureau sales to Federal agencies and their contractors totaled 350 MMcf in 1989, an increase of about 10% when compared with last year's sales. This increase was due largely to the U.S. Department of Defense Strategic Defense Initiative projects and the National Aeronautics and Space Administration's (NASA) resumption of space shuttle flights, which include associated projects that use large volumes of helium. Sales to the U.S. Department of Energy continue to decline.

The Federal agencies purchase their major helium requirements from the Bureau of Mines. Direct helium purchases by Defense, NASA, Energy, and the National Weather Service constituted most of the Bureau's Grade-A helium sales. All remaining helium sales to Federal agencies were made through Bureau contract distributors, who purchased equivalent volumes of Bureau helium under contracts described in the Code of Federal Regulations (30 CFR 602). Some of the contract distributors also have General Services Administration helium supply contracts. These contracts make relatively small volumes of helium readily available to Federal installations at lower freight charges by using the contractors' existing distribution systems.

future use in the Bureau of Mines helium conservation storage system, which includes the conservation pipeline network and the Cliffside Field near Amarillo, TX, totaled 35.1 billion cubic feet (Bcf) at yearend. The conservation storage system contains crude helium purchased by the Bureau under contract, Bureau helium extracted in excess of sales, and privately owned helium stored under contract. During 1989, 547 MMcf of private helium was delivered to the Bureau's helium conservation storage system and 659 MMcf

was withdrawn, for a net decrease of 112 MMcf of private helium in storage.

TRANSPORTATION

All Grade-A gaseous helium sold by the Bureau was shipped in cylinders, modules (large gas cylinders), special railway tankcars, or highway tube semi-trailers. Small gas cylinders are filled at the Amarillo plant, and railway tankcars are filled at the Exell plant. Other shipping containers for gaseous helium may be filled at either plant. Bureau liquid helium was shipped in dewars and semitrailers from the Exell plant exclusively. Private industrial gas distributors shipped helium primarily as a liquid in semitrailers. These semitrailers delivered the liquid helium to distribution centers where some of it was gasified and compressed into trailers and small cylinders for delivery to the end user. The remaining liquid helium was sold as bulk liquid or repackaged in dewars of various sizes for delivery.

PRICES

The Bureau of Mines price, f.o.b. plant, for Grade-A helium has been maintained at \$37.50 per Mcf since October 1, 1982, when it was raised from the \$35.00 per Mcf price established in 1961. The price for Grade-A helium from private producers is also about \$37.50 per Mcf. The Bureau trailer-load liquid helium price was \$45 per Mcf during all of 1989 with additional charges for container services and rent. The typical private industry price for liquid helium was also \$45 per Mcf gaseous equivalent plus surcharges. The Bureau has submitted a report to Congress on options for the routine adjustment of helium prices.

FOREIGN TRADE

Exports of Grade-A helium, all by private industry, increased by 20% in 1989 to 796 MMcf (table 7). About 53% of the exported helium was shipped to Europe. Belgium-Luxembourg, France, and the United Kingdom, collectively,

IN THE UNITED STATES IN 1989**

received about 88% of the European helium imports. About 34% of the U.S. helium exports went to Asia, with Japan taking about 85% of this helium. Other exports were as follows: 3% each to North and South America; over 2% each to Australia-New Zealand, the Middle East, and Central America; and less than 1% each to Africa and the Caribbean. The shipments of large volumes of helium to Western Europe were attributed to helium use in cryogenic research and superconducting equipment. Significant volumes were also being used in breathing mixtures for diving, welding, and as a lifting gas. Although no helium was imported in 1989, import tariffs on helium remained at the 3.7% rate established on January 1, 1987. No further decreases in import tariffs are currently scheduled.

WORLD REVIEW

World production of helium, excluding the United States, was estimated to be 250 MMcf, most of which was extracted in Poland and the U.S.S.R. The remainder was produced in small plants in China and India.

BACKGROUND

The Bureau of Mines role in helium matters dates back to the First World War when the Army and Navy became interested in using helium as an inert lifting gas and contacted the Bureau, because of its natural gas expertise, for assistance. In 1925, the Government's Helium Program was officially placed under Bureau control by Congress (Helium Act of 1925). In 1929, the Bureau's Amarillo, TX, large-scale helium extraction and purification facility was built and began operation. During World War II, demand increased significantly and four more small Government helium plants were built.

New technology increased helium demand in the 1950's and led to the construction of the Keyes Oklahoma plant in 1959. Dwindling Hugoton-Panhandle Field natural gas supplies aroused concerns that no economic source of helium would exist by the turn of the century.

In 1960, Congress replaced the 1925

Act with new legislation. The purposes of the Act were to provide for conservation of helium for essential Government activities and to promote development of a private helium industry. The Act directed the Secretary of the Interior to purchase and store helium for future Government use and to operate and maintain helium production and purification plants and related helium storage, transmission, and shipping facilities.

Purchases for the conservation pro-

gram were made under 22-year contracts with private natural gas companies, which added crude helium extraction capabilities to their existing gas processing facilities. Four companies built five crude helium plants. The Bureau constructed a high-pressure pipeline to transport the helium from Bushton, KS, and intermediate points, to the Bureau-owned Cliffside Field, for storage.

Helium needs of the Federal agencies, particularly the U.S. Department of Defense, NASA, and the U.S. Department of Energy, have been met and there is enough helium in storage to meet their foreseeable needs for up to 100 years, depending on how much helium will be needed by future Government programs. The entire Federal helium demand is now supplied by the Exell Helium Plant as all other Government plants have been dismantled or "mothballed."

In the mid-1970's, the Bureau began accepting privately owned crude helium for storage in Cliffside under long-term contracts. Private industry has a 1-year

supply of helium in Government storage, assuming all market requirements would come from storage.

Resources

Domestic measured and indicated helium resources as of January 1, 1989, the latest figures available, are estimated to be 535 Bcf. The total identified helium resources are about 1 Bcf more than reported in 1988. The increase is attributed to the reevaluation of the helium reserves of several fields in the midcontinent and southwest areas of the United States. The resources include measured reserves and indicated resources estimated at 257 and 32 Bcf, respectively, in natural gas with a minimum helium content of 0.3%. The measured reserves included 36 Bcf stored by the Bureau in the helium conservation storage system. Measured helium resources in natural gas with a helium content of less than 0.3% are estimated to be 36 Bcf. Indicated helium resources in natural gas with a helium content of less than 0.3% are estimated to be 210 Bcf. Approximately 165 Bcf, or 93%, of the domestic helium resources under Federal ownership are in the Riley Ridge area and the Church Buttes Field in Wyoming, and in the Cliffside Field in Texas.

Most of the domestic helium resources are located in the midcontinent and Rocky Mountain regions of the United States. The measured helium reserves are located in approximately 92 gasfields in 11 States. About 87% of these reserves is contained in the Hugoton Field in Kansas, Oklahoma, and Texas; the Keyes Field in Oklahoma; the Panhandle and Cliffside Fields in Texas; and the Riley Ridge area in Wyoming. The Bureau of Mines analyzed a total of

174 natural gas samples from 18 States during 1989 in conjunction with its program to survey and identify possible new sources of helium.

TECHNOLOGY

Until recently, all superconductors required liquid helium (-452°F) to reach superconducting temperatures. Current research on superconductors has resulted in the discovery of superconducting materials that operate above liquid nitrogen temperatures (-320°F). These new superconductors have physical limitations, such as brittleness and poor current-carrying capacities that have limited their use in various superconducting applications. If these problems are solved, the new materials could replace liquid helium-cooled superconductors and adversely affect the liquid helium market. Most researchers seem to think it will be at least 5 to 10 years before the new materials affect liquid helium demand.

Meanwhile, technology that uses liquid helium to produce superconducting temperatures continues to be developed and operated. Liquid helium continues to be used at Fermi National Accelerator Laboratory for Tevatron/Tevatron 1, which was the world's first superconducting particle accelerator. The liquid helium-cooled superconducting magnets used in this accelerator provide an intense and extremely steady magnetic field using only a fraction of the energy required by conventional electromagnets. The Tevatron is presently the highest-energy particle accelerator in the world (1.6 trillion electron volts). In addition, the Department of Energy has already selected the magnets it proposes to use in the Superconducting Supercollider (SSC). The SSC magnets will be similar to those used at Fermi, which are liquid helium-cooled, because they have been proved and tested in operation. When completed, the SSC will have about 20 times the power of the Tevatron (40 trillion electron volts). The proposed Texas site for the SSC was selected by Energy in January 1989.

Testing of the six liquid helium-cooled electromagnets supplied for the

Large Coil Task was completed at Oak Ridge National Laboratory. These six magnets each incorporated slightly different designs, which were being tested to determine the best configuration for the confinement of fusion systems for the production of clean nuclear energy. Although these magnets are the largest ever tested (8 tesla, or 160,000 times as strong as the magnetic field of Earth), they are only one-third to one-half the size of those needed for proposed fusion reactors. Successful operation of these magnets gives researchers more confidence in using superconducting magnets for fusion containment.

Liquid helium use in magnetic resonance imaging (MRI) continues to increase as the medical profession accepts and develops new uses for this equipment. MRI equipment is providing accurate diagnosis of medical problems where exploratory surgery was required previously. Another medical application being developed uses MRI to determine by blood analysis if a patient has any form of cancer.

Lifting gas applications are increasing. Many companies besides Goodyear are now using "blimps" for advertising. The U.S. Navy and U.S. Air Force are investigating the use of airships to provide early warning systems to detect low-flying cruise missiles. The Drug Enforcement Agency has installed six radar balloons along the southern border of the United States to detect drug smugglers. In addition, NASA is now using helium-filled balloons to sample the atmosphere in Antarctica to determine what is depleting the ozone layer that protects Earth from harmful ultraviolet radiation. Similar work is also underway in the Arctic. A stealth blimp is being tested by the Army's Intelligence and Electronic Warfare Center in New Jersey.

Helium is being used to develop several Strategic Defense Initiative (SDI) applications such as the antisatellite (ASAT) rocket, chemical laser, and rail gun. The ASAT rocket uses liquid helium-cooled infrared sensors for target location and guidance. Gaseous helium is used in the lasing gas mixture of the chemical laser, and liquid helium is used to cool the tracking telescope. This telescope is used to locate the target and aim the laser beam. High-

pressure gaseous helium provides the initial push that inserts the projectile into the bore of the rail gun at a velocity of about 1,100 miles per hour. Electromagnetic energy applied along the bore accelerates the projectile to a final velocity of about 9,000 miles per hour. Easing of tensions with the U.S.S.R. and Eastern Bloc nations might slow development of SDI weapons.

Superconducting magnetic energy storage (SMES) is also being investigated to provide power for Department of Defense laser systems. SMES allows the accumulation and storage of electrical energy over the long term (hours) and discharges it in minutes.

Other evolving technologies that require the unique properties of helium are (1) metastable helium for energy storage, which involves raising helium electrons to an excited energy state and then stabilizing the atom there; (2) fiber-optic production, where an ultrapure atmosphere is required; (3) helium-filled plastic pillows, where low density is required to simulate a precursor wave from a nuclear blast; (4) helium ion tumor treatment, where large inert particles are required; (5) liquid helium-cooled superconducting microswitches, called Josephson junctions, which are much faster than conventional semiconductors and use less power; (6) "Aneutronic" nuclear fusion where nuclear energy is produced by fusion of deuterium and helium-3, which produces few or no neutrons; and (7) new helium-hydrogen breathing mixtures that enable deep-sea divers to reach depths below 1,700 feet.

¹All helium volumes herein reported are at 14.7 pounds per square inch absolute and 70°F .

INDIUM

By Stephen M. Jasinski

Mr. Jasinski is a physical scientist with the Branch of Nonferrous Metals. He has covered indium for 2 years. Domestic survey data were prepared by Lura Nightlinger, Nonferrous Data Section.

Domestic indium production was derived from the upgrading of crude indium metal and residues generated in the refining of zinc and other base metals. Two companies accounted for all refined indium produced in the United States. Domestic production data for 1989 were unavailable. The U.S. producer price for indium dropped throughout the year because of lower demand and increased world supply. The main uses were for indium tin oxide (ITO) and indium coatings, alloys, plating, and semiconductor compounds.

LEGISLATION AND GOVERNMENT PROGRAMS

On June 1, 1989, the Assistant Secretary of Defense announced the inclusion of indium in the National Defense Stockpile with a goal of 41,990 kilograms. Purchases were scheduled to begin at 2,488 kilograms annually for fiscal years 1990 and 1991.¹

CONSUMPTION AND USES

Domestic consumption was about 25,000 kilograms in 1989. Thin coatings of indium on glass, used in applications such as liquid crystal displays (LCD) and heat-reflecting window coatings, were the largest use in 1989, accounting for 45% of consumption. Other uses were for electrical and electronic components, 25%; solder and alloys, 20%; and research and other, 10%.

Indium was available in various forms, such as ingot, foil, shot, ribbon, wire, and powder. Standard-grade indium was generally used in solders, chemical compounds, plating solutions, and fusible alloys. High-purity

indium was used for manufacturing semiconductors and solar cells.

Thin film coatings on glass, which use indium oxide and ITO, have been the largest area of growth for indium usage in the past 3 years. Solar cells, computers, digital displays, and infrared reflective window coatings to reduce energy costs were some major applications. Another area of increasing importance during this period was the use of high-purity indium as a constituent in semiconductors, which are used mainly for infrared and radiation detectors, fiber optics, and other optoelectronic devices.

Applications involving thin coatings on glass can be divided into two categories, electrically conductive and infrared reflecting. Electrically conductive coatings, which comprise the largest group, were used primarily in LCD's for watches, television screens, portable computer screens, video monitors, and other related display devices. An LCD consists of a liquid crystal material bonded between two sheets of glass that are coated on the inside with a transparent indium oxide or ITO film, which acts as an electrode. A polarizing filter is placed on the outside of the glass, and the entire display is sealed in plastic. A small change in voltage applied to the electrode causes the crystal to become oriented in a distinct pattern and blocks polarized light emitted from the back of the display, thus producing the display.²

Some aircraft and locomotive windshields used a transparent ITO film as a demister or defogger. In this application, electric current heats the film to clear the glass. Indium coatings are more effective than other types of materials, but its use is limited because of the higher cost. Many automobile manufacturers have also experimented with this use but, because of the higher cost, most of them used a zinc-silver oxide

coating for quick defrost of windshields. In a similar use, glass doors on commercial refrigerators and freezers are kept free of condensation and frost by a heated thin film of indium oxide.

Another group of films includes transparent, infrared reflecting coatings on window glass to control energy losses by reflecting heat inward during the winter and out in the summer. For residential windows, the coating was usually applied to a plastic sheet and encased between two panes of glass. This prevents erosion of the coating and reduces the cost of production. Because the expense of retrofitting a commercial building remains high, other less expensive metals, such as silver, were used as a replacement for indium on new windows.

A major use of indium in Europe, and a growing application in the United States, was in the manufacturing of low-pressure sodium vapor street lamps. An indium oxide coating was used on the inside surface of the outer glass cover of the lamp. The indium oxide acts as an infrared reflector, which allows the bulb to operate at a higher temperature for improved efficiency.

Electroluminescent (E-L) lamps are thin, flat, flexible light sources used to backlight LCD screens, display panels, and switches for military and civilian applications. An E-L lamp consists of a layer of light-emitting phosphor material on an aluminum foil substrate. A transparent film of ITO, which acts as an electrode, is placed on the phosphor and illuminates the area when electricity is applied. E-L lighting penetrates fog, smoke, and haze making these lights essential in military and commercial aircraft. Tactical military aircraft used E-L lamps for instrument panels and marker lights, and commercial planes used the lamps primarily in safety lighting for aisles and doors.

High-purity indium was an important

element for semiconductor materials used in infrared detectors and optoelectronic photonic devices such as fiber optics, laser diodes, optical computers, and signal processing. Indium phosphide was the leading substrate material for optical integrated circuits and laser diodes.³ Indium antimonide and indium arsenide were used in infrared detectors for missile-guidance systems, night-vision instruments, and medical devices.

Copper-indium-diselenide (CIS) was a promising material for high-efficiency solar cells. CIS has demonstrated energy-conversion efficiency ratings of at least 9.7% for large panel units and 14.1% for small cells, with a goal of 15% to 20% efficiency by 2000. CIS cells were also more durable than other materials, such as amorphous silicon. For the cells to become economically viable, two other goals have to be achieved. They must have a 30-year lifespan, and the cost of production must drop from the current range of \$100 to \$240 per square meter (m^2) to near \$50 per m^2 . Other indium solar-cell materials, such as copper-indium-gallium-diselenide were more expensive to manufacture than CIS, but had higher energy conversion ratios.⁴

A major domestic use for indium has been as an alloying addition to bismuth, cadmium, lead, mercury, or tin to lower the melting point. These alloys can be used in such applications as a heat fuse material for fire-protection systems, or a holding material for the grinding of optical glass. Indium was used in combination with tin for glass-to-metal and glass-to-glass seals.

Low-temperature, indium-base solder was used as a replacement for tin-lead solder, because advanced electronic components can be damaged by the temperature of tin-lead solder. Indium-base solders melt at a much lower temperature and remain flexible over a greater temperature range. Unlike tin-lead solder, which can leach gold or other precious metals and cause a defective solder joint, indium does not react with those metals. The DOD was studying the inclusion of indium-base solders for military specifications.

Several manufacturers of pressurized water reactors used an alloy consisting of 80% silver, 15% indium, and 5% cadmium for nuclear control rods. This use declined in the United States in the early 1970's when orders for new nuclear powerplants began to drop. Fol-

lowing the Three Mile Island nuclear accident in 1979, all orders for new nuclear powerplants in the United States ceased, and subsequent consumption has been only for replacement rods.

Because of its softness and ability to cold-weld to itself, certain breath-analyzer units used an indium tube as a containment device. To obtain a specimen, the person exhales into the unit and a breath sample is crimped inside the tube and sent to a laboratory for analysis. This method, however, was losing its share of the market to electronic methods of detecting intoxicants.

Minor uses included indium-palladium and indium-gold alloys in dentistry, as a surface lubricant for abrasive compounds, and as an additive to lubricating oil to prevent corrosion. Certain radiation-detection badges used indium foil, because low-energy neutrons easily induce radioactivity in indium.

PRICES

A slight increase in world stocks of indium and reduced demand resulted in lower prices. The price of standard-grade, 99.97%-purity indium in the United States gradually decreased from \$9.65 per troy ounce in January to \$7.80 per troy ounce in December.

WORLD REVIEW

World refinery production in 1989 was about 115 metric tons. Belgium, France, Italy, and Japan were the largest producers. World consumption was about 110 tons. Japan and the United States were the largest consumers.

Canada

Cominco Ltd. commenced operations at its new indium refinery at Trail, British Columbia. The company planned to adjust the output to prevailing market conditions. Production capacity of the new facility was 30 tons per year. Problems with the startup of the plant caused production to be less than planned in 1989.

In January, Johnson Matthey Plc., United Kingdom, purchased facilities

for producing high-purity metals, including indium, in Spokane, WA, and Trail, British Columbia, from Cominco Ltd. Cominco Electronic Materials (CEM) produced high-purity indium and other metals for semiconductors and a variety of indium solders, wire, and sputtering targets at the two production facilities. The purchase included Crystal Research Inc., another subsidiary of Cominco that conducted research on high-purity metals at Vancouver, British Columbia. Johnson Matthey continued operations at the existing plants using source material from Cominco. The new company, Johnson Matthey Electronics, was headquartered in Spokane.

Falconbridge Ltd. and Indium Corp. of America planned to complete a new indium recovery plant at Falconbridge's Kidd Creek Mine at Timmons, Ontario, in late 1990. Indium Corp. planned to refine the material at its plant in Utica, NY, and to gradually increase its production to about 30 tons per year. Canada would become the world's largest producer of refined indium upon completion of these projects.

Japan

Nippon Mining Co. Ltd., the largest producer of indium in the world, began developing a new lead-zinc deposit on Hokkaido, which according to the company contained an estimated 3 million tons of ore. Indium, silver, and copper were expected to be produced as byproducts.⁵

Japan increased its reported output of refined indium from 27 tons in 1987 to 49 tons in 1989, thereby becoming the largest producer in the world. The reported figure included indium produced from lower purity metal imported from Europe and North America. Therefore, actual production was estimated at 31 tons in 1989. Consumption in Japan was estimated at 60 tons in 1989 and was expected to increase substantially over the next 5 years. The leading uses of indium in Japan were for transparent, electrically conductive coatings on glass, electroluminescent lamps, and semiconductors.

CURRENT RESEARCH

In May 1989, space shuttle mission

STS-30 conducted experiments on producing high-grade indium in a weightless environment. Indium Corp. of America supplied several indium rods for use in the Fluids Experiment Apparatus. In the process, an indium rod was slowly moved through a heat source, which caused the impurities to concentrate at one end of the rod, resulting in a high-purity metal. The results of the study were being analyzed. A similar experiment was expected to be performed on STS-32 in January 1990.⁶

Several companies developed high-speed indium phosphide computer chips for data transmission. The chips operate at speeds up to 250 billion oscillations per second (GHz), compared to silicon materials, which usually operate below 2 GHz. The chips use High-Electron-Mobility-Transistors (HEMT), in which the impurities are not in the regions in which the charge-carrying electrons travel, resulting in faster speeds.⁷ The chips were expected

to be used to send data via optical fibers and for satellite transmission. Other HEMT applications under development included collision-avoidance radar for cars and radar systems for smart weapons, which can discern a target's shape though fog or smoke.⁸

OUTLOOK

World reserves and anticipated increases in production capacity are sufficient to meet expected demand for indium through 2000. Consumption of indium is expected to increase gradually in this period, especially for LCD's, semiconductor materials, and in low-temperature solder for military and commercial electronics. Other uses, such as nuclear control rods, which have a lifespan of 15 years, and fusible alloys should remain steady.

BACKGROUND

Definition, Grades, and Specifications

Indium is silvery-white in color and has a brilliant metallic luster. It is softer than lead, very ductile and malleable; hence, it is well suited for use in solders and low-melting alloys. It retains these plastic-like properties to temperatures near absolute zero. Indium does not work harden, can endure considerable deformation through compression, and cold-welds easily.

Some physical constants of pure indium are chemical symbol In; atomic number, 49; atomic weight, 114.82; melting point, 156.61° C; boiling point, 2080° C; and density, 7.31 grams per cubic centimeter at 20° C. Standard grade is 99.97% purity, and high grades are available from 99.99% (4N) to 99.99999% (7N) purity.

Industry Structure

NA Not available.

dence, RI, and Indium Corp. of America, Utica, NY, the only refiners of indium in the United States, produce indium primarily from imported zinc residues, low-grade indium bullion, and indium scrap. Arconium, Indium Corp., and Johnson Matthey Electronics produce high-purity indium shapes, ingots, and foil. Metalspecialties Inc., Fairfield, CT, and Powmet Inc., Rockford, IL, occasionally recover indium from old scrap.

Because indium is primarily recovered from residues, slags, flue dusts, and intermediate compounds resulting from zinc smelting, world mine production is inferred from the average indium content of zinc ore mined. Canada is the largest producer of zinc in the world, therefore, its mine production was believed to contain the largest quantity of indium.

Refining capacity was historically based in Europe. However, in recent years refining capacity shifted to Asia

and North America because of increased production in Japan and planned expansions in the United States and Canada. The major world refiners were:

Company	Location
Billiton Metaalindustrie NV	Netherlands
Cominco Ltd.	Canada
Capper Pass Ltd.	United Kingdom
Empresa Minera del Centro del Perú S.A. (Centromin-Peru)	Peru
Metaleurop	Federal Republic of Germany
Do.	France and Italy
Metallurgie Hoboken-Overpelt	Belgium
Mining and Chemical Products Ltd.	United Kingdom
Nippon Mining Co. Ltd.	Japan

Geology-Resources

Indium occurs predominantly in solid solution in sphalerite, but has been reported in other base-metal ores of copper, lead, and tin. It is not known to occur in the native state. The average indium content of the Earth's crust was estimated at 0.1 parts per million (ppm).⁹ The indium content of mined zinc deposits ranged from 0 to 100 ppm. The highest known indium occurrences are in vein, replacement, and contact metasomatic sulfide deposits, especially those containing tin minerals. The indium contents of these deposits typically range from 100 to 21,000 ppm. Deposits include the Central City District, CO, the Argentine Andes, the Cornwall tin district in England, and the Mount Pleasant tin deposit in New Brunswick, Canada.¹⁰ Because indium was frequently recovered as a byproduct of zinc, world indium reserves were based on estimates of the average indium content of zinc ore for a particular region.

Technology

Processing.—A variety of methods were employed to recover indium, depending on the source material and indium content. Indium was primarily recovered as a byproduct of zinc processing. Among the more common methods of recovery were leaching the indium-containing material with sulfuric or hydrochloric acid and extracting

the crude indium from solution by cementation on aluminum or zinc sheets.

Solvent extraction with organic solutions was used to recover indium from dilute solutions. Another method involved the precipitation of indium phosphate selectively from slightly acidic solutions and conversion to oxide by leaching in a strong caustic soda solution, followed by reduction of the oxide to metal. During the smelting of zinc concentrates, the indium concentrates in the zinc-lead bottom metal and is separated from that portion by chlorination under molten salt, forming an indium-rich slag. Indium is recovered from the slag by leaching and cementation on zinc or aluminum sheets. The indium deposits on the sheets as a low-density, sponge-like mass, which breaks away and floats to the surface of the solution. The indium sponge is washed, briquetted, melted, and cast into anodes for electrolytic refining.¹¹

Byproducts and Coproducts

Domestically refined indium was a minor byproduct of processing base metal ores or zinc residues. The value of recovered indium was negligible in relation to the value of zinc production. Coproducts include tungsten, molybdenum, silver, and tin.

IODINE

By Phyllis A. Lyday

Mrs. Lyday, a physical scientist with the Bureau of Mines, has been the commodity specialist for iodine for 11 years. Domestic survey data were prepared by Blanche Hughes, mineral data assistant, and international data tables were prepared by Peter Roetzel, international data assistant.

Three producers of crude iodine supplied approximately one-half of domestic demand; the remainder was imported. Because some exports and imports are in product categories rather than crude products, net imports are not clearly developed. The major world producer, Japan, produced iodine from brines associated with gas production. The second largest producer, Chile, produced iodine as a coproduct of sodium nitrate.

DOMESTIC DATA COVERAGE

Domestic production data for iodine are developed by the Bureau of Mines from a voluntary survey of U.S. operations. Of the four operations to which a survey request was sent, three responded, representing an estimated 55% of the total production shown in table 5.

LEGISLATION AND GOVERNMENT PROGRAMS

The Food and Drug Administration extended the provisional listing for Red Dye No. 3, erythrosine containing 58% iodine by weight, until January 29, 1990, for cosmetic uses.¹

STRATEGIC CONSIDERATIONS

The National Defense Stockpile (NDS) contained 6.1 million pounds of crude iodine valued at \$54 million in inventory at yearend. The stockpile

goal remained at 2.6 million kilograms (kg) (5.8 million pounds). Responsibility for the NDS was transferred from the Federal Emergency Management Agency and the General Services Administration to the Department of Defense (DOD) (Public Law 100-180). Within DOD, the Defense Logistics Agency (DLA) was to handle the buying, selling, and storing of NDS materials. Executive Order 12626 designated the Secretary of Defense as the National Defense Stockpile Manager.

The National Defense Authorization Act of 1989 (Public Law 100-456) authorized the stockpile manager to dispose of 19 materials, including iodine, determined to be in excess of stockpile requirements. DLA announced that offers for the purchase of iodine would be considered during fiscal year 1989. At yearend 1988, 200,000 pounds was disposed of, leaving 137,657 kgs (303,482 pounds) in excess of the goal at yearend 1989 that was valued at \$2.4 million or \$17.24 per kg (\$7.82 per pound).

PRODUCTION

IoChem Corp., located 2 miles east of Vici, OK, produced iodine by the blowing-out process. IoChem expanded capacity from about 1 million pounds per year to about 4 million pounds per year. North American Brine Resources operated two miniplants at Dover and Hennessey in Kingfisher County, OK. The plants were at oil field reinjection disposal sites where iodine concentrations ranged up to 1,200 parts per million (ppm). The company completed a new \$5 million plant in Harper County. Woodward Iodine Corp., a subsidiary of Asahi Glass Co. of Japan, produced iodine from brines using the blowing-out process.

CONSUMPTION AND USES

Iodine was used in animal feed supplements, catalysts, inks and colorants, pharmaceuticals, photographic equipment, sanitary and industrial disinfectants, stabilizers, and radiopaque medium. Other uses included production of high-purity metals, motor fuels, iodized salt, and lubricants.

A major use of iodine is as a catalyst in the production of acetic acid by the Monsanto process. BP Chemicals Inc. modified the process to coproduce acetic acid and acetic anhydride. BP is the second largest acetic acid producer with a capacity of 870,000 tons.²

Uniroyal Chemical Inc. is a major consumer of iodine for use as an oxidizer in the production of rubber chemicals and elastomers with joint ventures in Brazil, India, Korea, and Mexico. Uniroyal Chemical Co. was purchased with \$240 million cash and \$560 million as assumed debt in a leverage buyout by a management led team.³

Ecolab Inc., a major consumer of iodine for use in cleaning products, sold Henkel KGaA, its West German counterpart, an 11.8% voting interest in preferred stock for \$110 million.⁴

GAF Corp. is a major consumer of pyrrolidone-base chemicals that can be used as an environmentally safe cleaning solvent replacing chlorofluorocarbons.⁵

Eastman Kodak Co., a major consumer of iodine in photographic uses, formed a new business unit, Eastman Fine Chemicals, that included Sterling Organic external chemical sales business and sections of Eastman Chemicals specialty organic operations.⁶

Mallinckrodt Inc., a subsidiary of International Minerals & Chemical Corp., began marketing a nonionic contrast medium for radiology and cardiology X-ray procedures. The United States market for X-ray contrast media

is about \$500 million annually. The worldwide market was more than twice the U.S. market.⁷

Ceralure, an iodine-containing lure for the Mediterranean fruit flies, developed by the U.S. Department of Agriculture, may replace the use of helicopter sprays.⁸

PRICES

The average declared c.i.f. value for imported crude iodine was \$17.68 per kg (\$8.05 per pound). The average declared c.i.f. value for imported crude iodine from Japan averaged \$17.64 per kg (\$8.00 per pound). The average declared c.i.f. value for iodine imported from Chile was \$18.01 per kg (\$8.17 per pound).

Quoted yearend U.S. prices for iodine and its primary compounds are shown in table 2.

FOREIGN TRADE

The U.S. Government adopted the Harmonized Commodity Description and Coding System (Harmonized System) as the basis for its export and import tariff and statistical classification systems. The system is intended for multinational use as a basis for classifying commodities in international trade for tariff, statistical, and transportation purposes. The Harmonized System as proposed includes resublimed and crude iodine under the same code, and the duty rate is free.

WORLD REVIEW

The World Health Organization, headquartered in Geneva, Switzerland, published "Guidelines for Iodine Prophylaxis following Nuclear Accidents" (EH-35). The guidelines were a result of experience gained from the Chernobyl nuclear accident that exposed population groups to radioactive iodine.

Capacity

The data in table 4 are rated capacity for plants as of December 31, 1989. Rated capacity is defined as the maxi-

imum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that in the judgment of the author can be brought into production within a short period of time with minimum capital expenditure.

Mine capacity for iodine is based on

rated capacity as reported by the company, by another government agency, or another published source.

Chile

Sociedad Química y Minera de Chile (SOQUIMICH) was the largest producer of iodine in Chile. The María Elena and Pedro de Valdivia plants produced iodine, sodium nitrate, potassium nitrate, and sodium sulfate. SOQUIMICH continued to operate a plant at Puelma. SOQUIMICH had a joint venture with Israel Chemicals

Ltd. named Compania Quimica Internacional de Desarrollo (IDC Co.) dedicated to research and development in the inorganic chemicals and fertilizers.⁹

North Lily Mining Co. of the United States formed a joint venture, named Taltal Joint Venture, with Zurfund International Ltd., Canada, to mine iodine. North Lily will operate the deposit known as the Yolanda Project through Minera Northern Resources, a wholly owned subsidiary. Davey McKee Corp. was retained by the Taltal Joint Venture to undertake a feasibility study of the Yolanda Project.¹⁰

Other companies active in iodine production in Chile included Amsterdam Chemical Pharmaceutical Minera

(ACF Minera), a joint venture of the Sociedad Contractual Minera Lagunas and the Amsterdam Pharmaceutical Co. of the Netherlands. ACF Minera was operating a plant originally built by Minera Lagunas. The plant had been expanded with a \$3 million investment. The crude product was shipped to the Netherlands for use by the producing company rather than for an open market.¹¹ Cia Minera Chilbras, a Chilean-Brazilian joint venture, produced iodine from nitrate deposits in the Salar de Bellavista.¹² The Merck Pharmaceutical Co. of the Federal Republic of Germany was involved in a project to produce between 4 to 5 tons per year of iodine from nitrate tailings

near Huara in the Iquique region.¹³ Compania Minera Sierras de Tarapaca began production of iodine at the San Pedro plant 37 kilometers east of Pozo Almonte, Tarapaca. The plant cost \$2 million and had a 360 tons per year of capacity.¹⁴ Banco Bilbao Vizcaya S.A., Spain, announced a \$19.2 million iodine recovery facility to be built on 1,184 hectares of land purchased for \$14 million from Cia Minera Gran Tamarugal S.A. The plant planned to produce 4,750 tons of iodine the first 10 years with production destined for markets in Europe.¹⁵ Compania Minera del Alba operated a small plant at Salar de Lagunas.

Indonesia

The only producer of crude iodine was the state-owned pharmaceutical firm, P. T. Kimia Farma, that operated a plant at Watudakon near Mojokerto, East Java.

Japan

Production of iodine was from underground brines associated with natural gas. Japan was the world's leading producer of iodine in 1989. Six companies operated 17 plants with a total production capacity of 20 million pounds per year.

United Kingdom

Thornton Processing Ltd., Bradford, reported that during 1988 more

than \$2 million worth of iodine was recovered at the Caledonia plant from industrial residues, principally those generated from growing sodium iodide crystals.

CURRENT RESEARCH

Because of their reaction with metals in the presence of water, alkyl halides may find use in metal recovery and refining and methyl iodide in metallurgical processing. Because algae serve as a major source of environmentally occurring methyl iodide, a microorganism approach in the metallurgical process could be possible in the future.¹⁶

When natural rubber, a polymer, is treated with iodine, it becomes 10 orders of magnitude more highly conducting than native rubber. If further research can improve the conductivity, then commercial applications could be possible.¹⁷

A researcher with Nippon Steel Corp., Japan, used a catalyst of cadmium and cesium iodides to make liquid crystalline polyesters that could be used in magnetic recording tapes, dielectrics in capacitors, and thermal printer ribbons.¹⁸

Three experiments to grow lead iodine crystals were completed during a National Aeronautics and Space Administration's *Discovery* space shuttle flight of September 1988. Lead iodide crystals are used as image intensifiers for X-ray and gamma-ray films. Larger crystals would produce better films. Crystals grown in

space are superior to Earth-grown crystals for some applications.¹⁹

OUTLOOK

Iodine production capacity in the United States and Chile has doubled during the past decade, ensuring an adequate world supply. Uses for iodine in specialty chemicals has remained stable. New processes have decreased the amount of iodine while demand has increased. For example, a patent was obtained that required less iodine to provide the same sanitizing ability.

BACKGROUND

Definitions, Grades, and Specifications

Commercial crude iodine normally has a minimum purity of 99.5%. Resublimed iodine is usually 99.9% purity. Most iodine is converted for industrial use to potassium iodide, sodium iodide, and other inorganic compounds, as well as numerous organic compounds.²⁰

Geology-Resources

Iodine occurs in rocks and soils, surface and underground brines, and in caliche ores. Michigan brines contain about 30 parts per million (ppm) of iodine in the Sylvania Formation of Devonian age. California brines contain 30 to 70 ppm of iodine in brines associated with oilfields in the middle

Miocene age, Monterey Formation, and the lower Pliocene age Repetto Formation. Louisiana brines contain about 35 ppm of iodine. In Oklahoma, iodine concentrations associated with oil and gas range between 150 to 1,200 ppm. In Woodward County, OK, the iodine occurs in the Morrowan Formation of Pennsylvania age.

Extensive iodine-bearing nitrate ores occur in caliche deposits in a belt several hundred kilometers long in the Atacama Desert of northern Chile. The ore layers are 1 to 3 meters thick, usually flat or gently dipping and near the surface. Evaporate minerals such as lautarite (CaI_2O_6) and dietzeite ($2\text{CaO} \cdot \text{I}_2\text{O}_5 \cdot \text{CrO}_3$) occur as cementing material in unconsolidated surface material or as veins and impregnations in bedrock.

Japanese brines contain 50 to 135 ppm of iodine in the Kiwada, Otadai, and Umegase Formations of the Kazusa Group of Pliocene age. The major iodine-producing area was the southern Kanto Gasfield, which extends over Chiba, Tokyo, and Kanagawa Prefectures. Iodine was produced in the Niigata and Nakojo Gasfields in Niigata Prefecture, on the Sea of Japan side of central Japan, and the Sadowara Gasfield in Miyazaki Prefecture, southern Kyushu.

In Indonesia, iodine occurs with trace amounts of bromine in brines associated with oil. The most important iodine-producing area is the Gungjang anticline of sandstone and diatomaceous marls of the Upper Pliocene, Kailiberg Formation.

TABLE 5
CRUDE IODINE: WORLD PRODUCTION, BY COUNTRY¹

(Kilograms)

Country ²	1985	1986	1987	1988 ^p	1989 ^c

^c Estimated. ^p Preliminary. W Withheld to avoid disclosing company proprietary data.

¹ Table includes data available through May 30, 1990.

² In addition to the countries listed, New Zealand also produces elemental iodine, but data are not available and available information is inadequate for formulation of reliable estimates of output levels.

³ Reported figure.

⁴ Excludes U.S. production.

On Okinawa, iodine occurs in concentrations of about 85 ppm in the Tomigusuku Formation of the Shimajiri Group of late Miocene-early Pleistocene age.

Technology

In the United States and Japan, iodine is removed from brines by processes that separate the brines from any associated oil or gas. In the blowing-out process, brine is acidified and iodine is liberated by reducing the pH to about 3. A countercurrent stream of air transports the liberated iodine to a second tower in which the iodine is absorbed by a solution of hydriodic acid. The iodine settles, is filtered, and melted under concentrated acid. Brine stripped of iodine is treated and then reinjected into its subsurface formation of origin.

In the absorption process, brine is passed through an absorber and the waste brine is neutralized and sent to a disposal well. The absorbent laden with iodine is treated with an alkaline solution to regenerate the absorbent and

eludes iodine as sodium iodide. Iodide is precipitated under acid.

Japanese plants also use an ion-exchange resin. Upon saturation, the iodine is eluted using a caustic solution that regenerates the resin. Iodine is then processed with a sodium chloride solution and melted under acid.

Chilean caliche deposits are mined by open pit methods. The ore is leached with an alkaline solution to dissolve the iodine as sodium iodate, which is converted to sodium iodide. Iodine is precipitated by reacting with additional alkaline solution. The precipitated iodine is filtered in bag filters and the iodine free-leach solution is returned to the nitrate-leaching cycle.

Economic Factors

Prices.—Changes in the official price of crude iodine have in the past been initiated during shortages. Because iodine cannot be substituted in radiopaque, animal feeds, catalysts, and stabilizers readily, shortages tend to cause the accumulation of inventories. An ad-

equate supply tends to stabilize the price.

Costs.—Electrical costs for maintaining the pumps to bring the brine to the surface, for air-blowing the iodine, and for reinjecting the brine are major components of maintenance costs. Capital costs have been estimated at \$20 per pound of annual iodine production. These costs include high-quality stainless steels because iodine is highly corrosive. In addition, the brine must be leased from private landowners over large acreage for many years. The principal material cost is for chlorine because 1 pound is required for every 1.4 to 1.8 pounds of iodine produced.

Taxes.—Crude and resublimed iodine enter the United States duty free. Calcium and cuprous iodine has a 25% ad valorem for non-most-favored-nation status. Potassium iodide has a 2.8% ad valorem for most-favored-nation status and 7.5% ad valorem for non-most-favored-nation status.

Depletion Provisions.—The domestic and foreign depletion allowances for iodine are 14% of gross income, and they may not exceed 50% of net income without the depletion deduction.

Operating Factors

Environmental Requirements.—The reinjection of waste brine is a limiting factor to the production of iodine. During 1982, the Environmental Protection Agency (EPA) reclassified disposal wells for spent brine after halogen extraction as Class 5 wells. All of the reinjection wells for iodine in Oklahoma were drilled for the reinjection of waste associated with brine production or oil and gas effluent.

Toxicity.—Iodine is absorbed by the body and concentrated in the thyroid. Iodine is essential to higher animals and humans. A normal person requires about 75 mg of iodine per year, which is usually consumed as iodized salt that contains 1 part sodium or potassium iodide to 100,000 parts of sodium chloride. Iodine deficiency is a major cause of goiter.²¹

The maximum safe concentration for short-term air environment exposure of up to 1 hour is 1.0 ppm. Exposure of the lungs and eyes can be irritating at

concentrations of 0.1 ppm and should be avoided. Greater exposure can cause severe irritations to the eyes and the respiratory tract and may lead to pulmonary edema.

In 1979 and 1986, nuclear accidents caused the release of radioactive iodine, I^{131} , into the atmosphere. Ingestion of potassium iodide, KI, can reduce the amount of radiation absorbed by the thyroid gland.²²

IRON ORE

By Peter H. Kuck and Cheryl M. Cvetic

Dr. Kuck has been the commodity specialist for iron ore since 1986. Ms. Cvetic joined the Bureau of Mines in 1988 and has a background in geology and international business. The domestic survey data were compiled and analyzed by Sarah P. Guerrino, Chief of the Ferrous Data Section. The world production table was prepared by Peter J. Roetzel in the International Data Section.

A cursory glance at the salient statistics in table 1 suggests that the domestic iron ore industry made little headway in 1989. In actuality, dramatic technological changes occurred that will have far-reaching effects on the entire iron and steel sector in both North America and the rest of the world.

The United States produced 59.03 million metric tons (Mmt) of usable iron ore during the year. Although the tonnage was only slightly more than that of 1988, significant improvements were made in pellet quality. For the first time, fluxed pellets accounted for more than one-third of production. Fluxed or partially fluxed pellets were being made at six of the Nation's nine active taconite plants. A 10th plant, the E.W. Davis Works at Silver Bay, MN, was reactivated in December, but did not begin producing pellets until January 27, 1990.

Mine shipments of pellets, concentrates, and direct shipping ore totaled 58.30 Mmt, again an amount only slightly higher than that of 1988. Combined U.S. imports of ore, concentrates, and agglomerates decreased 3% to 19.60 Mmt, with Brazil and Venezuela gaining market share at the expense of Australia and Canada. Exports, in contrast, have been slowly creeping upward since 1985. Virtually all of the 5.37 Mmt exported in 1989 went to Canadian steel companies that hold equities in U.S. taconite projects. Consumption of iron ore by the iron and steel industry rose slightly between 1988 and 1989 to 73.06 Mmt. Pig iron production was 50.69 Mmt, virtually the same as in 1988, for an average output of 4.22 Mmt per month. On December 31, 48 blast furnaces were in operation, 2 less than at the end of 1988.

DOMESTIC DATA COVERAGE

U.S. production data for iron ore are developed by the Bureau of Mines from two separate voluntary surveys of domestic operations. The annual "Iron Ore" survey (1066-A) provides the basic data used in this report. Of 31 addressees to whom the 1066-A form was sent, 30 responded, representing 99.99% of total production shown in tables 1 through 4. Production for nonrespondents to the annual survey can be estimated from monthly surveys (1066-M), from railroad reports, or from reported production levels in prior years. This information may be supplemented by employment data, mine-inspection reports, and information from consumers.

Data on consumption and stocks of iron ore and agglomerates at iron and steel plants were provided by the American Iron Ore Association (AIOA). AIOA also provided data on ore shipments from loading docks on the upper Great Lakes as well as receipts at transfer docks and furnace yards nationwide. The dock and steel plant data were compiled jointly by AIOA and the American Iron and Steel Institute (AISI). Data on consumption of iron ore for nonsteel end uses were compiled from information gathered from other Bureau surveys.

LEGISLATION AND GOVERNMENT PROGRAMS

Congress enacted the Omnibus Trade and Competitiveness Act (Public Law 100-418) on August 23, 1988, to enhance the competitiveness of the Nation's industries and to improve the management of

U.S. trade strategy. This comprehensive act, included among other items, provisions modifying U.S. customs laws and tariff schedules. Subtitle B of the new law requires that all tariff schedules after January 1, 1989, conform to the nomenclature of the internationally established Harmonized System—a global system of classifying products for tariff purposes that had been adopted earlier by many major trading countries.

The new law restructured both the import and export classification systems. The new schedule B classification is now based on the organizational framework of the Harmonized Tariff Schedule of the United States (HTSUS). That is, equivalent import and export items are assigned the same 10-digit classification code. In the case of iron ore, seven subheadings replaced the two less definitive ones in use since September 1963.

Various Executive and Congressional mandates have directed that all Federal Agencies convert their statistics to the International System of Units in a timely manner. The principal regulations governing the conversion are contained in the Metric Conversion Act of 1975 (Public Law 94-168), as amended in 1988 (Public Law 100-418). All of the iron ore trade statistics collected by the Bureau of the Census are now being compiled and published in *metric* units. The Bureau of Mines also has begun publishing its statistics on iron ore production and consumption in *metric* units. To convert from metric tons to long tons, multiply by 0.984207.

EMPLOYMENT

Statistics on employment and productivity in the U.S. iron ore industry in

FIGURE 1
U.S. IRON ORE PRODUCTION AND IMPORTS FOR CONSUMPTION

1989, shown in table 2, were derived from quarterly employment data supplied by the Mine Safety and Health Administration (MSHA) and from production data derived from Bureau of Mines surveys. Both sets of data were obtained from producers' reports.

The statistics include production workers employed at mines, concentrators, pelletizing plants, and in repair and maintenance shops, but do not include 798 persons engaged in management, research, or officework at mines and plants. Employees engaged in ore preparation, such as sintering, at blast furnace sites are not included. An additional 140 individuals were engaged in the secondary beneficiation of iron ore for heavy media and other nonsteel uses.

Because employment data reported to MSHA are primarily for safety analysis, hours spent by salaried employees in mines or plants may be included by operators in the total number of hours worked at individual mines or plants. This has resulted in understatement of

calculated productivity by 10% to 25% for some operations, but its effect on others is not known. If company reporting practice is consistent, however, comparison of productivity from one year to the next should be reasonably valid.

Average quarterly employment was 10% more than that of 1988, with at least two mine operators calling back laid off workers to meet increased pellet demand from domestic steel producers and start up idled capacity. The additional personnel enabled the iron ore industry to boost its output of usable ore by 3%. The relatively small gain in output is somewhat misleading because 214 production workers were recalled during the last quarter of 1989 to help renovate the idled operations at Silver Bay and Babbitt, MN.

Total hours worked rose 10% because of the renovation project, the recalls, and increased level of production. The increase in demand came at a time when at least three operations in the Lake Superior District had begun switching over

to fluxed pellet production or making other major technological improvements. The conversion to fluxed pellets adversely affected productivity because pelletizing lines and grinding lines had to be shut down so that existing equipment could be modified and new equipment installed. As a result, operating parameters and procedures had to be readjusted. The switchover at the Tilden Mine from hematite to magnetite also helped to temporarily lower productivity. Consequently, average productivity for usable ore in the Lake Superior District was 7.4% lower than that of 1988. Because the district accounts for the bulk of U.S. output, the average productivity for the entire industry dropped 6.9%.

PRODUCTION

The outlook for the domestic iron ore industry has changed dramatically since the disastrous summer of 1986 when

FIGURE 2
EMPLOYMENT AT IRON MINES AND BENEFICIATING PLANTS

* Includes workers in Wisconsin for years prior to 1984.

monthly pellet production dropped below the 3.5-Mmt level. At that time, USX Corp. was shut down by a nationwide work stoppage, and LTV Corp. had just filed for reorganization under chapter 11 of the Federal Bankruptcy Code. However, by reducing costs, recapitalizing, adopting new technologies, and improving pellet quality, the iron ore industry extricated itself from a difficult situation that skirted total economic collapse. A strengthening of demand for finished steel products in the wake of these improvements caused domestic iron ore shipments to jump 36% between 1986 and 1988. Ore sales continued to improve in 1989, with shipments reaching 58.30 Mmt, the highest level since 1981. Two taconite operations, the Empire and Minorca Mines, set new records for pellet production in 1989. Total output of usable ore was equivalent to about 71% of installed production capacity on January 1, 1989. This percentage was a

considerable improvement over that of 1987 and 1986, when the utilization factors were 55% and 46%, respectively. Secondary factors contributing to the 1988-89 turnaround were the weak U.S. dollar, which made the importation of some steels less attractive and increased exports of goods fabricated from steel; higher prices for quality steel scrap; increased demand for steel worldwide; and the Federal Voluntary Restraint Arrangements program, which reduced steel imports to a little more than 20% of the U.S. market.

Iron ore was produced by 20 open pit mines and 1 underground mine. Fourteen mines produced ore for the iron and steel industry, while the remainder shipped ore mainly to cement plants. Installed production capacity for usable ore at yearend was estimated at 83 Mmt per year, including 79 Mmt of capacity for pellets. Effective production capacity for pellets was at least 12 Mmt less than installed

capacity. Only five of the nine operational pelletizing plants utilized more than 85% of their installed capacities, despite the upswing in demand since 1987.

An average of 3.2 tons of crude ore was mined in 1989 for each ton of usable ore produced. This ratio does not take into account the tonnage of waste rock or overburden removed. The ratio of total materials mined to usable ore produced was probably greater than 5:1. Low-grade ores of the taconite type mined in Michigan and Minnesota accounted for 99% of total crude ore production. U.S. production of pellets totaled almost 57 Mmt, 97% of usable ore output. The average iron content of usable ore produced was 63.4%.

The iron ore industry of the United States and Canada had finally begun to untangle itself from the web of financial problems created by the collapse of steel demand in 1985 and 1986. This collapse accelerated the reduction of U.S.

steelmaking capacity, which started in 1978, and triggered a major restructuring of the iron ore and steel industries on both sides of the border. Since 1986, the two industries have introduced major changes aimed at lowering operating costs and improving competitiveness.

The first phase of the restructuring of the iron ore industry occurred in the summer of 1986, when the industry was experiencing one of its worst years since the Great Depression. However, some of the organizational changes introduced then were still being implemented in 1990. The second phase of the restructuring took place in the summer of 1989, and mainly affected Canadian mines. This second phase culminated with the transfer of the Quebec Cartier Mining Co. from USX Corp. to a partnership formed between Dofasco Inc., Cia. Auxiliar de Empresas de Mineracao (CAEMI), and Mitsui & Co. Ltd. (See "Canada.")

LTV Corp., Wheeling-Pittsburgh Steel Corp., and Sharon Steel Corp. were all forced to file for bankruptcy at the time of the 1986 collapse, but continue to operate under the protection of chapter 11 of the Federal Bankruptcy Code. The bankruptcy problems of the three integrated steel producers immediately spilled over into the iron ore industry, which had been under direct control of United States and Canadian steel companies for decades. The Reserve Mining Co., a 50-50 joint venture between Armco Inc. and LTV, was forced to suspend production in July 1986 and was eventually sold by the bankruptcy court to Cyprus Minerals Co. in August 1989. The mining partners of the bankrupt steel companies have continued, for the most part, to ship pellets to the three companies' blast furnaces and have relied patiently on the courts and lengthy legal negotiations to resolve their financial claims. Several claims were settled in 1989, pending court approval.

In April 1989, Cleveland-Cliffs Inc. (CCI) tentatively settled its bankruptcy claims against LTV Steel Co. Inc., the steelmaking group of LTV Corp. CCI brought suit after LTV Steel rejected its Tilden Mine obligations, related purchase contracts, and a royalty agreement at its LTV Steel Mining Co. subsidiary. Under terms of the settlement, CCI received an unsecured claim of \$205 million for damages. CCI also assumed an additional 10% interest in the adjoining Empire Mine from LTV on January 1, 1990. The

equity transfer left each company with a 25% interest in Empire, which had the capacity to produce 8.1 Mmt per year of fluxed pellets. Other partners in the mine were Inland Steel Co. (40%) and Wheeling-Pittsburgh (10%). CCI also had the right to supply 75% of any future iron ore requirements of LTV above its existing equity interests as long as CCI's prices were competitive. The terms of the settlement were approved by the U.S. Bankruptcy Court for the Southern District of New York on August 17, 1989. As part of the settlement, LTV agreed to reject its 12% interest in the Tilden Mining Co. However, the claims of several major creditor groups were still to be resolved.

A large part of CCI's claims against Wheeling-Pittsburgh were settled earlier in September 1988. As part of the 1988 settlement, Wheeling-Pittsburgh assumed its 10% interest in the Empire Mining Partnership on January 1, 1989, but surrendered its 4% interest in the Tilden Mining Co. In exchange, CCI was allowed an unsecured claim of \$100 million for damages resulting from the steel producer's rejection of its Tilden obligations. Wabush Mines of Labrador and Quebec was allowed a similar claim of \$59 million, but two lesser claims by Wabush were being disputed. An exchange of equities in Wabush was proposed toward the end of 1989, but a number of details were still under negotiation. LTV and Wheeling-Pittsburgh had interests in Wabush of 15.6% and 10.2%, respectively.

Minnesota

Minnesota produced 70% of the national output of usable ore in 1989. Production of pellets totaled 40.76 Mmt, equivalent to about 72% of installed production capacity of the State's six active taconite plants. Utilization of active pelletizing capacity by the six, though, was 91%. The remainder of the output consisted of hematite concentrates produced by LTV Steel from natural ores. A seventh taconite plant, the E.W. Davis Works at Silver Bay, was being refurbished by Cyprus.

National Steel Pellet Co. (NSPC) produced 4.76 Mmt of standard acid pellets at its Keewatin complex in 1989.¹ The pellets averaged 65.10% iron (Fe), 4.92% silica (SiO₂), and 0.010% phosphorus (P) on a wet basis. The complex, situated at the southwestern end of the

Mesabi Range, operated at full capacity for most of the year. About 70% of the production was railed on the Burlington Northern to the Allouez Terminal at Superior, WI, and later loaded onto vessels for delivery to the Great Lakes steelworks of National Steel Corp. (NSC) in Detroit. The remaining 30% was hauled in 160-car unit trains to NSC's smaller steelworks at Granite City, IL.

NSPC was a wholly owned subsidiary of NSC. NSC was controlled in turn by NKK Corp., the second largest steel producer in Japan. In May 1990, NKK increased its equity in NSC from 50% to 70% and took steps to acquire an additional 20% from its partner, National Intergroup Inc.

All of LTV Steel's natural ore production came from its McKinley Extension Mine, 4 kilometers (km) north of Aurora. The mine, operated by LTV Steel's Northwest Ore Div. under a lease from USX, shipped 592,000 metric tons (mt) of beneficiated sinter fines and 20,000 mt of 1- by 4-inch coarse ore in 1989.² The lump ore was being added by LTV Steel and outside customers to their electric arc furnaces to assist in the oxidation of impurities and to serve as a coolant. Excessive capacity and large stocks of pellets continued to be a problem for LTV Steel Mining. In January 1989, LTV Steel Mining laid off 92 hourly employees at its Hoyt Lakes operation, 32 km east of the city of Virginia. In recent years, normal seasonal layoffs in response to the end of the shipping season had been about 64 employees, but the company laid off more employees than usual in anticipation of projected cutbacks in production later in the year.

On November 5, LTV Steel Mining laid off one-third of the 1,400 hourly and salaried employees at Hoyt Lakes for 2 weeks. During the 2-week period, production was cut back about 50% to trim pellet stocks. According to mine officials, the temporary cutback was part of a broader action taken by the parent company, LTV Steel, to reduce excessive inventories in its production system. During the fourth quarter of 1989 and the first quarter of 1990, the domestic steel industry experienced a modest drop-off in orders, especially from manufacturers of automobiles and appliances. LTV was a major supplier of finished steel to both consuming industries.

The Hoyt Lakes operation had a rated annual capacity of 8.1 Mmt of standard

acid pellets and shipped 7.68 Mmt in 1989. The design capacity of the mining complex, though, was 11 Mmt per year.

In January 1990, representatives of LTV Steel Mining met with Minnesota Pollution Control Agency (MPCA) officials to discuss ways of improving the quality of surface waters in the vicinity of the Dunka pit. The Dunka pit, 6 km east of Babbitt at the northeastern tip of the Mesabi Range, was one of six pits supplying crude taconite to the Hoyt Lakes plant. In early 1989, environmental monitoring teams discovered that rain and melted snow percolating through 4.9 square kilometers (km^2) (1,200 acres) of stockpiled waste rock were picking up excessive amounts of cobalt, nickel, and zinc. The three metals apparently were being leached from minor sulfides that had begun to oxidize in some of the stockpiles.

LTV Steel Mining has been closely monitoring seepage from the Dunka stockpiles as part of a 1986 agreement with the State. Water samples taken from the Bob Bay area of Birch Lake, 800 meters (m) northeast of the pit, also had elevated levels of the three metals. Partly because of the elevated levels in Bob Bay, the MPCA issued a notice of violation to the company, charging that the seepage exceeded water quality standards. Citizen groups were concerned because the 31- km^2 (7,600-acre) lake drained into the environmentally sensitive Boundary Waters Canoe Area Wilderness. The situation was further complicated because there were at least five inactive copper-nickel workings on the southeastern side of the string-bean-shaped pit. The old workings are in an area where the Biwabik Iron Formation has been metamorphosed and truncated by gabbros of the younger Duluth Complex. LTV Steel Mining submitted a preliminary plan to deal with the seepage problem in the fall of 1989 and was taking steps to change the configuration of some of the stockpiles.

The Hibbing Taconite Co. (Hibtac) produced 8.24 Mmt of acid pellets, falling somewhat short of the record 8.79 Mmt set in 1988.³ The pelletizing plant, which was expanded in 1979 to 8.2 Mmt, had an effective capacity of 9.0 Mmt at the end of 1989. Hibtac's biggest customer was Bethlehem Steel Corp., which owned 70.3% of the joint venture. The remaining equity was divided between CCI (15.0%), which managed the

complex, and Stelco Inc. (14.7%). In December, Hibtac began developing a new mining area southwest of its existing section 36 pit. The new area was to encompass parts of the former Mahoning natural ore pit, worked by Pickands Mather & Co. from 1923 to 1973.

Minntac, the largest iron mine in the United States, produced 9.9 Mmt of fluxed pellets and 2.3 Mmt of standard acid pellets.⁴ The output from the complex at Mountain Iron matched the 12.2 Mmt produced in 1988, but fell far short of its installed capacity of almost 19 Mmt. Minntac was owned and operated by the USS steel segment of USX, the largest integrated steel producer in the country.

The bulk of the beneficiation facilities at Mountain Iron were switched from acid to fluxed pellet production in July 1988 at a cost of more than \$8 million. A number of improvements were made to the concentrator at that time, including the installation of a flotation circuit to reduce silica levels in the new fluxed pellet. Refinements were made to the circuit in 1989 that raised the iron content of the new pellet while further reducing its silica. The limestone-dolomite fluxed pellet produced during the 1989 campaign contained 62.22% Fe, 3.96% SiO_2 , and 0.0147% P on a wet basis. For comparison, the acid pellet produced in 1986 averaged 5.40% SiO_2 . The 50-50 blend of limestone and dolomite was being shipped from Michigan to Duluth in self-unloaders and then transferred to Duluth Missabe and Iron Range Railway Co. (DM&IR) ore cars that would normally return empty to the pelletizing plant.

An additional 2-Mmt-per-year pelletizing line, idle since 1982, was started up in August 1989 to meet increased demand for fluxed pellets from the company's blast furnaces at Gary, IN, and Braddock, PA. Both fluxed and acid pellets were shipped to the company's integrated steelworks at Lorain, OH, which was placed in mid-1989 under the operational control of a joint partnership with Kobe Steel Ltd. Limited amounts of acid pellets also went to the Weirton Steel Corp. in West Virginia. About 1.44 Mmt of pellets was railed to Geneva Steel's works at Orem, UT, as part of a 5-year contract signed in 1987.

The output of Eveleth Mines grew for the fourth consecutive year and was the highest since 1981. The joint venture produced 5.03 Mmt of partially fluxed

pellets, 17% more than in 1988. The magnetite concentrate from the taconite was mixed with Peridur and a 1% limestone additive to make a pellet averaging 64.56% Fe, 4.97% SiO_2 , 0.016% P, and 0.67% lime (CaO) on a wet basis. Eveleth was managed and partly owned by the Oglebay Norton Co., which had an 18.5% equity in the venture. The remaining equity was divided between Armco Inc. (35.1%), the Rouge Steel Co. (31.7%) and Stelco (14.7%). In June 1988, Eveleth reactivated the second of two pelletizing lines at its Fairlane plant, 11 km south of the city of Eveleth. This older line, which had been idle since July 1982, gave Fairlane a total effective capacity of 6.2 Mmt per year. At yearend, Eveleth employed about 670 hourly and 130 salaried personnel.

In late 1987, Oglebay Norton filed an environmental assessment plan with the Minnesota Department of Natural Resources seeking approval to expand the north pit of the Thunderbird Mine toward the city of Virginia. Under the long-term plan, Eveleth would expand the pit by 400 acres and create three new stockpiles. One of these stockpiles would be in the old Rouchleau pit on the southeastern edge of the city of Virginia.

More than two-thirds of the 15.8 Mmt of crude taconite mined in 1989 came from the north pit. The south pit provided about 3.5 Mmt, with the remainder coming from the new Spruce Hill reserve. Stripping of the Spruce Hill reserve began in 1986, but mining did not actually start until November 1988. The highway between Leonidas and West Eveleth had to be relocated because of the Spruce Hill Project. The reserve is near the old Spruce Mine on the northwestern edge of the south Thunderbird pit.

In the spring of 1989, Inland Steel Mining Co. obtained the rights to mine a large taconite reserve in the central part of the Mesabi Range. The new property, the Biwabik-West Taconite reserve, was near the city of Gilbert, about 10 km southeast of Inland's Minorca mining and pelletizing complex. Shortly after acquisition, company officials drafted a plan calling for immediate development of the property. The ores would be used to supplant Minorca's dwindling reserves and would be recovered using the same surface mining techniques employed elsewhere on the range. The new pit would be known as the Laurentian Mine because of its proximity to the Laurentian Divide.

In late November, the board of directors of Inland Steel Industries Inc. formally approved development of the Laurentian Project. Inland Steel Mining, a wholly owned subsidiary of the Inland Steel Co., expected to spend \$20 million on the mine, which would provide iron units for the parent company's integrated steelworks at Indiana Harbor, IN. The Laurentian ore would be trucked 10 km to Inland's existing beneficiation plant on the northeastern edge of the city of Virginia. Minorca produced a record high 2.50 Mmt of fluxed pellets in 1989 and was still operating at almost full capacity. If the present rate of production were maintained, the existing pit at Minorca could be exhausted as early as 1992. The new ore body would provide the plant with more than 15 years of reserves. Inland also hoped to negotiate leases on adjoining properties that could supply an additional 25 years of reserves.

The current plan calls for the Laurentian ore to be blended with Minorca ore beginning in 1991. Blending would extend the life of the Minorca pit until 1995, when mining would be shifted entirely to the new ore body. A dedicated haul road would be constructed from the pelletizing plant through the Pike River Basin to the proposed mine site. Inland planned to build a series of berms to reduce nuisance noise from the operation. Overburden and waste rock would be used to construct a 12-m high sound barrier along the section of haul road that would border Gilbert. The company was experimenting with several new methods of blasting designed to minimize ground shock to homeowners.

The Laurentian Project would be the first entirely new taconite mine to come on-line in Minnesota in more than a decade. However, environmental permits still had to be obtained from the U.S. Army Corps of Engineers, the Minnesota Department of Natural Resources, the Minnesota Pollution Control Agency, and three local governments. The required environmental impact statement was released in final form in August 1990. Inland also considered mining two other sites, the Ordean Reserve west of Minorca and the East Rouchleau pit on the outskirts of Virginia, but temporarily shelved both of these projects.

In August 1988, the Governor of Minnesota met in Denver with Cyprus executives to explore new ways of reopening Reserve's mining complex at the extreme

northeastern end of the Mesabi Range. At that time, CCI and Northfield Mining Inc. also expressed an interest in acquiring or managing the defunct operation. Reserve's principal assets consisted of the Peter Mitchell Mine near Babbitt and the E.W. Davis pelletizing plant 65 km to the southeast at Silver Bay. State officials had become increasingly concerned because key machinery at both sites had begun to deteriorate from the harsh Minnesota winters and lack of maintenance. The bankruptcy trustee had also sold half of the flotation cells in the concentrator to pay expenses. Potential buyers were discouraged by several additional obstacles, including liabilities for the sprawling Milepost 7 tailings basin and the questionable viability of the reactivated operation if demand for pellets dropped back to 1986 levels. In short, the chances of finding a suitable buyer were diminishing daily.

The Denver talks led to the drawing up of a maintenance agreement between the State, Cyprus, and the bankruptcy trustee in October 1988. Under the terms of the agreement, Cyprus began stabilizing the situation at the two sites, but was not obligated to buy the operation.

By the spring of 1989, the outlook for Babbitt and Silver Bay had improved considerably. On April 21, Cyprus tentatively agreed to pay \$40 million in cash for the bankrupt company's assets. The acquisition agreement was filed with the U.S. Bankruptcy Court for the Southern District of New York, and a hearing was scheduled for June 12. CCI and Northfield were given until June 5 to better the offer from Cyprus. On June 5, CCI bid \$44.5 million. On the day of the hearing, both companies increased their bids substantially. Although CCI's final bid was \$54 million, the bankruptcy judge awarded Reserve's assets to Cyprus for \$52 million, after weighing recommendations from Reserve's bondholders, the trustee, and the State of Minnesota. According to a spokesperson for the State of Minnesota, one of the principal reasons for the judge's ruling in favor of Cyprus was that Cyprus had sufficient cash on hand, while CCI did not. Another reason was that Cyprus had already negotiated agreements with the Mesabi Trust Co. (which held the mineral rights to the Peter Mitchell Mine) and some other involved parties. The sale to Cyprus was expected to provide Reserve's bondholders with \$45 million after expenses.

The final details of the sale and bankruptcy settlement were completed on August 25, 1989. The operation was renamed Cyprus Northshore Mining Corp. The sale included the company railroad that runs from the mine to Silver Bay. The environmentally sensitive Milepost 7 tailings basin was leased to Cyprus by the bankruptcy trustee for a minimum of 5 years. Cyprus was expecting to spend at least an additional \$30 million refurbishing the mining complex and improving pellet quality to meet current industry standards. New equipment was to allow Cyprus to produce fluxed pellets and use different organic binders in place of the traditional bentonite.

After settlement, Cyprus moved quickly to reopen both the mine and plant. The coal-fired electric generating station at Silver Bay, which provided power for the processing facilities, was restarted on November 16. Drilling was resumed that same week at the mine. Contracts, totaling more than \$5 million, were let to upgrade the pelletizing plant and the Milepost 7 tailing disposal system. The installation of a hearth layer for the two largest pelletizing furnaces and related retrofitting alone cost \$2.6 million. The hearth layer work on the two 1964-vintage furnaces was completed on December 20. Four of the six smaller furnaces installed when the processing plant was commissioned in 1955 may be upgraded at a later date.

On December 27, Cyprus formally reopened the mine at Babbitt. The Governor of Minnesota attended the ceremonies and was given the honor of detonating the first blast since the 1986 closure. The Chief Executive was one of the individuals instrumental in convincing Cyprus to acquire the idled complex. On January 5, 1990, 150-car unit trains began hauling crushed ore on the 76-km long railroad extending from Babbitt to the concentrator at Silver Bay.⁵ Reserve removed so much overburden at the mine between 1979 and 1983 that mining can be carried out for 10 to 14 years with little or no additional stripping.

Cyprus was planning to produce 1.7 Mmt of standard acid pellets in 1990 and started shipping after the Soo Locks opened in late March. Armco Inc. had agreed to buy 1.5 Mmt per year for the next 7 years. If all goes well, the Northshore operation could be producing 4.0 Mmt per year by 1994. On January 12, 1990, a fire broke out in the pelletizing

plant and completely destroyed two electrostatic dust collectors. No one was injured, but the fire caused an estimated \$1 million damage to the fluid ionics section of the plant. Startup of the No. 12 furnace, which was to have begun on January 15, was delayed about 2 weeks. The No. 11 furnace was not brought on-line until mid-March.

At the time of the fire, Cyprus had 88 employees at Babbitt and 238 at Silver Bay. About 90% of those hired between June 1989 and March 1990 were former employees of Reserve and had an average age of more than 50. Additional details on the startup of Cyprus Northshore are given in reference 5.

Michigan

Michigan produced about 26% of the national output of usable ore in 1989. More than 98% of the production consisted of pellets produced from ores mined at the Empire and Tilden Mines near Ishpeming in Marquette County. Both mining ventures were managed and partially owned by CCI's Cleveland Cliffs Iron subsidiary. The company's wholly owned Republic Mine remained idle throughout the year. Production of pellets totaled 15.41 Mmt, of which 8.24 Mmt was produced at the Empire plant and 7.17 Mmt was produced at Tilden.⁶ The Empire plant operated beyond its rated capacity, setting a new production record and surging past the 95% mark reached in 1987 when it made 7.75 Mmt of pellets. The output of the Tilden plant was up 4% from that of 1988, despite delays associated with the startup of the new magnetite operation.

From 1982 to 1987, Tilden was used as a swing producer because it had higher operating costs than Empire. The economics of the Tilden operation was hobbled by the mineralogy of the taconite. The ores of fine-grained martite and common hematite were much more difficult to beneficiate than the magnetite-rich varieties of taconite found elsewhere in the Lake Superior District. In March 1988, Tilden's three solvent partners—the Algoma Steel Corp. Ltd., CCI, and Stelco Inc.—decided to make the mining complex more competitive by upgrading the Tilden concentrator so that it could process both magnetite and hematite. The magnetite-rich taconite would come from the Cliffs Drive III ore body at Schoolhouse Lake, about 1 km north of the existing pit. Conversion of the pelletizing

plant would cost \$7.5 million; development of the new pit, about \$6 million. An additional \$15 million was required to buy new equipment and upgrade existing facilities. In November 1988, CCI and its two Canadian partners decided to completely underwrite the \$30 million project with equity funds instead of using outside sources for funding and ordered Tilden's engineering staff to immediately begin modifying the concentrator. Preproduction stripping at the new pit, which had already begun in July 1988, was accelerated. Equity interests in the new Tilden Magnetite Partnership were divided as follows: Algoma, 50%; CCI, 33.3%; and Stelco, 16.7%.

The beneficiation part of the refurbished plant had been scheduled to begin producing magnetite in early August 1989, but startup had to be postponed 2 weeks because of engineering problems with the 54 new magnetic cobbles. Development of the ore body also took longer than anticipated. Despite these problems, the converted operation reached 88% of designed concentrating capacity in December 1989 and, by yearend, had produced 1.8 Mmt of the new pellets. An additional \$1.7 million had been set aside for eliminating production bottlenecks, perfecting the beneficiation process, and improving pellet quality. As a result of the capital improvements, Tilden was able to make both magnetite and hematite pellets in either standard or fluxed grades. The operation became more flexible and cost competitive, but had to sacrifice capacity, at least for 1989 and 1990. Tilden was currently able to produce 4.1 Mmt per year of magnetite pellets, but only 2.7 Mmt of hematite pellets. Hematite pellet capacity could be quickly raised to 4.1 Mmt with additional capital expenditures if pellet demand in North America improved dramatically.

The Republic Mine in the western half of Marquette County was shut down in October 1981 at the beginning of the 1982-84 recession and has been maintained since then in a standby status. On June 27, 1989, CCI formally appealed the 1989 tax assessment on the inactive mining and pelletizing complex to the Michigan Tax Tribunal. In Michigan, mining companies are required to pay a specific ore tax to the local township in lieu of property taxes. In this case, the ore tax was determined and paid to the township of Republic. CCI claimed that the specific

ore tax should have been only \$206,000, instead of the \$527,000 billed by the township. Republic Township quickly filed a response to the company's appeal. At the end of the year, both sides were still waiting for the tribunal to set a prehearing date. The outcome of the appeal was important to the mining communities of the Upper Peninsula because CCI is challenging the way in which the specific ore tax was computed. A ruling in the township's favor could lead to increased ore taxes on the much larger Empire and Tilden Mines. Six of the thirteen local units of government agreed to pay part of the legal fees incurred by Republic Township.

CCI's appeal disputed two items used to compute the ore tax on the Republic Mine: (1) the township's use of a published price to determine the value of Michigan ore, and (2) the rated capacity of the idled pelletizing plant. The company claimed that fundamental changes in the North American iron ore market, such as the increased number of spot sales, had made the published price inaccurate and that the lower prevailing market price should have been used instead. Because the Republic Mine was inactive, its rated capacity was used in the tax formula in place of a 5-year average of production. When the mining complex was shut down in 1981, the pelletizing plant had two lines and was able to produce 2.7 Mmt per year of pellets averaging 63.3% Fe on a wet basis. This was the figure that the township supervisor used in his 1989 tax determination. CCI, though, moved some of its equipment to other mines several years ago and argued that Republic had only one operational pelletizing line at the end of 1988, limiting production to 1.3 Mmt per year.

Later in the summer, CCI announced that it would not reopen Republic in 1990, as had been rumored. The company decided not to make any decision about the idled complex until corporate staff could better define near-term production costs and evaluate adverse forecasts put forth by some industry analysts. At the time of the 1981 shutdown, Republic was owned by the Marquette Iron Mining Partnership, a joint venture between Jones and Laughlin Steel Corp. (which later became part of LTV Steel), Cleveland-Cliffs Iron, Wheeling-Pittsburgh, and the International Harvester Co. CCI acquired full ownership of Republic after the other

three filed for chapter 11 bankruptcy protection.

At the beginning of 1989, the M.A. Hanna Co. donated 22.81 km² (5,637 acres) of mining properties in the Menominee Range to the State of Michigan. The land was part of the former Groveland Mine, 21 km northeast of Iron Mountain and 6 km east of Randville. About one-fourth of the land was covered by tailings ponds and other impoundments. An additional 8.90 km² (2,200 acres) that included the old pit was acquired in late December by a real estate company based in the Bahamas. Between 1959 and 1962, the Groveland operation produced 2 Mmt of concentrates from a jasper-type ore. In 1963, Hanna built a 2-Mmt-per-year pelletizing plant at Groveland to process a 60% magnetite-40% hematite blend made from ore averaging 35% Fe.⁷ The plant operated until December 1982, supplying a pellet that contained 63.1% Fe and 6.95% Si. The Michigan Natural Resources Commission incorporated the land into the Copper Country State Forest, making future development of the remaining 100 Mmt of taconite less likely.

Missouri

The Pea Ridge Iron Ore Co. operated the smallest of the 10 active mining and pelletizing complexes in the United States. The Pea Ridge Mine is on the northeast flank of the Ozark uplift in Washington County near Sullivan, MO. The operation produced slightly more than 1 Mmt of iron ore products in 1989 and was the only active underground iron mine in the country. More than 90% of the production consisted of olivine-enriched pellets made from magnetite concentrate containing 70% Fe and less than 1% SiO₂. The addition of 5% olivine increased the reducibility of the pellet while improving its high-temperature properties in the blast furnace and increasing its resistance to low-temperature breakdown. The complex also produced heavy-medium magnetite for coal cleaning, as well as a variety of iron oxides for ferrites, pigments, and ceramic magnets.

During the first quarter of 1990, Pea Ridge received increased attention because of the uniqueness of the deposit and the novel steps taken by the engineering staff to solve problems shared by the entire North American iron ore industry. After a decade of work, the company had

made significant progress in lowering the phosphorus content of the magnetite concentrate used as pellet feed. The phosphorus came from apatite and several rare-earth minerals that form inclusions in the fine-grained massive magnetite. Control of phosphorus is critical in the making of quality steels. The ideal situation is to keep the phosphorus level as low as possible in the pellets, coke, and fluxes so that even minor amounts of the element cannot accompany the iron into the steel. In 1979, pellets from Pea Ridge averaged 0.080% P. At that time, the ore feeding the concentrator typically ran 0.60% P. Since then, the company has been able to gradually reduce the pellet phosphorus content to 0.020%.⁸

The improved liberation of phosphate minerals was achieved by installing additional magnetic separators between 1981 and 1985 and by switching over to a larger and more sophisticated flotation circuit. The new phosphate flotation circuit became fully operational in September 1988. Amine, fatty-acid, and fatty-alcohol collectors all were tried and eventually discarded. A suite of proprietary collectors developed specifically for Pea Ridge concentrates was being used in 1990. Preliminary tests suggested that the pellet phosphorus content could be reduced even further to 0.015% by finer grinding.

In April 1988, the Missouri Division of Geology and Land Survey (DGLS) entered into a cooperative agreement with Pea Ridge to map in detail selected levels of the mine. The U.S. Geological Survey (USGS) agreed to provide financial and technical support for the underground mapping project. The Pea Ridge Project had been incorporated into DGLS' larger "Operation Basement" study, which also involved surface mapping of exposed Precambrian rocks in the St. Francois Mountains. Preliminary data indicate that many similarities exist between the basement rocks of southern Missouri and those of South Australia, especially in terms of age, composition, and apparent origin. The striking resemblance between the two basements excited exploration geologists because South Australia is the host for the world-class Olympic Dam deposit discovered in 1975. The Olympic Dam ore body averages 1.6% copper and 0.06% uranium oxide (U₃O₈) and also contains economically significant amounts of gold, silver, and rare earths.

Some geologists speculated that Pea Ridge could be an outlier of a much larger Olympic Dam-type deposit. To help test the Olympic Dam model, Cominco American Inc. drilled two holes on the undeveloped Boss-Bixby Precambrian copper-iron deposit. Like Pea Ridge, Boss-Bixby was discovered in the 1950's by drilling a prominent magnetic anomaly. This second Precambrian deposit was in Dent County, about 65 km southwest of Pea Ridge, and bordered on the western edge of the Viburnum Trend. The Viburnum Trend was the largest lead producing district in the United States in 1989. Cominco was planning to drill into Boss-Bixby from new underground workings in its neighboring lead mine.

DGLS and USGS were extremely interested in mapping the Pea Ridge Mine because it was one of only a few sites in the midcontinent region where geologists could examine the buried Precambrian basement in three dimensions. Pea Ridge is referred to as a "blind" ore body because none of it is exposed at the ground surface. The dike-like mass of magnetite is covered by 400 m of relatively flat-lying, barren sedimentary rocks and extends almost vertically from the unconformity to an unknown depth greater than 1,000 m. The deepest working and development levels were at 754 m and 815 m, respectively, in mid-1990. The underground mapping project has already revealed that the deposit is far more complex than originally thought in terms of both structure and mineralization. The volcanic host rocks consist of at least four different types of brecciated rhyolite porphyries, which are believed to be remnants of a Precambrian collapse caldera.⁹ Veins and carbonate pods exist that are rich in monazite, allanite (a cerium-yttrium epidote), and at least five other rare-earth minerals. The Rolla Research Center of the Bureau of Mines was working with the company to determine if it would be economically feasible to recover the rare earths as a byproduct of the iron ore operations.

New York

On November 23, 1989, NL Chemicals Inc. shut down its magnetite concentrating operation at Tahawus in Essex County, NY. The company and its predecessor, NL Industries Inc., had been producing heavy-medium quality concentrate from crude magnetite stockpiled at the MacIntyre Mine. There had been no

mining at the site since 1982. The bulk of the concentrate was being railed to eastern coal mines for coal washing.

The MacIntyre Mine was opened by the National Lead Co., the grandparent of NL Chemicals, in July 1942 to provide ilmenite (FeTiO_3) for the titanium dioxide (TiO_2) pigment industry. At the time, the ilmenite was desperately needed to replace supplies of beach sands from India, which had been cut off at the beginning of World War II. Crude magnetite was recovered as a byproduct of the ilmenite operation. During the 40-year period, National Lead recovered 12 Mmt of ilmenite and 18 Mmt of magnetite from 60 Mmt of crude ore.¹⁰ The ilmenite was shipped to National Lead's TiO_2 plants in Sayreville, NJ, and St. Louis, MO. National Lead dominated the titanium pigment market for many years, accounting for as much as 60% of the country's output of TiO_2 , but lost ground when its sulfate process became uncompetitive with the newer, more economical chloride process. Officials of NL Chemicals estimated that 31 Mmt of ilmenite and 21 Mmt of magnetite remain in the deposit.

The MacIntyre and other ore bodies in the Sanford Lake District are part of a large Precambrian anorthosite massif that forms the central part of the Adirondack Mountains. The ore bodies of ilmenite and vanadiferous-titaniferous magnetite occur as massive lenses in the anorthosite or as bands in gabbro associated with the anorthosite. Iron mining in the district dates back to 1832, when a forge was built near Sanford Lake by a group of entrepreneurs led by Archibald McIntyre.

NL Chemicals was to maintain an active presence at the mine and had initiated a voluntary reclamation program going beyond requirements set by the New York State Department of Environmental Conservation. The company kept its State mining permit in force, continued to ship concentrate from existing stockpiles, and planned to sell crushed stone to contractors. In August 1989, NL Chemicals acquired a 72-year lease on the 53-km long railroad line extending from the mine to the trunk line of the Delaware & Hudson Railway at North Creek. The lease was obtained at a public auction from the General Services Administration for \$950,000. The branch line was built by the Federal Government between 1942 and 1944 to eliminate truck haulage of the concentrates. At the end of 1989, the company deeded the branch

line to the Essex County Industrial Development Agency (IDA), but subleased it back for 5 years. The purchase and subsequent subleasing agreement prevented the rail line from being torn up for scrap and gave NL Industries an option to reopen the mine in the distant future. Deeding the rail line to the county reduced carrying costs because the IDA is a tax exempt organization. The rail line was critical to future mine development because of Tahawus' isolated location.

Other States

Geneva Steel of Utah continued to expand production at its open pit mines in the Iron Springs District of Iron County. The district, 24 km west of Cedar City, has provided magnetite and hematite ores for blast furnaces in the Rocky Mountain region on an intermittent basis since 1923. Coarse ore and fines were shipped 370 km on the Union Pacific Railroad to Geneva's integrated steelworks at Provo. The ore was hauled twice a week in 75-car unit trains. The 100-ton railcars were originally built to carry pellets from USX's former Atlantic City Mine in Wyoming to Geneva. The actual mining was contracted out to the Gilbert Development Corp. Run-of-mine ore averaging 55.1% Fe, 6.7% SiO_2 , and 0.27% P was crushed and screened at the Comstock-Mountain Lion Mine, two adjoining properties leased by Geneva from CF&I Steel Corp. of Pueblo, CO. Gilbert Development also produced wet screened and magnetically cobbled material from old stockpiles of lean ore at the former Iron Mountain Mine, 8 km to the southwest. Mining was also underway at the new Excelsior and Chesapeake, two smaller ore bodies on the northeastern edge of Iron Mountain. The Excelsior and Chesapeake material was averaging 58.7% Fe, 5.2% SiO_2 , and 0.30% P on a wet basis. A total of 776,000 mt was shipped from the district in 1989.¹¹ More than 50% of the material consisted of fines, which could not be charged directly into Geneva's three blast furnaces and had to be sintered.

In South Dakota, Pete Lien & Sons Inc. mined low-grade hematite at the CF&I pit near Nemo in Lawrence County. The mine was reopened in 1988 after a hiatus of 9 years. The company produced direct-shipping ore averaging 32.0% Fe. Production was limited by the relative remoteness of the Black Hills mine site from consumers. The bulk of the ore was shipped to the Dakota cement

plant operated at Rapid City by the State Cement Commission.

CONSUMPTION AND USES

Consumption of iron ore rose less than 2% owing to a leveling off of demand from the iron and steel industry. Consumption for ironmaking and steelmaking totaled 73.55 Mmt, including 65.60 Mmt in blast furnaces, 7.12 Mmt in sintering plants, 0.49 Mmt for production of direct-reduced iron (DRI), and 0.34 Mmt in steelmaking furnaces. An additional 10,000 mt was used by the industry for miscellaneous and unspecified purposes. Monthly consumption of pellets, direct-shipping ore, and merchant sinter by the industry averaged 6.09 Mmt, compared with 5.99 Mmt in 1988. Reported consumption of iron ore for manufacture of cement, heavy-medium materials, animal feed, ballast, ferrites, pigments, and other nonsteel products was 1.21 Mmt.

The near-term outlook for the iron and steel industry had improved considerably since the 1986 collapse. U.S. production of hot metal and pig iron totaled 50.69 Mmt in 1989, only a fraction more than in 1988, but still the largest tonnage since 1981. Hot metal and pig iron production was extremely stable throughout the year, averaging 4,224 mt per month. The deviation from the mean was never more than 10% for any one month. Monthly iron ore consumption statistics reflected this stability, which developed after overall demand for steel mill products had strengthened in the fall of 1987.

Consumption of pellets, direct-shipping ore, and merchant sinter for the first 6 months was 38.45 Mmt, a 9% increase from the same period in 1988. The situation reversed in the second half of the year, with blast furnace output dropping below corresponding 1988 levels. During 1989, the number of blast furnaces in operation ranged from 48 to 52. At year-end, 48 of the 83 blast furnaces available were on-line. The monthly blast furnace data show how pig iron production has stabilized since 1986, when the number of furnaces operating dropped from 50 to 31 over a 7-month period. The industry continued to dismantle obsolete furnaces and improve active furnace utilization. Twenty-nine blast furnaces had been scrapped since December 1983.

Consumption of iron ore and all types of agglomerates reported to the AISI by integrated producers of iron and steel

totalled 78.75 Mmt. This included 61.74 Mmt of pellets; 13.66 Mmt of sinter, briquettes, etc; and 3.35 Mmt of natural coarse ore. Of the primary ore consumed, 73% was of domestic origin, 10% came from Canada, and 17% came from other countries. Other materials consumed in sintering plants included mill scale, flue dust, limestone and dolomite, slag and slag scrap, and coke breeze. Other iron-bearing materials charged to blast furnaces included steel-furnace slag, mill scale, and slag scrap.

STOCKS

Stocks of iron ore and agglomerates reported at U.S. mines, docks, and consuming plants have been gradually dropping for more than 30 years. This trend temporarily reversed itself in 1988, but continued downward in 1989. At yearend, total industry stocks were 21.70 Mmt, only 3% more than the record low set in 1987. The renewed decline was caused primarily by a cutback in domestic ore stocks at furnace yards. As a result of the cutback, furnace yard stocks stood at only 15.73 Mmt, a 61% drop from the 39.93 Mmt reported at yearend 1978. Combined stocks at furnace yards and receiving docks included 13.03 Mmt of domestic ores, 2.45 Mmt of Canadian ores, and 2.43 Mmt of other foreign ores. Mine stocks at yearend were 29% more than those of 1988 because of unusually cold weather in November and the early shutdown of loading ports on the Upper Great Lakes in mid-December.

End-of-month stocks reported at mines peaked at 12.12 Mmt in March and continuously declined to 4.11 Mmt in November. Stocks of ore at consuming plants were 180° out of phase with those at the mines, ranging from a low of 9.31 Mmt in April to a high of 15.73 Mmt in December. As in previous years, these variations were principally caused by the seasonal nature of ore shipping on the Great Lakes.

Stocks of unagglomerated concentrates reported at pelletizing plants totaled 0.56 Mmt at yearend and ranged in Fe content from 55% to 70%. This material is not included in mine stocks of usable ore reported in the accompanying tables because it is considered an intermediate product. Stocks of byproduct ore also have been excluded since 1983 from the

mine stock data to avoid disclosing company proprietary information.

TRANSPORTATION

Vessel shipments of iron ore from U.S. ports on the Upper Great Lakes totaled 51.04 Mmt, about 3% less than those of 1988. Nearly 90% was destined for U.S. consumers, with the rest going to Canada. Shipments of iron ore through the St. Lawrence Seaway to U.S. ports on the Great Lakes totaled 4.88 Mmt and accounted for almost 25% of U.S. imports. The balance of imports, 14.71 Mmt, was shipped primarily through ports on the east and gulf coasts.

Ore shipments from three of the seven U.S. ports on the Upper Great Lakes decreased from the levels of 1988, with the largest decrease at Two Harbors, MN. Tonnage shipped from each port in 1989 is shown in the text table.

a record-breaking cold spell in mid-December. Early ice formation in the St. Marys River forced the Corps of Engineers to close the locks at Sault Ste. Marie, MI, on December 28, 2 weeks ahead of schedule. The early closing of the locks left 1.5 Mmt of pellets undelivered at Lake Superior loading docks.

No iron ore shipments were made from the dock at Silver Bay in 1989. However, coal was unloaded for the reopened powerplant beginning in October. The number of vessel shipments from the other six ports totaled 1,506, indicating an average cargo of 33,890 mt. Individual cargoes of 60,000 mt or more were loaded at five of the ports during the year, although the average shipment from individual ports ranged from 23,679 mt at Marquette to 46,421 mt at Taconite Harbor, MN.

On September 25, The Interlake Steamship Co. and other lake carriers raised freight rates between 6% and 13% to offset increased labor costs and

Port	Date of first shipment	Date of last shipment	Total tonnage (thousand metric tons)
Duluth, MN	Apr. 1	Dec. 19	7,408
Two Harbors, MN	Mar. 14	Dec. 25	9,503
Silver Bay, MN ¹	—	—	—
Taconite Harbor, MN	Mar. 26	Dec. 19	8,217
Superior, WI	Mar. 25	Dec. 22	11,052
Marquette, MI	Mar. 24	Jan. 2	9,117
Escanaba, MI	Mar. 23	Jan. 19	5,742
Total ²			51,038

¹No pellets have been shipped since Nov. 1987. However, Cyprus Minerals Co. acquired all of the facilities of the defunct Reserve Mining Co. in Aug. 1989 and was in the process of refurbishing the beneficiating and pelletizing complex at Silver Bay. The port was reopened in Oct. 1989 so that coal could be delivered to the complex's idled electric generating station. The generating station was restarted on Nov. 16.

²Covers the 1989 navigation season, which extended from Mar. 14, 1989, to Jan. 19, 1990.

Source: Lake Carriers' Association, 1989 Annual Report.

The decline in overall shipments was primarily the result of adverse winter weather. At the end of October, cumulative shipments were slightly ahead of those of 1988. However, an inordinate number of storms delayed sailings in November. The storms were followed by

shipyard expenses. The shipping industry continued to give discounts on class X vessels (i.e., vessels with hulls greater than 1,000 feet in length), but the discounts were less generous than in the past. The different rates are compared in the text table.

From	To	Dollars per long ton ¹			
		Oct. 13, 1988		Sept. 25, 1989

Published bulk vessel freight rates from the Gulf of St. Lawrence to Lake Erie and Lake Michigan were \$5.00 and \$7.00 per ton, respectively. Freight rates for self-unloading vessels were \$1.50 per ton higher.

The two principal issues concerning U.S. lake shipping in 1989 continued to be the proposed construction of a second Poe-class lock at Sault Ste. Marie and the question of sharing domestic lake and coastal trade with Canadian vessels.¹² The latter issue was rejuvenated in 1987 during negotiation of the United States-Canada Free-Trade Agreement (FTA), causing both the Reagan and Bush Administrations to review the justifications for existing cabotage laws. Title I of the Merchant Marine Act of 1936 mandates that all domestic waterborne commerce be conducted in vessels that are built in, owned by, and crewed by the United States. The Government of Canada wanted these cabotage restrictions waived as part of the FTA. In exchange, U.S. vessels would have been allowed to carry cargo between Canadian ports. Because of the complexity of the cabotage issue, United States and Canadian negotiators agreed to exclude the controversial section dealing with maritime services from the final trade agreement. However, the cabotage issue could be resurrected at any time during the annual review process. United States and Canadian iron ore shipments on the Great Lakes for 1985-89 are compared in the text table.

vessels were in actual operation in 1989. However, these 65 represented 97.7% of available carrying capacity.

Construction of a second Poe-sized lock at Sault Ste. Marie continued to be stymied by funding problems.¹³ The new lock was desperately needed as a backup to prevent total paralysis of bulk shipping on Lake Superior should the Poe be shut down for more than 30 days. The new lock would also be needed to accommodate the growing number of class X vessels projected for the 21st century.¹⁴ The Water Resources Development Act of 1986 (Public Law 99-662) authorized construction of the new lock, but required 35% of the funding to come from non-Federal sources. New estimates made by the Corps of Engineers in October 1989 indicate that the lock will cost \$256 million.

The Soo Lock Funding Alternatives Task Force formed by the Great Lakes Commission has recommended that the lock be built at full Federal expense. The task force concluded that the cost-sharing provision should be waived because of the uniqueness and international nature of the project. The 101st Congress was considering legislation that could end the funding impasse.

All-rail shipments of iron ore and agglomerates in the United States and Canada totaled 9.48 Mmt, compared with 7.14 Mmt in 1988. This was the highest tonnage ever reported for the two countries, breaking the record just set in

amounted to 2.31 Mmt, substantially more than the 1.32 Mmt hauled in 1988.¹⁵ Shipments from USX's Minntac Mine at Mountain Iron to the reactivated Geneva works in Utah accounted for 1.44 Mmt, or 63% of the all-rail total. An additional 169,000 mt of Minntac pellets was railed to USX's Edgar Thomson steelworks at Braddock, PA. About 696,000 mt of Eveleth pellets went to USX's Fairfield works near Birmingham, AL, on a trial basis. Shipments of pellets and small quantities of natural ore to the Ports of Duluth and Two Harbors totaled 17.15 Mmt for a total ore movement on the railway of 19.42 Mmt during the 1989-90 shipping season. More than 1 Mmt of pellets was also hauled all rail via the Burlington Northern to NSC's two blast furnaces at Granite City, IL.

Published railway freight rates for pellets from mines to upper lake shipping ports were unchanged in Minnesota in 1989. The volume rate for pellets from the western Mesabi Range to the Allouez docks at Superior remained at \$5.01 per long ton. In the third quarter of 1989, the rate for pellets from the Marquette Range of Michigan to Presque Isle was raised from \$2.15 per long ton to \$2.35. The rate to Escanaba remained at \$3.03. Escanaba also had a handling charge of 3.5 cents per long ton since 1980.

Rail rates from lower lake ports to a number of consuming points were raised between 4% and 12% on January 16, 1989. Most ore transfer charges were unchanged. At Lake Erie ports, ore transfer charges from rail-of-vessel or dock-receiving areas direct into railway cars ranged from \$1.00 to \$1.20 per long ton. Key rail rates for 1986-89 are compared in the text table.

Published nominal ocean freight rates for iron ore from eastern Canada to U.S. mid-Atlantic ports were \$3.50 to \$3.75 per deadweight ton (dwt) of cargo, but some spot rates quoted for cargoes of 60,000 to 110,000 dwt were as low as \$2.75 per dwt.

Loading district	United States and Canadian ore shipments on the Great Lakes (thousand metric tons)

¹As a result of the Staggers Rail Act of 1980, which partially deregulated the railroads, it has become difficult to obtain accurate freight rate data. Published tariff rates are only suggested rates and may be significantly higher than the actual contract rates.

²Quotation discontinued.

Sources: Cleveland-Cliffs Inc., Minnesota Mining Directory, and Skillings' Mining Review.

grades of Lake Superior pellets. A long ton unit (ltu) is equivalent to 0.01 long ton, or 22.4 pounds. The quotation included delivery to rail-of-vessel at lower lake ports. The Eveleth special grade of Oglebay Norton was listed slightly higher at 74.00 cents per ltu. Mineral Services Inc. continued to quote its lower price of 58.00 cents per ltu set in August 1985. At that time, Pickands Mather and Inland abandoned the traditional lower lake pricing base and began quoting 59.40 cents per ltu for pellets delivered to hold of vessel at upper lake ports. At yearend 1987, Inland dropped the price of its Minorca pellets to 46.84 cents per ltu, but Pickands Mather refused to follow. The 59.40 and 46.84 quotations were still in effect at the end of 1989. USX also decided to retain its 1987-88 quotation. The price for Minntac acid pellets was left at 37.344 cents per dry ltu of iron, delivered into railcars at the Minnesota mine. This price equated to about \$23.83 per long ton of undried pellets containing 63.82% Fe and 2.51% moisture. The range of all of the above prices was approximately equivalent to \$34.50 to \$46.37 per long ton of pellets containing 64% Fe, delivered rail of vessel at lower lake ports.

Prices for most Canadian and other foreign ores marketed in the United States are normally not published. The one exception was CCI's quotation for Wabush pellets, which remained at 63.5 cents per ltu f.o.b. Pointe Noire, Quebec. The average f.o.b. value of all Canadian ores and agglomerates imported by the United States, as determined from data compiled by the Bureau of the Census, was \$34.30 per metric ton (mt). This value was slightly higher than the average

Canadian pellet value of \$33.37 because Canada also sold limited quantities of high valued, specially processed concentrates to the U.S. chemical industry. Other average f.o.b. values compiled under the new harmonized tariff system are compared in the text table.

steel industry. Virtually all exports consisted of pellets and concentrates shipped via the Great Lakes to Canadian steel companies that are partners in U.S. taconite projects in Minnesota and Michigan. Consumption of iron ore at Canadian blast furnaces totaled 13.98 Mmt,

Type of product	Country of origin	Average unit value (dollars per metric ton)

Fine ores	Brazil	16.50
Do.	Canada	35.03
Do.	Mauritania	17.04
Do.	Venezuela	23.64
Pellets	Brazil	28.21
Do.	Canada	33.37
Do.	Peru	24.64
Do.	Venezuela	29.25

Source: Bureau of the Census.

Published f.o.b. prices for DRI were also unchanged from those quoted in 1988, and were as follows, per mt: at Georgetown, SC, \$125 to \$135; at Contrecoeur, Quebec, \$115; and at Point Lisas, Trinidad and Tobago, \$120. In 1989, the customs value of DRI imported from Venezuela ranged from \$114 to \$118 per mt.

FOREIGN TRADE

U.S. exports of iron ore were slightly higher than those of 1988 because of improved demand from the Canadian

almost 6% more than that of 1988. U.S. material accounted for 5.44 Mmt, or 39% of the blast furnace total. An additional 147,000 mt of U.S. material was consumed at Canadian sintering plants.

U.S. imports of iron ore dipped slightly to 19.60 Mmt, despite the pickup in blast furnace activity. Total tonnage for 1989 was 12% greater than the mean of the previous 5 years, 17.51 Mmt, and was equivalent to about 26% of ore consumption. Sharp drops of imports into the Baltimore and Philadelphia customs districts (22% and 21%, respectively) offset small increases at lower lake and gulf ports. Canadian ores accounted for 44% of total U.S. imports; however, since 1982,

Canada has had to struggle to maintain its share of the increasingly competitive U.S. market. In 1989, Canada's share slipped to 11%, the lowest level in more than 10 years. Brazil, the second largest supplier, increased its share slightly to 6.9% from 6.7% in 1988. Venezuela was close behind with a 5.7% share and was more competitive in 1989 because it had a transfer vessel anchored at the mouth of the Orinoco River.

As a result of the Omnibus Trade and Competitiveness Act of 1988, much more detail became available on iron ore entering the United States after January 1, 1989. The eight new classification categories and their accompanying HTSUS numbers are listed in the text table.

HTSUS No.	Description
OXIDES	
2601.11.0030	Concentrates.
2601.11.0060	Coarse ores.
2601.11.0090	Fine ores.
2601.12.0030	Pellets.
2601.12.0060	Briquettes.
2601.12.0090	Sinter and other agglomerates.
SULFIDES	
2502.00.0000	Unroasted pyrites.
2601.20.0000	Roasted pyrites.
PRIMARY CHEMICALS	
2827.33.0000	Iron chlorides.
2833.29.2000	Iron sulfates.

WORLD REVIEW

At least 47 countries mined iron ore during the year, producing a total of 922 Mmt. The U.S.S.R. was the largest producer, with an output of about 172 Mmt of concentrate or direct-shipping ore plus 67.0 Mmt of pellets. Soviet production accounted for about 24% of the world's marketable output in terms of metal content. World production of pig iron, which directly reflects ore consumption, increased slightly to 539 Mmt.

The world ore trade was estimated at 424 Mmt, of which about 87% was oceanborne.¹⁶ Brazil, the leading exporter, shipped 113.7 Mmt to world markets in 1989, an increase of 8%. The top three customers of the Latin American giant were the European Community

(EC), Japan, and the Republic of Korea. Australian shipments, in second place, rose from 98.2 to 107.6 Mmt, primarily because of increased imports by Japanese steelmakers who produced 80.2 Mmt of hot metal in their blast furnaces. Australian exports to Europe stood at 21.09 Mmt (on a dry weight basis) and were down slightly from the record 22.19 Mmt of 1988. The recently expanded EC received a total of 140.3 Mmt of ore and agglomerates, again edging out Japan as the world's principal importer. Japanese imports increased 4% from 123.4 Mmt to 127.7 Mmt.

World production of pellets was estimated at 233 Mmt, about 91% of rated capacity. Preliminary data suggest that pelletizing plant output was only slightly higher than the 227.8 Mmt reported for 1988. Most plants in Brazil, Canada, Sweden, and the U.S.S.R. were operating close to capacity. Producers in India, Peru, and the United States began re-opening facilities idled in the wake of the 1981 downturn. More and more customers asked plant managers to switch to self-fluxed or olivine-base pellets. Dolomite-limestone fluxed pellets continued to be made in record amounts in Australia, Canada, Japan, and the United States.

World output of DRI was estimated by Midrex Corp. at 15.94 Mmt, about 63% of installed capacity.¹⁷ The low utilization rate was owing more to startup delays at new plants and other technical problems than to market factors. A breakdown by country is given in the "Iron and Steel" chapter. At eight gas-based plants, production actually exceeded rated capacity. Hot-briquetted iron (HBI), an enhanced form of DRI, was in considerable demand throughout 1989. Merchant DRI remained in direct competition with high-quality home scrap (i.e., scrap internally generated within the steelworks). The long-term outlook for DRI was favorable because of the rapid dropoff in the generation of home scrap since the advent of continuous casting. Efficiency improvements at rolling mills had made the home scrap dropoff even more pronounced.

The first of two Midrex modules was started up at the new Misurata plant in Libya. New units were also brought on-line in India and the Republic of South Africa, raising global DRI capacity from 24.39 Mmt to 25.11 Mmt. The improved utilization of existing gas-based facilities

in Indonesia, Mexico, and Venezuela was largely responsible for the 13% increase in world DRI production between 1988 and 1989. About 47% of the total output for 1989 was produced in Latin America. The four-module, 1.67-Mmt-per-year Soviet complex at Stary Oskol was operating at 102% of rated capacity and accounted for an additional 11% of the 15.94 Mmt.

In the past, iron ore exporters normally completed their annual price negotiations in Europe before fixing prices in Japan. The tradition arose because European contracts are based on the calendar year, while Japanese contracts are on an April-to-March fiscal year. However, for the third consecutive year, Japanese ore buyers completed key price negotiations before their European counterparts.

For the fifth year in a row, excess stocks of sinter fines overshadowed the negotiations. Ore producers, though, were determined to win price hikes and end the discouraging price descent that had plagued them for 7 years. Formal negotiations between Cia. Vale do Rio Doce (CVRD) and purchasing agents of the West German steel industry began on November 21, 1988, but stalled when CVRD insisted on a 20% price hike. Japanese steelmakers, realizing that some form of price hikes was inevitable, quickly settled with Hamersley Iron Pty. Ltd. on December 14, 1988. Hamersley, the largest producer in Australia, won price hikes of 13.0% for fines and 17.3% for lump. The speedy Hamersley accord forced CVRD to settle for similar price increases from Rohstoffhandel GmbH and Erzkontor Ruhr GmbH, breaking the impasse in Europe. The two agreements set the tone for all of the other negotiations. By the end of the negotiation period, every major producer had won price hikes ranging from 12.2% to 27.8%. As in past years, premiums were paid on pellets and lump. Prices negotiated under Japanese contracts for fiscal year 1989 were reported as shown in the text table (f.o.b., in U.S. cents per dry ton of iron).

On an f.o.b. (shipping port) basis, most 1989 prices apparently ranged from about \$9.25 to \$21.60 per dry metric ton (dmt) for fines, \$16.95 to \$21.70 per dmt for lump, and \$26.35 to \$35.70 per dmt for pellets. Delivered prices (at receiving port) were about \$2 to \$15 higher, depending on ocean freight costs. Seaborne trade in iron ore was at its highest level in more

than 8 years.¹⁸ The high shipping level was brought on by the continuing worldwide upswing in pig iron production. World production of pig iron was estimated to be 539 Mmt, an alltime high, with blast furnaces in the market economy countries operating at rates not seen since the peak year of 1979. The increase in iron ore trade came at a time when shipments of coking coal, grain, and several other major dry bulk commodities were also elevated. Shipowners were both delighted and wary because the increase came on the heels of 2 years of strong growth. Ocean freight rates for iron ore resumed their upward climb during the second half of 1988. Rates plateaued in the spring of 1989, dropped somewhat during the summer, but bounced back again in the fall. The recovery in freight rates helped make short-haul suppliers like Sweden and Mauritania more competitive. Published

rates for spot charterings to the EC from Western Australia ranged from \$7.90 to \$12.50 per dwt for cargoes of 120,000 to 140,000 dwt, compared with \$6.75 to \$9.70 in 1988. The 1989 rate ranges for other shipments to the EC are shown in the text table.

Rates for cargoes of 120,000 to 150,000 dwt to Japan from Western Australia ranged from \$4.85 to \$6.75. Higher rates applied to Port Latta in Tasmania because it cannot accommodate vessels greater than 95,000 dwt and is farther from Japan. Rates to Japan from the

Brazilian port of Tubarão for cargoes of similar size were \$11.65 to \$14.75.

Capacity

Integrated iron ore operations have become extremely complex and resemble medium-sized towns in some cases. The production capacity of an operation of this magnitude is determined by equipment limitations at several stages of recovery. To simplify analysis and make comparisons of individual mines easier, data were collected that represent the rated or design capacity at three key points in the recovery process: crusher-screen output, concentrator output, and furnace output. These three points were chosen because they serve to readily separate the mining, beneficiating, and agglomerating stages of the operation. At the first two points, the iron ore is already in a marketable form and can be diverted for sale or tolling if bottlenecks occur either downstream at the operation or upstream at competitors' facilities.

Changes in the economics of the process could also make diversion feasible. Table 18 shows world pelletizing capability at the close of 1989. The data represent the rated capacities of 82 plants in 26 countries. Five of the plants were near or part of integrated steelworks and had no captive iron mines. A sixth, the natural-gas-based merchant operation in Bahrain, was also dependent on imported feed. A significant part of the data was collected by the International Iron and Steel Institute in 1987. The table excludes plants that have not produced since 1982. Four of these idled plants are identified in the table footnotes because they could be reactivated in some realistic scenarios. Table 18 also excludes all of the world sintering plants. Similar tables were being developed by the Bureau of Mines that list world crude ore production capability and world concentrating capability.

Australia

The Australian iron ore industry produced 108.7 Mmt of marketable material in 1989, breaking its previous record of 105.3 Mmt set in 1987. The major producers were trying to operate at full capacity to meet growing world demand for lump ore, but were hampered by labor disputes and work stoppages. Pellet production increased slightly to 3.6 Mmt. There were two pellet producers:

Savage River Mines Ltd. and a subsidiary of the Broken Hill Pty. Co. Ltd. (BHP), the BHP Steel International Group. Shipments of ore and pellets reported by individual companies were as follows, in Mmt: Hamersley Iron Pty. Ltd., 49.91; Mount Newman Mining Co. Pty. Ltd., 27.01; Robe River Iron Associates, 22.34; Goldsworthy Mining Ltd. (GML), 6.20 (dry); BHP-Yampi Sound, 3.50; BHP-Middleback Ranges, 2.62; and Savage River Mines Ltd., 2.29. Exports of ore and pellets rose 10% between 1988 and 1989 because of increased sales to China, Japan, the Republic of Korea, and Taiwan. Exports totaled 108.1 Mmt, with 53% of the tonnage going to Japan.

In May 1989, Hamersley, Mount Newman, and Robe River concluded negotiations on a second generation of long-term contracts with the Japanese steel industry. The new contracts required annual price negotiations and were much shorter in duration than in the past—extending for only 7 years instead of 15 to 30 years. The base annual tonnage specified by the contracts was equivalent to about 30% of Australian capacity.

Hamersley, the largest iron mining company in Australia, reported record shipments and earnings in 1989. Shipments were 22% more than those of 1988 and consisted of 29.55 Mmt of sinter fines (–6 millimeters [mm]) and 20.33 Mmt of lump ore (–30 + 6 mm). The hematite ore came from two open pit mining complexes in the Pilbara region of Western Australia. Together, the two mines, Mount Tom Price and Paraburdoo, had an installed annual capacity of 46 Mmt of marketable product. The productivity of the entire Hamersley operation jumped dramatically following the reorganization of the company in 1987. Hamersley was a wholly owned subsidiary of CRA Ltd. and had more than 3,700 employees in Western Australia.

Development of the Channar Mine, 20 km east of Paraburdoo, was well underway with production scheduled to begin in January 1990 at the rate of 3 Mmt per year.¹⁹ The mine was to be managed by Hamersley, with all of the output going initially to integrated steelworks in China under long-term contracts. The operation was a joint venture between CRA (60% equity) and China Metallurgical Import & Export Corp. (40%). Channar consists

of five ore bodies having combined proven reserves of 290 Mmt averaging 63.0% Fe and 0.006% P. The 64 East and Channar ore bodies were being developed first. The ore was to be crushed on-site and then transported 20 km by overland conveyor to Hamersley's neighboring Paraburdoo Mine. The overland conveyor consisted of two flights, each approximately 10 km long. The first flight was built in a curve to avoid adverse topography between the mine and the midpoint transfer station. At Paraburdoo, the ore was to be run through the existing tertiary crusher, screened, and then blended with Paraburdoo material. From Paraburdoo, the ore blend was to be railed to Hamersley's porthead at Dampier on the Indian Ocean.

Mount Newman, the second largest iron ore operation in Australia, moved to increase production after a series of work stoppages in late 1988. The managing partners, led by BHP Minerals Ltd., were involved in lengthy labor negotiations with the unions. The negotiations were expected to lead to significant changes in work practices. If adopted, these changes could improve productivity by as much as 20%.

By mid-1989, development of Orebody 25 (Ferro Gully) was well underway, and production from Orebody 29 (Marra Mamba) had significantly increased. However, on August 30, part of the south wall of the Mount Whaleback pit collapsed.²⁰ The collapse severely hampered the company's efforts to increase production because it isolated a large deposit of high-grade ore and cut Mount Whaleback's production rate by one-third. The collapse was attributed to the oxidation of pyrite in a black shale unit that weakened the entire section. No one was injured, but rock bolts had to be installed to prevent further slippage. New haul roads also had to be constructed and substantial amounts of overburden removed. Mount Newman engineers began increasing production from the central and western ore bodies to compensate for the lost output from the eastern ore body. The pit was eventually redesigned with the 20 Mmt-per-year in-pit crusher being relocated further east.

Robe River's shipments rose dramatically between 1988 and 1989 because of increased sales to Kawasaki Steel Corp. Kawasaki raised its purchases from about 750,000 mt to 2,500,000 mt after Mount Newman was forced to limit deliveries.

Robe River was in the midst of a major expansion and was scheduled to expand capacity to more than 25 Mmt per year by 1992. The company's stockpiling, ship-loading, and rail terminal facilities are at Cape Lambert at the eastern end of the Dampier Archipelago. The railroad from the East Deepdale Mine to Port Walcott and Cape Lambert was being upgraded to handle 200-car unit trains capable of hauling 15,000 to 20,000 mt of ore. The ore stockyards and loading facilities at Cape Lambert were also being modernized. The port modernization will increase Robe River's loading capability from 110,000 mt per day to 150,000 mt per day.

During the first quarter of 1989, Goldsworthy commissioned its new 3.0-Mmt-per-year beneficiation plant at Port Hedland. The plant was using jigs and spirals to recover the concentrate by gravity separation. BHP-Utah Minerals International, the minor partner in Mount Goldsworthy Mining Associates, was considering buying out CFG-Iron Holdings Pty. Ltd. (a 100% subsidiary of Hanson PLC. and Consolidated Gold Fields PLC). The purchase of Hanson's 70% would allow BHP to integrate the Goldsworthy operation into BHP's Mount Newman venture and consolidate the Finucane Island and Nelson Point loading facilities in Port Hedland.

In South Australia, the Long Products Division of BHP began developing a new area in the South Middleback Ranges.²¹ The new area encompassed three separate deposits: the Iron Duke, the Iron Duchess, and the Iron Knight. The three deposits would supply high-grade ore to BHP's Whyalla steelworks over the next 25 years and would replace depleted reserves at BHP's Iron Baron Mine. The \$50 million project was being managed by Baulderstone Hornibrook Group, with Kinhill Engineers Pty. Ltd. responsible for design of the ore-handling plant. The new Iron Duke pit was turned over to BHP in September 1989. The existing rail line was being extended, together with powerlines and a water pipeline, from the Iron Baron Mine to the new area. The ore-handling plant and railroad were to be jointly commissioned in February 1990.

Pickands Mather & Co. International and its five Japanese partners were in the process of restructuring the ownership and operation of Savage River Mines. Under the restructuring, Pickands

Mather would acquire all of the other interests on October 1, 1990. At the same time, capacity would be drastically cut back from 2.5 Mmt to 1.3 Mmt. The Tasmanian mining and pelletizing complex, in operation since 1986, had been experiencing financial difficulties. Savage River had been scheduled to close in September 1990, but the restructuring would extend the life of the complex to 1995.

Canada

The Canadian iron ore industry was in the midst of a major restructuring. Six mining complexes operated during the year, but the two smallest, Adams and Sherman, were permanently closed on March 31, 1990. Both MacLeod and Mount Wright had new owners by the end of 1989. The solvent partners of the complexes at Carol Lake and Wabush were discussing how to adjust equities to compensate for the defaults of Wheeling-Pittsburgh and LTV.

Most of the industry operated near capacity throughout 1989, despite these changes. The supply and demand picture was almost identical to that of 1988. The six complexes shipped a total of 40.9 Mmt of iron ore products on a wet basis.²² Production was estimated to be 40.6 Mmt, about 81% of active capacity. Canadian iron and steel plants consumed 15.5 Mmt of ore and agglomerates, about 4% more than the tonnage reported for 1988. Preliminary data indicated that exports were about 30.2 Mmt on a wet basis, down slightly from the previous year. The main market for Canadian ore continued to be Western Europe. In 1988, Canada's three largest customers were the EC (53.9%), the United States (33.4%), and Japan (7.2%). Pellets made up 57.6% of the tonnage exported that year; concentrates, 42.4%.

The Iron Ore Co. of Canada (IOC) shipped 15.14 Mmt of iron ore products from its docks at Sept-Iles, Quebec. The total included 8.11 Mmt of standard acid pellets (including 391,000 mt of pellet chips), 1.73 Mmt of fluxed pellets, 5.13 Mmt of concentrates, and 177,000 mt of Schefferville red ore. All of the material, except the red ore, was produced at the company's Carol Lake complex in Labrador. The beneficiating part of the Carol Lake operation is designed to produce 10 Mmt per year of concentrate for direct sale and 10 Mmt per year of pellet feed. The agglomerating part of the operation set a new production record of

10.72 Mmt, despite some loss in capacity owing to the production of fluxed pellets. The two Carol Lake pelletizing plants have a total of six traveling-grate furnaces with a combined design capacity of 10.5 Mmt per year. Furnace operating rates were at an alltime high, while fuel oil consumption rates were at the lowest levels on record. The shipment of red ore exhausted the stockpile of blended Schefferville ores that had been maintained at the Sept-Iles yards since 1983. IOC closed its Knob Lake mines near Schefferville at the nadir of the 1982-84 recession because of declining demand in the United States for direct-shipping ores and problems in developing a viable market for a Schefferville sinter feed.

Quebec Cartier Mining Co. (QCM) was the largest producer in North America in 1989, edging out IOC by less than 1 Mmt. QCM shipped 7.95 Mmt of concentrate, 6.58 Mmt of acid pellets, and 1.59 Mmt of fluxed pellets from its terminal at Port Cartier. All of the marketable concentrate and pellet feed came from the company's Mount Wright mining complex near Fermont. The Mount Wright ore had been averaging 32.1% Fe and was typically a fine-grained specularite with less than 5% magnetite. Proven in situ reserves exceed 2.5 billion tons. In 1989, the beneficiating plant at Mount Wright processed about 16.5 Mmt of concentrate containing 64.0% Fe and 4.7% SiO₂. The concentrate was being shipped 415 km on the company-owned Cartier Railway to Port Cartier in unit trains of about 19,000 mt.

For the third year in a row, the Port Cartier pelletizing plant operated above the 8.0 Mmt level, far exceeding its original design capacity of 6.0 Mmt per year. In late 1989, the company purchased 10 new pelletizing disks that effectively raised the plant's capacity to 8.4 Mmt per year. The Port Cartier plant, completed in 1979, had two traveling grate furnaces with a combined design output of 7.50 Mmt per year. The older of the two furnaces, which started up in November 1977, was set up to produce low-silica pellets for direct reduction plants. Concentrate for the low-silica line was routed through an upgrading plant employing wet high-intensity magnetic separators. Both fluxed and acid varieties have been produced. The low-silica fluxed pellet, introduced in 1986, had been averaging 66.08% Fe, 0.020% P, and 2.27% SiO₂ on a dry basis.²³ The SiO₂ content of the

low-silica acid pellet tended to be slightly lower and, in past years, ranged from 2.15% to 2.30% SiO₂ on a dry basis. As in 1988, most of the low-silica pellets went to the DRI plants of Sidbec-Dosco Inc. at Contrecoeur, Quebec, and Georgetown Steel Corp. at Georgetown, SC. It is important to point out that less than 15% of the 1989 production run was devoted to low-silica pellets. The bulk of Port Cartier's output was standard acid pellets averaging 64.56% Fe, 0.009% P, and 4.74% SiO₂ on a wet basis.

Since August 1989, QCM has been owned by Dofasco Inc. (50% equity), Mitsui & Co. Ltd. of Japan (25%), and Companhia Auxiliadora de Empresas de Mineracao (CAEMI) of Brazil (25%). Dofasco, the largest integrated steel producer in Canada, was to take 2 Mmt of fluxed pellets annually from the Port Cartier plant under a long-term contract that took effect in March 1990. The fluxed pellets were being shipped 1,500 km up the St. Lawrence Seaway to Dofasco's four blast furnaces at Hamilton, Ontario. The takeover of QCM allowed Dofasco to replace fluxed pellets from its Adams and Sherman Mines with less expensive ones from Port Cartier and still satisfy Hamilton's requirements. The two smaller mines, near Kirkland Lake in northern Ontario, were closed as scheduled following the changeover. Dofasco had been buying pellets from QCM on the open market for several years, making extensive blast furnace trials unnecessary.

The sale of QCM was a somewhat complicated affair. On March 31, 1989, Dofasco purchased 25% of the outstanding shares of QCM from USX Holdings Inc. The USX unit then signed a letter of intent to sell the remaining 75% of its equity in the mining operation to Elder Resources North America, a subsidiary of an Australian investment group. However, Dofasco decided to exercise its right of first refusal and purchased the other 75% of QCM from USX on June 30. The Canadian steelmaker acquired control of the Cartier Railway Co. and U.S. Steel Canada Inc. as part of the agreement. USX reportedly sold QCM as part of its asset redeployment program.

Mitsui and CAEMI were invited to become partners to help increase sales of QCM ore outside North America. The two accepted Dofasco's offer and bought 50% of QCM on July 31. Both companies were prominent in the international iron ore industry. Mitsui was a major

Japanese trading company with direct or indirect ownership interests in iron mines in Australia and Brazil. Mitsui was the largest importer of iron ore into Japan in 1989 and was responsible for about 22% of the tonnage delivered to the Japanese steel industry. CAEMI was a Brazilian industrial group whose main interests were in mining and metallurgy. The Brazilian company was set up in 1950 to run the Serra do Navio manganese mine of Industria e Comercio de Minerios S.A. (ICOMI) in the Federal Territory of Amapa, but had since diversified into iron mining and the transportation of bulk materials. CAEMI owned 70% of Minerações Brasileiras Reunidas S.A. (MBR), the second largest iron ore producer in Brazil, and had an international network of sales agents that marketed both iron and manganese ores.

Wabush Mines shipped 6.20 Mmt of pellets, approaching the record of 6.32 Mmt set in 1984. The company's beneficiating and agglomerating complex at Pointe Noire, Quebec, exceeded its rated capacity of 6.1 Mmt by 2%. Three types of pellets were made—comparable acid and fluxed pellets containing no more than 1% manganese (Mn) and an acid grade containing 2% Mn.

All of the pellet feed for Pointe Noire came from the Scully Mine in southwestern Labrador, which had been in operation since 1965. The mine and concentrator are near the town of Wabush at the southern end of the Labrador Trough. Over 50 years of reserves averaging 35.2% Fe remain, and less than 60% of the ore body had been stripped. The principal ore mineral is a friable, specular hematite that occurs in a highly folded, Lake Superior-type banded iron formation of Early Proterozoic age. The specularite is frequently associated with manganese in the form of pyrolusite or psilomelane.

Blending of the high- and low-manganese iron ores was required to ensure a constant ore grade for the concentrator. Humphrey spirals were used to make an initial concentrate, which was then fed to high-tension electromagnetic separators for further upgrading. Two types of concentrate were created by the blending process. One ran 66.45% Fe, 2.50% SiO₂, and 1.05% Mn; the other, 65.30% Fe, 2.54% SiO₂, and 2.04% Mn. At the beginning of 1989, Dofasco, Stelco, and the four other active partners in Wabush agreed to upgrade operations.

A new stacker was commissioned at the Pointe Noire yards in mid-1989, and new equipment was ordered to reduce stack emissions from the pelletizing plant. A computerized truck dispatch system was installed at the Scully, and two new 170-short ton production trucks were purchased for the pit.

At yearend, the active partners were evaluating a proposal that would restructure ownership interests and resolve problems created by the bankruptcy filings of LTV and Wheeling-Pittsburgh. The bankruptcy claims against LTV for defaulting on the Wabush venture were excluded from the LTV settlement agreement approved in August 1989. LTV notified the partnership that it no longer wished to participate in the venture and put its 15.6% interest up for sale. The solvent partners had rights of first refusal under the existing project agreement. Wheeling-Pittsburgh's shares in the partnership were being held temporarily by CCI with approval of the bankruptcy court.

Algoma's integrated steelworks at Sault Ste. Marie, Ontario, consumed more than 4 Mmt of iron ore products in 1989. Receipts included about 2.4 Mmt of Tilden pellets brought across Lake Superior from Marquette, MI, and 1.23 Mmt of superfluxed sinter railed down the northeastern shore of the lake from Wawa.

The Algoma Ore Division at Wawa had been shipping sinter to Sault Ste. Marie since 1939. The bulk of the iron units for the sinter came from siderite mined at the George W. MacLeod Mine, an open stope and pillar operation in the Michipicoten Range, a complex assemblage of Precambrian volcanic and sedimentary rocks. Approximately 313,000 mt of purchased roll scale, 180,000 mt of Michigan limestone, 70,000 mt of iron oxide wastes from Sault Ste. Marie, and 50,000 mt of petroleum coke were mixed with the siderite to make the 1.23 Mmt of superfluxed sinter. The final product averaged 48.4% Fe and 7.7 SiO₂.

In August 1989, Algoma announced that it was halting all underground development work at the MacLeod.²⁴ The phaseout was to have been completed by April 1990. The halt affected 44 of the 350 employees in the Ore Division. Despite significant improvements in productivity, the siderite operation had been struggling to remain competitive. The mining and sintering of siderite, as

practiced at Wawa, was more costly than taconite mining and pelletizing, which was better suited to economies of scale. The mine was left with approximately 9 Mmt of usable reserves, which will permit Algoma to continue mining siderite until mid-1992.

During 1990 and 1991, Algoma will conduct cost studies to determine if it is feasible to substitute recyclable iron-rich waste materials from steelworks in the Great Lakes region for a significant part of the siderite. These waste materials could come from Sault Ste. Marie, Dofasco's steelworks at Hamilton, or a number of U.S. operations. The increased use of mill scale and other steelmaking wastes could have at least two advantages. First, the steelmaking wastes would raise the iron content of the sinter while diluting the silica. Second, the wastes would reduce environmental pollution control costs, both at Wawa and the originating steelworks. The sintering plant, which was commissioned in 1966, was already under orders from the Ontario Ministry of the Environment to reduce sulphur dioxide emissions. The wastes would lower the sulphur content of the sinter feed, reducing sulphur dioxide levels proportionately. If successful, the recycling project could extend the life of the MacLeod Mine beyond 2002.

As mentioned earlier, Dofasco closed the Adams Mine at Kirkland Lake and the Sherman Mine at Temagami on March 31, 1990. Factors that reportedly led to Dofasco's decision were as follows: difficult mining conditions, declining ore grades, high rail transportation costs to Dofasco's blast furnaces at Hamilton, and the small size of the two operations relative to other North American iron mines. Both mines were managed by Cliffs of Canada Ltd., a subsidiary of CCI, and had been in a highly unfavorable cost position since 1985. The Adams Mine began production in 1963 and was owned by Jones & Laughlin (now part of LTV Steel) until 1971. The Sherman Mine began production in 1968 and was 90% owned by Dofasco, with the remaining 10% controlled by Tetapaga Mining Co. Ltd., a second Canadian subsidiary of CCI. Each mining complex had an annual capacity of 1.1 Mmt per year and about 315 employees. Dofasco and CCI developed a compensation and benefit program to alleviate the effect of the shutdown on the two mining communities. The program consisted of a \$4 million

fund for regional development and a 3-year continuation of mine realty taxes totaling \$3.8 million.

Both Ontario complexes operated continuously throughout 1989, although actual mining was suspended for a few weeks during the summer. The Adams produced 1.14 Mmt of fluxed pellets averaging 60.92% Fe and 5.30% SiO₂ on a wet basis.²⁵ The Sherman joint venture had a slightly lower output of 1.03 Mmt, but the chemical specifications of its pellets were almost identical to those from the Adams. The two pelletizing plants continued to produce at full capacity until closure.

Chile

Cia. Minera del Pacifico S.A. (CMP) produced 8.44 Mmt of pellets and ore in 1989, setting a new record for the restructured company.²⁶ Dramatic increases in production at both the El Romeral and El Laco Mines more than offset a 3% drop in output at the Huasco pelletizing plant. The Huasco plant operated close to full capacity, making 3.48 Mmt of self-fluxing pellets for blast furnaces and 0.25 Mmt of pellets for DRI plants. The 4.0-Mmt-per-year facility also generated 396,000 mt of special pellet feed and 121,000 mt of pellet chips. As in past years, the bulk of the preconcentrate feed for Huasco came from the beneficiation plant at the El Algarrobo Mines, about 85 km by rail to the southeast. The Algarrobo plant, which employs a dry magnetic separation process, made 4.60 Mmt of preconcentrates averaging about 60% Fe from 6.04 Mmt of crude ore. After the preconcentrate reached Huasco, it was ground finer and put through a wet magnetic separator to raise the iron content to 68% and drop the phosphorus content below 0.05%. The Huasco concentrator can process up to 5.5 Mmt per year of preconcentrate and had more than enough capacity to satisfy the single grate kiln unit. CMP was planning to increase the capacity of the pelletizing plant to 5.0 Mmt per year and reopen the Los Colorados Mine to meet the plant's increased requirements for preconcentrate.

Production of direct-shipment ore at El Romeral totaled 4.05 Mmt, 46% more than in 1988. The tonnage consisted of 2.08 Mmt of sinter fines averaging 65.2% Fe on a dry basis and 1.97 Mmt of lump ore. In December 1988, work began at El Romeral on the construction of a \$15 million grinding and concentrating plant

with a capacity of 1.2 Mmt of ore per year. The new plant would supplement the existing wet magnetic concentrator, which could process up to 4 Mmt of ore per year. The new concentrator was scheduled to start up in mid-1990 and was to make pellet feed from ores that would have been rejected in the past because of their high-phosphorus content.

El Laco, CMP's new magnetite operation in the High Andes, produced 80,000 mt of lump ore and 55,000 mt of sinter fines. The open pit mine is 4,800 m above sea level and is worked only 4 or 5 months of the year because of the severity of the weather at that altitude during the winter. Shipping began in November 1988. So far, all of the shipments have gone to Altos Hornos de Zapla in Argentina as part of a 5-year contract that called for the delivery of 360,000 mt of lump ore. The lump ore and fines were being trucked across the border to a rail-side storage area at Estación Olacapatos. About 65,000 tons of product was railed during 1989 from Olacapatos to the Zapla steelworks at Palpala.

CMP shipped 8.84 Mmt of ore and pellets in 1989, 16% more than in the previous year. Exports accounted for 7.74 Mmt or 88% of the total. Almost all of the remaining 12% was shipped in coastal vessels to the Huachipato steelworks at Talcahuano in Region VIII. The integrated steelworks was operated by Cia. Siderurgica Huachipato S.A., a sister company of CMP. Both the iron mines and the steelworks are owned by Cia. de Acero del Pacifico S.A. de Inversiones (CAP), the former parastatal iron and steel group that was privatized in 1987.

Thirteen countries purchased material from CMP. Of the 7.74 Mmt exported, 62% went to Japan, 14% to the Federal Republic of Germany, and 9% to France. The Japanese steel industry has taken El Romeral fines for more than 20 years. The purchases were covered by a series of long-term sale agreements worked out in the early 1970's when Mitsubishi Corp. and other Japanese trading companies agreed to help finance the modernization and expansion of the Chilean iron ore industry. Mitsubishi also participated in the financing of the Huasco plant and had taken most of the plant's output since its startup in 1978. During the 1983-86 downturn in Western markets, CMP became concerned about its heavy dependence on the Japanese market and has since signed long-term

contracts with steelmakers in France, the Federal Republic of Germany, the Republic of Korea, and Mexico.

CAP has almost 1 billion tons of demonstrated or inferred reserves distributed between seven mining properties as shown in the text table.

production in both the Lorraine and Normandy basins gradually declined over the past 15 years because of competition from less expensive and better quality ores from Australia, Brazil, and Canada.

Between 1980 and 1989, pig iron production in France fell 19% because

level of 20.1 Mmt in 1989. The largest gains during the decade were made by Australian and Canadian suppliers. French imports from Liberia and Mauritania were halved, but the biggest loser was Sweden, which dropped from second to seventh place.

At the end of 1989, there were only three producers in France: Arbed SA and Usinor Sacilor in the Lorraine Basin and Société Métallurgique de Normandie (SMN) in the West. The last mine in the Pyrénées, the Batere, was closed in 1987. Arbed had two underground mines, Montrouge and Ferdinand, in the Bassin d' Amermont, northwest of Thionville. In 1989, 3.46 Mmt of ore from the two mines was railed across the border to Arbed's three blast furnaces at Esch-sur-Alzette in Luxembourg. Usinor Sacilor operated the Mairy, Moyeuve, and Orne-Roncourt Mines near Briey. In the West, SMN was in the process of phasing out operations at its Soumont Mines south of Caen. Some of the Soumont personnel were to be transferred to mines in Lorraine. A limited amount of relatively low phosphorus ore was also coming from Rouge in the Department of Ile-et-Vilaine.

Liberia and Guinea

Liberia was able to export 12.75 Mmt of iron ore products in spite of its declining economic situation. The tonnage was only 7% less than the 13.65 Mmt shipped in 1988. The four largest buyers on a tonnage basis were the Federal Republic of Germany (46%), Italy (23%), France (8%), and Belgium (7%).

Production was restricted to two operations, the Bong Mining Co. complex northwest of Salala in Bong County and the Yekepa complex of the LAMCO Joint Venture in Nimba County. At the beginning of 1989, Bong was planning to expand mining to the Bong Peak area of its concession, while LAMCO was working with the Governments of Guinea and Liberia to develop the Pierre Richaud deposit across the border from Yekepa.

Société des Mines de Fer de Guinée pour l'Exploitation des Monts Nimba (MIFERGUI-NIMBA) was formed in 1973 to speed development of the Pierre Richaud deposit, but the joint Guinean-Liberian project was stymied by the subsequent decline of world iron ore prices

Property	Administrative region	Reserve base (million metric tons)
El Romeral	IV	237

The company had additional resources at Cerro Imán northwest of Copiapó, at Mina Carmen northeast of Chañaral and at El Pleito south of Los Cristales. Cerro Imán and Mina Carmen are both in the Atacama Desert at the northern end of Chile's coastal magnetite belt.

France

In 1975, France was the sixth largest iron ore producer in the world, with an output of 49.65 Mmt. However, as the following table shows, iron ore

a number of obsolete furnaces were closed as part of the EC steelmaking rationalization program. At the same time, the country's exports of ore dropped from 8.7 Mmt to 3.5 Mmt. The Lorraine ores were at a disadvantage in recent years because of their high-phosphorus content, which was at odds with the increasingly stringent chemical requirements of advanced steelmaking. Total imports of ore declined from 18.6 Mmt to 12.6 Mmt between 1980 and 1983, but returned to pre-1983 levels and reached a record-high

Year	Production (thousand metric tons)				
	Lorraine region ¹	Western region ²	Pyrenees ³	Other	Total
1950-59	441,925	28,581	2,537	399	473,441
1960-69	558,375	33,456	1,131	161	593,122
1970-79	452,268	18,891	792	—	471,951

between 1982 and 1988. A 17-km-long railroad and turnaround was to be built from the Pierre Richaud mine site on Mount Nimba to the existing LAMCO railway terminal at Yekepa. The Guinean ores would then be railed the additional 265 km to LAMCO's port facilities at Buchanan, where they could be blended and wet screened before export. Use of LAMCO's existing infrastructure was needed to make the Guinean mine economically viable. The cost of constructing a separate rail line more than 350 km to Mount Nimba from the Guinean railway terminus at Kankan would be prohibitive. From Kankan, the ore would have to be railed an additional 660 km to the harbor at Conakry. The existing rail line from Conakry to Kankan was not designed for heavy-duty traffic and would have to be upgraded to handle ore cars. Iron ore loading facilities and docks would also have to be constructed at Conakry.

The joint Guinean-Liberian project is considered essential to the survival of the iron mines at Yekepa. High-grade reserves at the Nimba and Gbahi pits are almost exhausted. However, there is 400 Mmt of leaner reserves in the western area of the concession that could be developed with additional capital investment. The 400 Mmt figure includes 225 Mmt of lean ore left in the Tokadeh pit. LAMCO spent \$12 million to reopen Tokadeh in 1985. This ore averages only 47.9% Fe and has a relatively high level of phosphorus, but could be marketed if it were blended with the richer Guinean ores that run 68.1% Fe. In addition, the undeveloped ore bodies at Mount Gangra and Mount Yuelliton have proven reserves of 97 Mmt and 77 Mmt, respectively. Their ores are somewhat richer than those at Tokadeh and run about 54% Fe. Adoption of the blending proposal would extend the life of the Yekepa complex beyond 2010.

This original plan to blend medium-grade Liberian ores with richer material from Guinea has been shelved for the time being. Because of growing demand in Europe for high-grade lump ore, the present plan is to direct ship the Guinean ores through Buchanan.

In April 1989, the two Governments, LAMCO, and the other partners in MIFERGUI-NIMBA approved a general document outlining how the joint project would be legally and financially managed. A new company, Nimba

International Mining Co. (NIMCO), was to be set up in a neutral, offshore country and would take charge of all revenues and development funds. The Yekepa Mines would serve as a bridging operation and would continue to ship ore to Buchanan until the Guinean mine reached full production. This bridging operation would prevent key parts of the old LAMCO infrastructure from deteriorating. The Pierre Richaud has 315 Mmt of measured and indicated reserves and would be mined at the rate of 6.0 Mmt per year. Unfortunately, the future of the entire project is uncertain because of subsequent political events.

On July 29, citing exhaustion of its high-grade reserves, LAMCO halted all mining at Yekepa, but continued to process and ship stockpiled ore from Buchanan. The Government responded by terminating the concession and placing all of LAMCO's assets under the direct control of the Liberian Mining Corp. (LIMINCO)—the parastatal partner in the LAMCO Joint Venture. Shortly afterward, African Mining Consortium Ltd. (AMC) agreed to manage the Yekepa concession for LIMINCO and take over the bridging operation. AMC is a new company formed by British and North American investors that has ties to Hanna. AMC was to mine some 12 Mmt of blendable ore that remained on the Liberian side of the border at a rate of about 4 Mmt per year. Management of the mine was formally transferred to AMC on November 1. Gränges AB and the other private investors in LAMCO have since sold their assets in Liberia to LIMINCO for the symbolic sum of one dollar. Gränges was still negotiating the transfer of its interests in MIFERGUI.

AMC had just shipped its first 300,000 mt of ore when the political situation deteriorated. In December, insurrectionist forces invaded Nimba County from the Ivory Coast. At yearend, Liberia was embroiled in civil war. By May 1990, the insurgents had captured Yekepa, the rest of Nimba County, and most of Grand Bassa County. A subsequent Government counterattack failed to dislodge rebel units from Buchanan. Unconfirmed reports from rebel territory stated that the Yekepa complex and most of the rail line to Buchanan had escaped serious damage. Both sides seemed interested in preserving the infrastructure of the country. Bong's mining and pelletizing facilities were not damaged by the fighting

because of their isolated location, but the company was eventually forced to suspend shipments and halt production after rebel forces reached the suburbs of Monrovia. The political instability in Liberia was of grave concern to potential investors in the MIFERGUI-NIMBA Project.

Mexico

Mexican iron ore producers continued to satisfy most of the needs of the country's iron and steel industry. The competitiveness of the Mexican mines was strengthened when international iron ore prices rose at the beginning of 1989. Total production of usable ore was 14.8 Mmt, a drop of 9.7% from the 1988 tonnage. Pena Colorada S.A. and Siderugica Lazaro Cardenas-Las Truchas S.A. (SICARTSA) were the principal producers of ore and agglomerates, accounting for 36.5% and 26.8% of the national total, respectively. Mexican ore reserves were estimated to be 587 Mmt.

Mexican blast furnace operators continued to use pellets for the bulk of their iron units. Total pellet production was estimated to be 7.53 Mmt, significantly less than total demand. As a result, 440,000 mt of pellets had to be imported from Brazil and Chile to meet the demand of the SICARTSA II complex in the State of Michoacan. Pena Colorada was the leading pellet producer in 1989 with 3.07 Mmt or 40.8% of the national total. The output was the highest ever in the history of the enterprise, with the Minatitlan pelletizing plant operating at full capacity for the first time since its startup in 1974. With the exception of Pena Colorada, all five of the other pellet producers cut back their output. SICARTSA I experienced the sharpest drop, with pellet production falling 23.4% from its 1988 level. The loss in output was primarily the result of an extended work stoppage. SICARTSA is part of the State-controlled SIDERMEX Group and has financial ties to Altos Hornos de Mexico S.A. de C.V.

The Cerro Nahuatl mining complex of HYLSA S.A. reached an optimal level of production during its first full year of operation. The new operation in the State of Colima was to be the principal source of iron ore during the 1990's for Las Encinas, S.A., HYLSA's mining subsidiary. Las Encinas had a pelletizing plant at nearby Alzada and a second mine at Pihuamo in the neighboring State of Jalisco. About 90% of the capital investments

approved by the Las Encinas management were earmarked for the Nahuatl project.

The SIDERMEX Group also invested heavily in its iron ore operations in 1989. About 36% of its total investments for the year went to upgrade operations at the Hercules mining complex near Sierra Mojada in Coahuila. The Hercules complex was operated by Minera del Norte, S.A., another of SIDERMEX's subsidiaries, and produced concentrate averaging 65.0% Fe.

South Africa, Republic of

The South African iron ore industry had its best year since 1981. Production reached 30 Mmt, with 14.6 Mmt going for export. Exports increased 32% between 1988 and 1989, putting the country ahead of Liberia and Venezuela in terms of gross tonnage. The jump in exports moved the Republic of South Africa from ninth to seventh place in the list of major exporting countries.

Iscor Ltd. shipped 20.94 Mmt of iron ore products during the year and was by far the largest of the country's seven producers. Approximately 17 Mmt came from the company's Sishen open pit operation north of Postmasburg in Cape Province. The bulk of the Sishen material was railed to the deepwater terminal at Saldanha Bay for export. The terminal exported 7.93 Mmt of lump ore and 3.98 Mmt of fines in 1989.²⁷ The 11.92 Mmt represented 81% of the country's total exports, with most of the tonnage going to Japan and the EC. The South Atlantic port is an 861 km haul from Sishen. However, the rail costs are partially offset by the efficiency and 10,000-mt-per-hour capacity of the port's loading facilities. The berth at Saldanha Bay is similar in size to the No. 2 pier at Tubarao and can accommodate vessels up to 280,000 dwt.

Iscor also railed 9.02 Mmt of direct-shipping ore and concentrates to its wholly owned steelworks at Vanderbijlpark, Newcastle, and Pretoria. Part of the 9 Mmt came from the Thabazimbi Mine in the northwest quadrant of the Transvaal.

The underground and open pit operations at Thabazimbi produced about 2.4 Mmt of direct-shipping ore in 1989. The mine had seven separate sources of ore, but only four were being worked.²⁸ About half of Thabazimbi's output came from the new West Donkerpoort pit, which opened in 1988 and was producing

about 125,000 mt of run-of-mine ore per month. The original Donkerpoort pit was almost exhausted and had an output of only 26,000 mt per month. This older pit had less than 0.8 Mmt of high-grade ore remaining that was recoverable by surface mining, but had more than 3.5 Mmt of reserves at depth. Iscor's long-range mining plan called for the site to be converted to an underground mine at some future date. At least 28,000 mt per month was being taken from the Vanderbijl ore reserve. The East Mine, an underground operation, was producing about 78,000 mt per month. Mining of the East Kwagashoek ore body was scheduled to begin in 1993, following a scaledown of operations at the East Mine. The Bobbejaanwater ore body was being held in reserve.

The Thabazimbi ore was similar to that at Sishen. Both were composed largely of hematite derived from a Lake Superior-type banded ironstone. Thabazimbi was Iscor's oldest mine, in production since 1933. During the 57 years of operation, the mine produced 96.3 Mmt of high-grade ore, with 58% coming from underground workings.

Iscor made several changes in the iron-making part of its operations. The company produced 632,000 mt of DRI at its four-module complex in Vanderbijlpark in fiscal year 1987-88, but shut down its single DRI unit at Dunswart.²⁹ Steel-making was halted at Dunswart in October 1987. Both DRI plants were coal-based. The 150,000-mt-per-year Dunswart plant was built in 1973 and employed the Codir process. The 600,000-mt-per-year Vanderbijlpark DRI complex started up in 1984 and employs the SL-RN process.

Blast furnace operations at Iscor's Pretoria works were being scaled back in conjunction with the phasing in of the new Corex operation.³⁰ The Pretoria Corex plant is the first facility in the world to produce molten iron on an industrial basis by charging coal directly into the smelting furnace. A key feature of the Corex process is that it uses untreated raw coal in place of coke. Coking coal was becoming increasingly scarce in the Republic of South Africa, but the country had large reserves of coals of lower rank. Iscor was able to bypass the conventional coke oven-blast furnace route and substitute these cheaper and readily available noncoking coals. The process produces hot metal with carbon and silicon levels approaching blast

furnace standards. However, the sulfur content is much higher because of the substitution of raw coal for coke.

The Corex plant was completed in less than 3 years by Voest-Alpine Industrieanlagenbau and was commissioned on a trial basis in August 1988. Several modifications were made between February and November 1989, and the plant was turned over to Iscor on December 22. The new facility was designed to produce 300,000 mt of hot metal per year and was expected to be operating at about 80% of capacity by February 1990. Iscor located the plant at Pretoria, instead of Vanderbijlpark or Newcastle, for two reasons. First, Pretoria's two coke batteries were nearing the end of their operational life. Second, Pretoria's steelmaking operations needed the byproduct export gas generated by the Corex process.

In February 1988, the South African Government announced that it was abandoning industrial regulatory policies that had been in place for more than 60 years and would privatize many of the companies owned by the state. After a review that lasted more than a year, Government officials decided that Iscor would be the first of the parastatal companies to be sold. In May 1989, the South African Parliament passed legislation formally authorizing the sale of Iscor. Several restrictions on ownership were put into Iscor's articles of incorporation to prevent the company from turning into a monopoly or being dominated by foreign interests. In early October, the Government offered 83.8% of the shares in Iscor to the general public, with preferences and discounts being given to employees and pensioners of the company.³¹ The remaining 16.2% was retained by the state, for a total issue of 1.85 billion shares.

Spain

Four companies produced a total of 4.57 Mmt of iron ore products in 1989—Compania Andaluza de Mines, S.A. (3.26 Mmt), Agrupacion Minera, S.A. (0.79 Mmt), Prereducidos Integrales del Sur-oeste de Espana, S.A. (0.21 Mmt), and Metalquimica del Nervion, S.A. (0.31 Mmt). The output of Metalquimica consisted entirely of roasted pyrites recovered as a coproduct of its copper, zinc, and precious metals operations near Bilbao. Production of individual companies over the past 10 years is broken out in the text table.

Company	1979	1980	1981	1982	1983	1984	1985	1986	1987	1988	1989

Spain had the fifth largest steel industry in the EC but was a net importer of iron ore. A total of 6.94 Mmt entered the country during the year. Almost half of the material came from Brazil, which supplied 3.00 Mmt. Other suppliers included Australia (0.87 Mmt), Mauritania (0.87 Mmt), Liberia (0.84 Mmt), Canada (0.75 Mmt), and Venezuela (0.61 Mmt). A total of 2.39 Mmt was exported, with the bulk of the shipments going to other steel producing members of the EC. The five biggest customers were the Netherlands (0.77 Mmt), France (0.60 Mmt), the United Kingdom (0.32 Mmt), Romania (0.28 Mmt), and Belgium (0.23 Mmt).

Cia. Andaluza de Minas, S.A. (CAM) shipped 3.21 Mmt of Granada fines from its docks at the Mediterranean port of Almeria. The fines were recovered from heterogeneous, but predominantly hematitic, ores mined and processed at the company's Marquesado Mine in the Andalusia region of southeastern Spain. At least 32 different types of ore are recognized, ranging from compact carbonaceous hematite to micaceous, highly fractured goethite. The mine was connected to Almeria by a 100-km-long railway. CAM's sales improved significantly between 1988 and 1989. In 1988, the company shipped only 2.90 Mmt of products. The 1989 shipments would have been even higher if a severe storm had not seriously damaged the ship loader at Almeria on December 18. The loading boom was blown down into the sea, blocking the berth. CAM immediately declared force majeure and began work

on a replacement. The new loader was commissioned on May 19, 1990, but over 900,000 mt of sales was lost during the 5-month shutdown. On the positive side, the new unit will allow the port to handle 500,000 mt per month.³²

Vietnam and Laos

Vietnam, after 50 years of political conflict, war, and economic turmoil, had begun to seriously reevaluate its mineral resources. The reevaluation was part of the Government's reform program launched in 1986 to stimulate the stagnating economy by loosening bureaucratic restrictions. One of the goals of the program was to encourage growth by increasing mineral exports. A seemingly liberal law on foreign investment was adopted in January 1988 to attract capital and technical assistance from multinational companies.

Until 1987, little emphasis was placed on expanding the iron ore industry. The only integrated steelworks in the country was at Thai Nguyen, 60 km north of Hanoi. The steelworks had not been able to operate anywhere near its rated capacity of 200,000 mt per year of crude steel because of power shortages and transportation problems. In past years, a significant part of the iron ore for Thai Nguyen came from the nearby Trai Cau Mine in Bac Thai Province and some smaller mines near Lao Cai in Hoang Lien Son Province, northwest of Hanoi.

The most important iron mine in Vietnam is at Thach Ke in Nghe Tinh Province, 50 km southeast of the coastal city

of Vinh.³³ The magnetite deposit was discovered during an aeromagnetic survey and was extensively drilled between 1975 and 1984. The deposit is part of a skarn created when Triassic granite intruded Paleozoic carbonates. Reserves were estimated to be about 540 Mmt. The ore typically assays 61% total Fe, 1.8% Al₂O₃, 1.2% MgO, and 0.05% P. The open pit mine was still in the early stages of development, and the Vietnamese Ministry of Machinery and Metallurgy had approached the Japanese steel industry for technical and financial help.³⁴ Mining must be carefully planned because the site is only 1.5 km from the Gulf of Tonkin, and precautions will have to be taken to prevent the infiltration of seawater into the pit. Most of the ore would be exported to Japan in exchange for finished steel. Port facilities and roads would have to be built because there was very little infrastructure in the district.

The long-term outlook for iron mining was actually much more promising for Laos than for Vietnam. It has been known for 30 years that there were at least two world-class iron deposits in the Laotian Province of Xieng Khouang.³⁵ The upper reaches of the Mekong Basin have a number of other prospects of potential economic interest, both in Xieng Khouang and the adjoining Loei region of Thailand. The entire area is extremely mountainous, isolated, and poorly explored.

The largest of the two Laotian deposits was at Pha Lek Mountain,³⁶ about 60

km south-southwest of the provincial capital of Xieng Khouang. Massive lenses of magnetite have formed along contacts between numerous small granitic or dioritic intrusions and the Devonian sedimentary country rock. The contact metasomatic mineralization covers an area of 60 km², and more than eight ore bodies have been identified. The high-grade ore bodies lie close to the surface and would require minimal stripping.

The second deposit, Phou Nhouan,³⁷ forms a mountain ridge on the eastern border of the Plain of Jars, just north of Xieng Khouang. The 5-km-long ridge is made up of Triassic sandstones and shales with apparently conformable beds of ironstone. The ironstone, a mixture of magnetite and grey hematite, can be readily identified by its characteristic bands of dark-red hematite and iron-stained silica. Combined high-grade resources of the two deposits were estimated to exceed 1 billion mt. So far, exploitation of the two deposits has been blocked by the lack of infrastructure in Laos, the high capital cost of development, and the absence of

an integrated steelworks in the Mekong Basin. On a positive note, Laos had 3 operational hydroelectric plants—Tha Lat, Se Labum, and Nam Dong—as well as 53 sites where additional hydroelectric stations could be built, providing more than enough power for both an electric-furnace smelting complex and an electric-furnace steelmaking complex. The country also had significant reserves of coal in Vientiane and three other provinces that are suitable for coke production and sintering of fines.

OUTLOOK

About 98% of the demand for iron ore came from the iron and steel industry. The remaining 2% was used in the manufacture of cement, heavy-medium materials, pigments, ballast, agricultural products, or specialty chemicals. As a result, demand for iron ore was tied directly to the production of raw steel and the availability of high-quality steel scrap.

This relationship is shown for the United States in figure 3 which compares annual blast furnace production with the combined total of mine production, net ore imports, and blast furnace consumption of scrap. Because of this relationship, the reader is referred to the outlook sections in the "Iron and Steel" and "Iron and Steel Scrap" chapters. The dependence of the iron ore industry on steel demand is not expected to change in the near future.

In 1989, the world steel industry produced a record-high 783 Mmt of crude steel, drawing down large stockpiles of ore and agglomerates that had accumulated over the past decade. World demand for iron ore has improved considerably since 1987, but some serious marketing problems still have to be solved. During the 1980's, many iron mining companies were hurt by pig iron production cutbacks in the industrialized countries and were forced by economies of scale to either halt operations or build up stocks far above marketable levels. The cutbacks in pig iron production resulted from the following:

FIGURE 3

COMPARISON OF BLAST FURNACE PRODUCTION WITH THE SUM OF MINE PRODUCTION, NET ORE IMPORTS, AND BLAST FURNACE CONSUMPTION OF SCRAP

- Slackening demand for finished steel in the U.S. and several other industrialized countries who were struggling with recessionary forces,

- The proliferation of minimills that utilize electric arc furnaces and rely heavily on scrap,

- The increased use of scrap in basic oxygen furnaces (BOF's) at integrated steelworks, and

- The adoption of new ironmaking and steelmaking technologies.

In this last development, the installation of continuous casting equipment and the shutdown of obsolete open-hearth furnaces have improved the recovery of iron units while reducing the amount of in-house scrap available to the BOF. Because of these events, most iron ore suppliers were continually forced to lower their prices between 1981 and 1987 to maintain market share. This discouraging situation had eased somewhat since early 1988, but made mining companies reluctant to develop additional capacity and brought exploration to almost a complete standstill in North America.

Several world-class deposits remained undeveloped in 1990 because steelworks in the industrialized countries could not absorb additional mine production. The Carajás district in Brazil alone had 18 billion mt of high-grade ore resources, including 2.4 billion mt of measured reserves and 2.5 billion mt of indicated reserves. Other major undeveloped deposits that could be exploited exist in Alaska, Botswana, Eastern Siberia, Gabon, Guinea, Laos, and Senegal.

Improved demand for iron units led to a strengthening of spot prices for both standard and fluxed pellets between 1988 and 1990. Higher prices for quality scrap helped support the increase. However, prices for sinter fines remained weak because steelmakers in North America and Western Europe were forced to close several of their older sintering plants to comply with new environmental protection regulations. The price differential between pellets and fines was expected to exist for some time because several mines in developing countries had excess capacity to produce fines, but lacked the necessary risk capital needed to construct modern, state-of-the-art pelletizing facilities.

BACKGROUND

Definitions, Grades, and Specifications

Iron ore is composed of one or more minerals which, when heated in the presence of a reductant, will yield metallic iron. In commercial terms, the material must be minable at a profit to be called iron ore; otherwise, it is iron-bearing material, lean ore, or waste rock. Iron ore is normally composed of iron oxides, the mineral forms of which are magnetite, hematite, and goethite. Martite, a pseudomorph of hematite after magnetite, is commonly found in oxidized magnetite ores. Limonite is a general term for mixtures of cryptocrystalline minerals, predominantly goethite and hematite, which form bog iron deposits in the Eastern United States and oxidized capings in the desert regions of the West. Iron carbonate (i.e., siderite) and iron sulfides such as pyrite are sometimes used to make pig iron, but they must be calcined to drive off carbon dioxide or sulfur before being charged to the blast furnace. Iron silicates such as chamosite may contain up to 42% iron but are not used as iron ore except in rare instances where they cannot be separated economically from iron oxides or carbonate. The chemical formula and iron content of each of these minerals are given in the text table.

processing, is called usable ore or marketable ore. Usable ore includes lump ore, fines, concentrates, and agglomerates. Lump ore consists of particles 4.75 mm or larger. Fines are particles less than 4.75 mm in diameter; sinter feed consists mostly of fines larger than 100 mesh (147 micrometers), while fines smaller than 100 mesh may be classified as pellet feed. The products of beneficiation plants are called concentrates and are classified as coarse (+ 4.75 mm) or fine (– 4.75 mm) as indicated previously. Fine concentrates or natural ores are agglomerated to facilitate transportation and smelting; these products are called pellets, sinter, briquets, etc., depending on the agglomerating process used.

Taconite was originally applied to the hard, fine-grained, banded iron-bearing formation of the Mesabi Range. The term is now used to describe similar rocks in other parts of the world that contain low-grade ores with the same characteristics. If magnetite is the principal iron mineral, the rock is called magnetic taconite; if hematite is the principal iron mineral, the rock is called hematitic taconite or oxidized taconite. Jaspilite is used to describe relatively iron-rich banded hematitic iron formations of the type found in the Marquette and Vermilion Ranges of the Lake Superior District. Taconite pellets are iron oxide pellets produced from low-grade crude ores of the taconite type. In Minnesota, altered taconite from

Mineral	Crystal system	Chemical formula	Molecular weight	Iron fraction
Goethite	Orthorhombic	FeO(OH)	88.854	0.62853
Hematite ¹	Rhombohedral	Fe ₂ O ₃	159.692	.69943
Ilmenite	do.	FeTiO ₃	151.75	.36802
Magnetite	Isometric	Fe ₃ O ₄	231.539	.72360
Marcasite	Orthorhombic	FeS ₂	119.97	.46551
Pyrite	Isometric	do.	119.97	.46551
Pyrrhotite ²	Hexagonal	FeS	87.91	.63527
Siderite	Rhombohedral	FeCO ₃	115.856	.48204

¹Martite is a variety of hematite that occurs in octahedrons or dodecahedrons and is pseudomorphous after magnetite.

²Pyrrhotite always contains less iron than is indicated by the stoichiometric formula. Stoichiometric FeS is known as troilite and occurs mainly in iron meteorites.

Iron ore as mined in its natural state is called crude ore. Crude ore may be merchantable without processing or with minimal processing such as crushing and screening, in which case it is called direct-shipping ore. The final ore product of a mining operation, whether direct-shipping ore or the product of extensive

which silica has been partly leached by natural processes is sometimes referred to as semitaconite, or wash ore. Itabirite is a metamorphic rock with a schistose structure that is composed primarily of granular quartz, specular hematite, and some muscovite. The term was first used to describe a characteristic type of iron

formation in the Iron Quadrangle of Brazil that runs 30% to 50% Fe.

U.S. Lake Superior iron ores are graded and priced on the basis of chemical composition and physical structure. Bessemer ores contain 0.045% phosphorus or less; non-Bessemer ores contain more than 0.045% phosphorus; high-phosphorus ores contain 0.18% phosphorus or more. Manganiferous ore contains 2% or more manganese. Siliceous ore contains 18% or more of silica. Published prices for these ores are for a long or gross ton (2,240 pounds) of iron ore containing 51.5% iron, natural, delivered rail-of-vessel at lower lake ports. The natural iron content is based on gross weight, including moisture, and is always lower than the iron content calculated on a dry basis. Published prices for pellets are for a ton of contained iron, natural, delivered rail-of-vessel at lower lake ports. Although prices are still published for Bessemer, phosphoric, manganiferous, and siliceous grades, very little ore of this type (locally known as natural ore) is now produced in the Lake Superior District. More than 97% of the district's output is pellets.

In iron ore transportation on the Great Lakes, lower lake ports refer to receiving ports such as Burns Harbor, Cleveland, Detroit, Indiana Harbor, Lorain, Toledo, etc. Upper lake ports refer to ore loading ports such as Escanaba, Marquette, Superior, and ports in Minnesota. Head of the Lakes refers to the Duluth-Superior area on the western shore of Lake Superior.

Industry Structure

The history of iron mining in early America has already been reviewed in several other publications of the Bureau of Mines and its predecessor.³⁸ For additional information on the economic history of the entire U.S. iron and steel sector, the reader should refer to the comprehensive works of Father Hogan of Fordham University.³⁹

The history of the iron ore industry as it currently exists began in 1844 with the discovery of "hard" magnetite-hematite ores on the Marquette Range of Michigan and the subsequent founding of the Jackson Mining Co.⁴⁰ At first, lack of transportation facilities prevented rapid development. However, completion of a shipping canal at Sault Ste. Marie in 1855 opened the way for further development of mining in the Lake Superior region. By

1885, ore had been discovered in the Gogebic and Menominee Ranges of Michigan and Wisconsin, and annual production of ore had climbed to more than 2 Mmt, 20 times the volume in 1860. The high grade of these ores, combined with the low cost of water transportation, made them increasingly competitive at Eastern furnaces and forced many small mines in New York, Tennessee, and the Mid-Atlantic States to close. This trend was accelerated in the 1880's by production from the Vermilion Range and the discovery of the great Mesabi ore bodies in the 1890's. By the turn of the century, most of the Eastern mines had closed. In Alabama, production of iron ore increased nearly tenfold between 1880 and 1890, and Birmingham was established as a major ironmaking center. During this period, many steel companies acquired iron ore properties in the Lake Superior District, and the production of many smaller mines was consolidated by the formation of large mining companies. The mergers that took place in the steel industry between 1893 and 1905 basically organized the iron ore industry into the structure that exists today.

Hundreds of mines closed during the 1950's following the depletion of higher grade ores, rapidly rising imports, and the subsequent growth of the taconite industry in the Lake Superior District. By 1981, 15 mines accounted for 90% of the Nation's production of iron ore. By 1986, the 15 mines had been reduced to 10 because of increasing imports of steel and two deep recessions from which the iron ore and steel industries have not yet fully recovered.

In 1989, iron ore was produced by 21 companies operating 21 mines, 16 concentration plants, and 9 pelletizing plants. The mines included 20 open pits and 1 underground operation. However, only 10 mines accounted for 99% of the output. Virtually all ore was concentrated before shipment, and about 97% was pelletized. Most of the ore was produced by, or for the account of, 11 U.S. companies and 3 Canadian companies engaged in production of iron and steel. Domestic steel companies directly controlled about 76% of production; Canadian steel companies, about 11% of production. Consumption of iron ore and agglomerates was distributed approximately as follows: blast furnaces, 97.6%; direct reduction plant, 0.5%; steel fur-

naces, 0.3%; and manufacture of cement, heavy-medium materials, and other products, 1.6%.

During the 1980's, a quasi-symbiotic relationship existed between several iron ore operations in Canada and the United States because of ownership ties. In 1982, U.S. companies owned about 70% of Canadian production capacity for iron ore and held significant minority interests in iron ore mines in Australia, Brazil, Liberia, and New Zealand. Since then, Japanese interests have acquired part of the Canadian and overseas holdings previously owned by companies in the U.S. iron and steel sector.

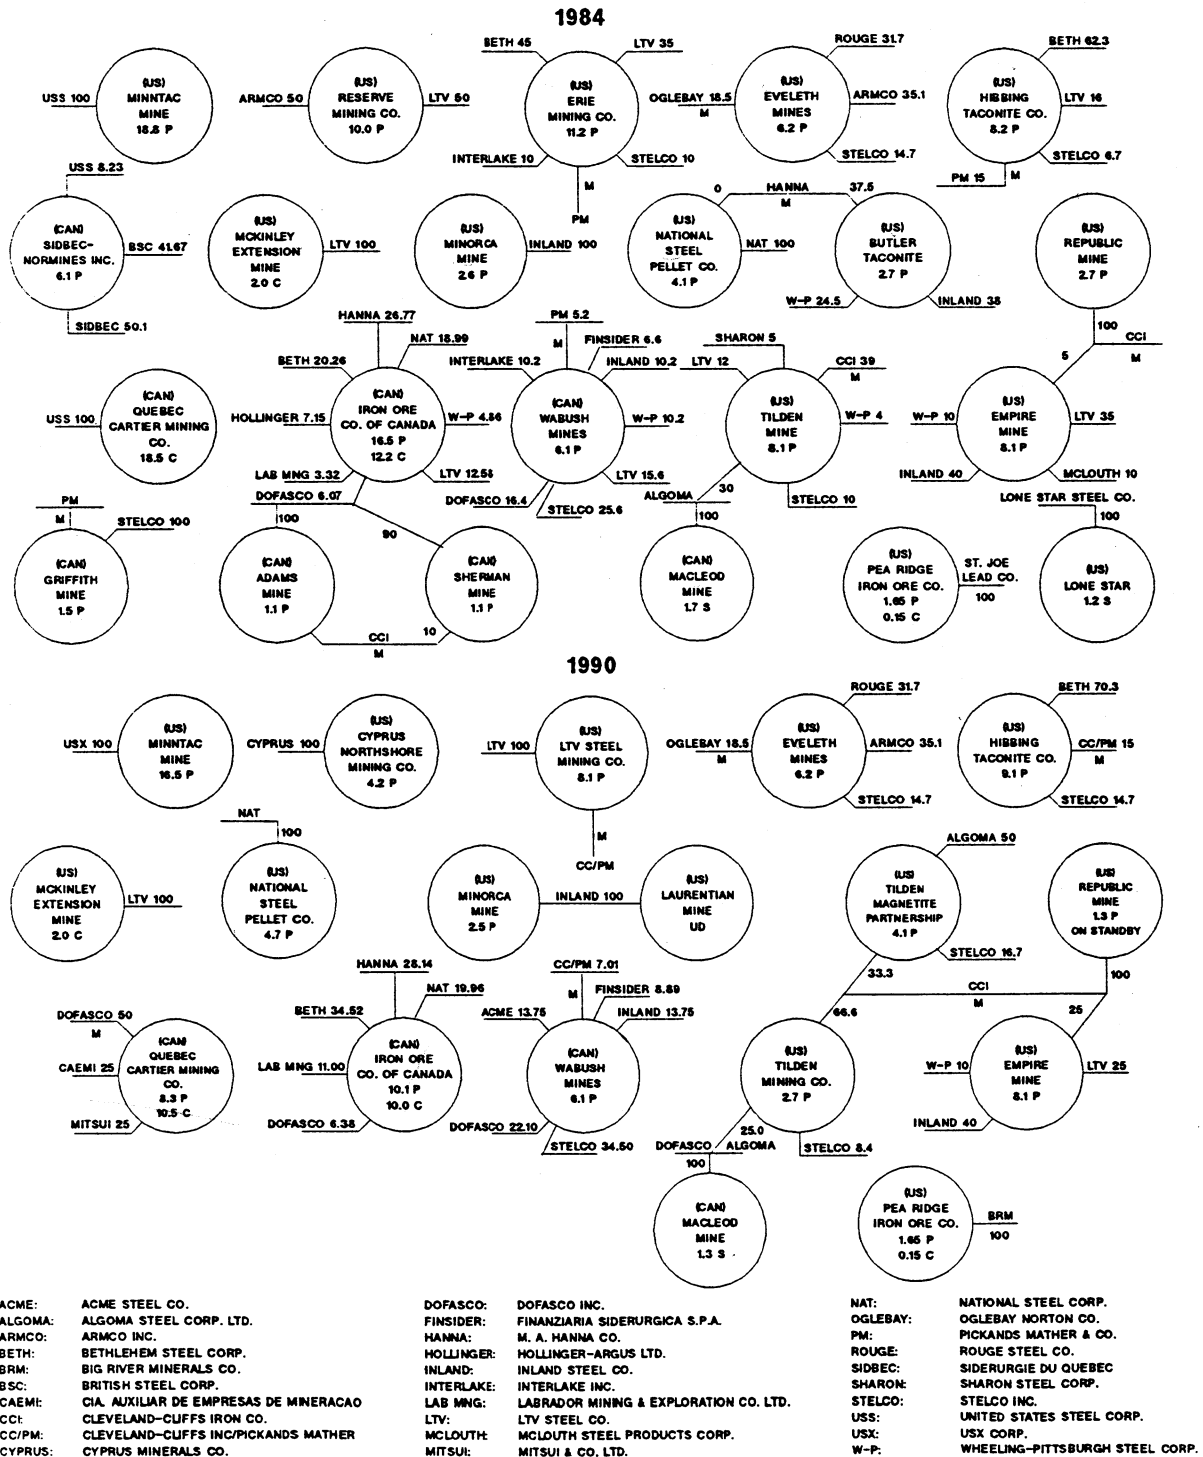

The iron ore industry of the United States and Canada has been undergoing a major restructuring since 1985 aimed at lowering pellet costs and improving financial health. The bulk of this restructuring occurred in the summer of 1986, when the industry was experiencing one of its worst years since the Great Depression. Most of the pellet producers had already streamlined their operations by late 1987, when overall demand for steel began to grow. The modest recovery accelerated in 1988, only to level off in 1989. Ownership shares and installed production capacity of United States and Canadian producers of iron ore in 1984 are shown in upper half of figure 4.⁴¹ The updated diagram shown in the lower half illustrates how pervasive the restructuring has been since then.

An increasing number of integrated steelworks in North America are using fluxed pellets. This newer, more easily reducible type of pellet is created by adding limestone and/or dolomite to the iron ore concentrate during the balling stage. Sufficient fluxstone is added to raise the ratio of $(\text{CaO} + \text{MgO})/(\text{SiO}_2 + \text{Al}_2\text{O}_3)$ in the pellet to above 0.6. Fluxed pellets comprised more than 25% of total U.S. production in 1989. Idle capacity was brought on-stream at three mining complexes on the Mesabi Range during 1989 to meet increased pellet demand. The idled complex of the Reserve Mining Co. at Silver Bay, MN, was renovated by Cyprus during the last quarter of 1988. Cyprus began shipping fluxed pellets in April 1990.

Combined United States and Canadian production represented only about 12% of the world output of usable ore in 1989. At least 45 other countries mined crude ore during the year. The leading producer was the U.S.S.R., which accounted for

FIGURE 4

PRODUCTION CAPACITY AND OWNERSHIP OF PRINCIPAL IRON MINES,
UNITED STATES AND CANADA, FOR THE YEARS 1984 AND 1990

about 24% of world output in terms of metal content, followed by Brazil with 19% and Australia with 12%. Trends in world mine production since 1985 are shown on a country basis in table 19. Major mines are listed individually in table 20.

In 1988, the U.S.S.R. produced 249.7 Mmt of direct-shipping ore and concentrate. A large part of the concentrate was consumed to make 67.9 Mmt of pellets. The bulk of the iron ore produced in Australia, Brazil, India, and the Republic of South Africa consisted of high-grade direct-shipping ore or products derived from much higher grade crude ores than those mined in the United States.

Geology-Resources

Iron is the fourth most abundant rock-forming element, comprising about 5% of the Earth's crust. Astrophysical and seismic evidence suggest that the element has also combined with nickel to make up the bulk of the Earth's core. A small part of the crustal iron has been concentrated by sedimentary, igneous, or metamorphic processes into deposits containing up to 70% of the element.

The largest concentrations of iron are found in banded sedimentary iron formations of Precambrian age. (See figure 5.) These formations currently supply most of the world's iron ore and constitute the bulk of the world's iron resources. Precambrian ores are mined extensively in Africa, Australia, Canada, China, India, South America, the United States, and the U.S.S.R. Individual banded iron formations (BIF's) can vary from 30 to 600 m in thickness. Some are relatively flat-lying, while others have been complexly folded by subsequent regional metamorphism. Some BIF's are exposed almost continuously along the margins of geosynclines and frequently underlie basin areas of hundreds or thousands of km². Most consist of fine-grained iron oxides and quartz, with accessory iron silicates and sometimes iron carbonate, and contain 20% to 40% iron. These rocks comprise ores of the taconite type mined in Canada, China, Norway, the United States, and the U.S.S.R.

Locally, the BIF's have been concentrated by natural processes to form high-grade deposits of hematite or goethite by leaching of silica and oxidation of ferrous minerals. The high-grade ores are classed as residual or replacement deposits, depending on whether removal of silica was

accompanied by introduction of additional iron oxide. The residual ores are usually earthy, porous, and contain 50% to 60% iron in their natural state. Examples are the soft ores of the Lake Superior District, the Schefferville District of Labrador, and the Krivoy Rog District of the Ukrainian S.S.R. Some soft ores appear to be merely decomposed bodies of BIF, containing 20% to 40% iron in the form of martite, hematite, or goethite. Example of the latter are bodies of "wash ore" in the western Mesabi Range, which are highly siliceous but easily concentrated by gravity methods.

Replacement ores in the Precambrian BIF's are usually dense, massive, and contain 64% to 68% iron. Often, the ores retain banded structures of the original sedimentary rock. Examples are the hard ores of the Vermilion Range, MN; Steep Rock and Michipicoten Districts of Ontario; Minas Gerais, Brazil; Fort Gouraud, Mauritania; and Sishen, Republic of South Africa.

Another class of sedimentary iron deposits, of regional importance in the Southeastern United States and Western Europe, are oolitic ironstones of Paleozoic to Cretaceous age. The formations are extensive laterally and contain 20% to 40% iron, but they differ from the Precambrian BIF's in several important respects. They are usually less than 15 m thick, and minable layers are often less than 6 m thick. The deposits rarely contain more than 48% iron, and most contain only 25% to 35% iron. The ore consists of very fine-grained hematite, quartz, chamosite, and siderite in varying proportions; sometimes enough calcite is present to make self-fluxing ore. The ore is usually high in phosphorus and difficult to beneficiate. Oolitic ironstones were mined until recently in Alabama, Newfoundland, and the United Kingdom, and are still mined extensively in France and to a lesser extent in central Europe. They are also mined in Egypt and comprise most of the iron resources of Pakistan.

A third type of sedimentary ore, consisting of siderite or limonite in flat-lying lenses up to 6 m thick, is mined in east Texas from the Weches Formation of Eocene age. The ore is associated with glauconitic sand and clay and contains up to 35% iron.

Massive deposits of magnetite, sometimes with hematite, thought to be of igneous origin, are important sources of

iron ore in many parts of the world. These deposits can contain as much as 65% iron and are often rich in titanium and vanadium, as at Lake Sanford, NY. There are two principal types of these igneous deposits: magmatic segregations and pyrometasomatic replacements. The first type is represented by irregular or layered masses that appear to have formed by segregation of magnetite crystals in magma, or as tabular, sheetlike bodies formed by injection of an iron-rich fluid into surrounding rocks. The Precambrian Bushveld Igneous Complex of the Republic of South Africa with its alternating seams of magnetite and chromite is frequently cited as an example of magmatic segregation and crystal settling. The sill-like ore bodies at Kiruna, Sweden, and Pea Ridge, MO, represent the injection version of the process. The magnetite ores in these last two deposits contain significant amounts of fluorapatite, which must be removed during beneficiation.

Pyrometasomatic deposits are concentrations of magnetite that have replaced portions of the limestone or volcanic country rock at or near the contact of an igneous intrusion. These deposits may be partly altered to hematite and contain up to 65% iron, depending on the extent of replacement. Garnet, epidote, and wollastonite are commonly formed along with the magnetite during the thermal metamorphism of the country rock. Deposits of this type are commonly associated with Jurassic or younger intrusives in the Western United States, Mexico, and western South America; they are also found in Pennsylvania. Examples are Iron Springs, UT; Eagle Mountain, CA; Hanover, NM; Cornwall and Morgantown, PA; El Romeral, Chile; and Marcona, Peru.

Total	8	9	NA	15.40
Oceania: Australia ¹¹	2	2	6	4.00
World total	58	82	NA	267.24

NA Not available.

¹Staged additions are treated at some mining complexes as if they were separate plants. Site data exclude plants that have had no production since 1982. Plants that produced after 1979, but have been continuously idle since 1982, are cited in the footnotes because they could be reactivated at some reasonable cost.

²The total for the United States includes the newer part of the E. W. Davis Works at Silver Bay, MN, but not the idled plant owned by Cleveland-Cliffs Inc. at Republic, MI. Cyprus Minerals Co. acquired the cannibalized Silver Bay facility in Aug. 1989 and resumed production in Jan. 1990. Cleveland-Cliffs has been considering reopening its 1.3 Mmt per year Republic plant, which has been on care and maintenance since 1981.

³Pellets produced from imported direct-shipping ores and/or concentrates.

⁴The older of the two plants operated by A/S Sydvaranger at Kirkenes has been idle since 1986. In addition, the 0.50 Mmt per year plant operated by Norsk Jernverk at Mo-i-Rana was shut down in Jan. 1987 for an indefinite period, leaving only one plant in Norway on-line.

⁵In early 1988, the capacity of the Svappavaara plant was upgraded from 2.8 to 3.5 Mmt per year. The 0.3 Mmt per year steel belt plant at Malmberget is used for both research and development purposes as well as ordinary production.

⁶Based on incomplete information.

⁷The Skopje plant operated by Rudnici i Zelezara was recently idled.

⁸Excludes the No. 1 pelletizing plant (capacity of 2.4 Mmt per year) of the Bong Mining Co. The No. 1 plant has been idle since 1980.

⁹The Nador plant operated by Société d'Exploitation des Mines du Rif (SEFERIF) has been idle for several years.

¹⁰There is an additional plant with a capacity of 1.8 Mmt per year at Mandovi in Goa, but it has been closed since 1982. The owner was planning to reopen the facility using high-grade blue dust from the Bellary Hospet area of Karnataka as feed.

¹¹There is an additional plant with a capacity of 3.0 Mmt per year at Dampier in Western Australia, but it has been closed since 1980.

^eEstimated. ^pPreliminary. ^rRevised.

¹Table includes data available through June 27, 1990.

²In addition to the countries listed, Cuba and Vietnam may produce iron ore, but definitive information on output levels, if any, is not available.

³Insofar as availability of sources permits, gross weight data in this table represent the nonduplicative sum of marketable direct-shipping iron ores, iron ore concentrates, and iron ore agglomerates produced by each of the listed countries. Concentrates and agglomerates produced from imported iron ores have been excluded under the assumption that the ore from which such materials are produced has been credited as marketable ore in the country where it was mined.

⁴Data represent actual reported weight of contained metal or are calculated from reported metal content. Estimated figures are based on latest available iron content reported, except for the following countries for which grades are Bureau of Mines estimates: Albania, China, Hungary, and North Korea.

⁵Nickeliferous iron ore.

⁶Reported figure.

⁷Series represent gross weight and metal content of usable iron ore (including byproduct ore) actually produced, natural weight.

⁸Bureau of Mines estimate of China's usable iron ore production. The ore grade of the series is equivalent to 50% Fe content to provide data approximately comparable with world marketable production.

⁹In actuality, run-of-mine ore in China averages only about 35% Fe. Production of crude ore, as reported by the Trust Fund Project on Iron Ore Information of UNCTAD was as follows, in thousand metric tons: 1985—131,500; 1986—142,480; 1987—157,000; 1988—154,380; and 1989—162,000.

¹⁰Includes magnetite concentrate, pelletized iron oxide (from roasted pyrite), and roasted pyrite (purple ore).

¹¹Includes "roasted ore," presumably from pyrite, not separable from available sources.

¹²Data are for year beginning Mar. 21 of that stated.

¹³Gross weight is exported iron ore (Mauritania exports all of its iron ore).

¹⁴Gross weight calculated from reported iron content based on grade of 66% Fe.

¹⁵Concentrates from titaniferous magnetite beach sands.

¹⁶Includes manganiferous iron ore.

¹⁷Includes magnetite ore as follows, in thousand metric tons, gross weight: 1985—3,607; 1986—4,000 (estimated); 1987—4,979; 1988—5,492; and 1989—6,594.

¹⁸Includes byproduct ore.

¹⁹Less than 1/2 unit.

NA Not available.

¹Includes only those mines, complexes, or mining groups that had shipments of at least 4.0 million metric tons in 1988 or 1989.²The mixed ore is considered to be the result of "hematite enrichment."³Other Goan shippers include Damodar Mangalji & Co. (Pvt.) Ltd., V.S. Dempo & Co. (Pvt.) Ltd., Societa de Fomento Industrial (Pvt.) Ltd., Minerals & Metals Trading Corp. of India Ltd., Orient Goa (Pvt.) Ltd., V.M. Salgaocar & Brother Ltd., A.V. Sarmalkar, and Sesa Goa Ltd.⁴Liberian Mining Corp. (LIMINCO) assumed full control of the LAMCO Joint Venture in late 1989. The mining complex was being operated for LIMINCO by a subsidiary of the African Mining Consortium Ltd.

IRON OXIDE PIGMENTS

By Donald P. Mickelsen

Mr. Mickelsen, a mineral industry specialist with 16 years Bureau of Mines experience, has been the commodity specialist for iron oxide pigments since 1985. Domestic survey data were prepared by the author, and international data tables were prepared by Audrey D. Wilkes, international data assistant.

U.S. mine production of crude iron oxide pigments increased significantly over that of 1988, while shipments increased moderately and value decreased. Total domestic shipments of finished natural and synthetic iron oxide pigments remained relatively unchanged from those of 1988. Synthetic iron oxides comprised 61% of all shipments. The sale of the Columbian Chemicals Inc.'s synthetic iron oxide business to Mobay Corp. was blocked by the Federal Trade Commission in March 1990.

Construction materials was the largest end use for iron oxide pigments, followed, in order of rank, by paints and coatings; colorants for ceramics, glass, paper, plastics, rubber, and textiles; ferrites; industrial chemicals; foundry sands; animal feed and fertilizer; and other end uses.

List prices for iron oxide pigments remained unchanged from those in 1988. Price increases proposed by one major producer had little effect on the market because of competitive pricing.

The United States imported more than twice as much iron oxide pigment in 1989 as it exported, but an exact

comparison with 1988 data could not be made because of the conversion to the Harmonized Tariff Schedule by the U.S. International Trade Commission and the consequent incompatibility of the 1989 and 1988 classifications. Exports of pigment-grade iron oxides decreased substantially compared with those of 1988. U.S. imports for consumption of natural iron oxide pigments decreased substantially while synthetic iron oxide pigments increased slightly, resulting in an overall slight decrease in iron oxide pigment imports. Imports of natural iron oxide pigments are no longer delineated by color. Synthetic black pigment imports increased significantly, although synthetic red and yellow pigments imports increased only slightly. World mine production of natural iron oxide pigments for reporting countries also increased slightly in 1989.

LEGISLATION AND GOVERNMENT PROGRAMS

On January 1, 1989, U.S. Customs regulations and tariff schedules were modified in accordance with the Omni-

bus Trade and Competitiveness Act (Public Law 100-418) enacted by Congress on August 23, 1988. This law was passed in order to enhance the competitiveness of the Nation's industries and to improve the management of U.S. trade strategy. Subtitle B of the new law required that all tariff schedules conform to the nomenclature of the internationally established Harmonized System—a global system of classifying products for tariff purposes.

The new law restructured both the import and export classification systems. The new schedule B classification is now based on the organizational framework of the Harmonized Tariff Schedule of the United States. That is, equivalent import and export items are assigned the same 10-digit classification code. In the case of iron oxide pigment imports, 10 subheadings that applied to natural iron oxide pigments have been replaced by 4 less definitive codes, which also include the synthetic iron oxide pigments. The four synthetic import subheadings are now represented by statistical subdivisions. Iron oxide pigment exports are also represented by the same four subheadings as the imports.

Public Law 100-418 also requires

¹ Revised.

¹ Data reflects conversion to the Harmonized Tariff Schedule, effective Jan. 1, 1989, Public Law 100-418, Subtitle B.

that U.S. Government agencies implement the use of metric units in their business activities by the end of fiscal year 1992. All of the iron oxide pigment trade statistics collected by the Bureau of the Census are now being compiled and published in metric units, as required by that law. Consequently, the Bureau of Mines will publish its iron oxide pigment statistics in metric units and has converted all numbers in the text and iron oxide pigment tables to metric tons, unless otherwise stated. To convert from metric tons to short tons, multiply by 1.10231.

PRODUCTION

Mine production of crude iron oxide pigments increased 37% over that of 1988, and shipments increased a moderate 15%. The bulk of these increases were attributed to stockpiling of crude material by one producer and an increase of sales for nonpigmentary purposes by another. Lower valued nonpigmentary iron oxide sales also accounted for an overall decrease in value of crude shipments of 4%. Four companies mined and shipped various grades of iron oxide pigments. One company in Georgia mined and shipped ocher; magnetite was mined and shipped by a company in Missouri; and, of two companies in Virginia, one mined and shipped sienna, umber, and ocher, and the other shipped umber. Cleveland Cliffs Iron Co., which permanently closed its Mather Mine in northern Michigan in 1979, continued to ship hematite from stockpiles. A new company, Swansea Minerals Inc., shipped minor amounts of a micaceous, specular hematite processed from mine tailings at the Swansea Mine, La Paz County, AZ.

Total domestic shipments of finished natural and synthetic iron oxide pigments, excluding regenerator oxide, steel plant waste, and magnetic iron oxide, remained relatively unchanged from those of 1988 in both quantity and value. Shipments of finished natural iron oxide pigments increased slightly in both quantity and value. These increases were influenced mainly by increases in the black magnetite and red iron oxide categories, which accounted for almost three quarters of the natural iron oxides shipped.

Synthetic iron oxide pigments, which dominate the industry, comprised about two thirds of total shipments and experienced slight decreases in quantity in 1989, while total value remained essentially unchanged from 1988 levels. Slight decreases in shipments of synthetic iron oxide pigments occurred across the board, although value remained constant.

Iron oxides recovered from steel-plant wastes, including regenerator oxide and steel-plant dust, were reported by six domestic companies in 1989. Shipments totaled 30,745 tons and were valued at \$4,163,000. Perox Inc., a regenerator oxide producer based in Pittsburgh, PA, was added to the Bureau of Mines survey in 1989. Of the remaining five companies who reported shipments, two showed increases, one remained the same, and two showed decreases when compared

with those of 1988.

Pigment-grade iron oxides for use in magnetic applications were produced domestically in 1989, but are not included in table 2. Production and shipment data for magnetic iron oxides are not publishable because of their proprietary nature.

Domestic iron oxide pigment producers underwent a year of acquisition activities in 1989. In January, Cambrex Inc., a company that had an agreement in principle to purchase Pfizer Pigment Inc., one of three dominant domestic producers, terminated that agreement owing to a lack of business performance in the second half of 1988.¹ In August, Columbian Chemicals Co. announced it had signed a letter of intent to sell its iron oxide pigment plant in St. Louis, MO, to Mobay Corp., a

**PRODUCERS OF IRON OXIDE PIGMENTS, REGENERATOR IRON OXIDES,
AND STEEL-PLANT WASTE IRON OXIDES IN THE UNITED STATES IN 1989**

Producer	Mailing address	Plant location
Finished pigments:		
American Minerals Inc.	Box 677 Camden, NJ 08101	Camden, NJ.
Blue Ridge Talc Co. Inc.	Box 39 Henry, VA 24102	Henry, VA.
Columbian Chemicals Co.	303 Hofmeister St. Louis, MO 63125	St. Louis, MO, and Monmouth Junction, NJ.
Cyprus Specialty Metals Co.	301 Lindenwood Dr., Suite 301 Milwaukee, WI 53207	Frazer, PA.
Hilton-Davis Co.	2235 Langdon Farm Rd. Cincinnati, OH 45237	Cincinnati, OH.
Hoover Color Corp.	Box 218 Hiwassee, VA 24347	Hiwassee, VA.
Mobay Corp., Inorganic Chemicals Div.	Mobay Rd. Pittsburgh, PA 15205	New Martinsville, WV.
New Riverside Ochre Co.	Box 387 Cartersville, GA 30120	Cartersville, GA.
Pea Ridge Iron Ore Co.	Route 4 Sullivan, MO 63080	Sullivan, MO.
Pfizer Pigment Inc.	640 North 13th St. Easton, PA 18042	Emeryville, CA; East St. Louis, IL; Easton, PA.
Prince Manufacturing Co.	700 Lehigh St. Bowmanstown, PA 18030	Quincy, IL, and Bowmanstown, PA.
Solomon Grind-Chem Services Inc.	Box 8288 Springfield, IL 62791	Springfield, IL.
Crude pigments:		
Cleveland-Cliffs Iron Co., Mather Mine and Pioneer plant (closed July 31, 1979; shipping from stockpile.)	1100 Superior Ave. Cleveland, OH 44114	Negaunee, MI.
Hoover Color Corp.	Box 218 Hiwassee, VA 24347	Hiwassee, VA.
New Riverside Ochre Co.	Box 387 Cartersville, GA 30120	Cartersville, GA.
Pea Ridge Iron Ore Co.	Route 4 Sullivan, MO 63080	Sullivan, MO.
Swansea Minerals Inc.	6360 E. Rose Circle Dr. Scottsdale, AZ 85251	Tempe, AZ.
Virginia Earth Pigments Co.	Box 1866 Pulaski, VA 24301	Hillsville, VA.
Regenerator and steel plant waste iron oxides:		
Armco Inc.	P.O. Box 191 Ashland, KY 41101	Ashland, KY.
Gulf States Steel Inc.	174 South 26th St. Gadsden, AL 35904	Gadsden, AL.
Perox	95 32nd St. Pittsburgh, PA 15201	Birmingham, AL, and Sharon, PA.
Petco Inc.	225 S. 600 East Lehi, UT	Lehi, UT.
Shance Chemical Corp.	1 Depot Plaza Mamaroneck, NY 10543	Philadelphia, PA.
Weirton Steel Corp.	400 Three Springs Rd. Weirton, WV 26062	Weirton, WV.

subsidiary of the Federal Republic of Germany company Bayer AG. Columbian Chemicals and Mobay are the remaining two of the three dominant domestic synthetic iron oxide pigment producers, and the sale was subject to Federal Trade Commission (FTC) approval. This sale was subsequently blocked by the FTC, which cited restricted trade as justification for seeking an injunction on the sale.²

CONSUMPTION AND USES

Iron oxide pigments were consumed mainly as an ingredient in construction

materials; in coatings; and as colorants for ceramics, glass, paper, plastics, rubber, and textiles. Consumption data shown in this chapter represent domestically produced and shipped iron oxide pigments as reported by producers. The United States also imports iron oxide pigments, which are distributed through various trading firms and color companies as well as by some of the domestic iron oxide pigment producers. The Bureau of Mines is unable to ascertain the end-use applications of these imported materials. End-use data shown in table 4 were based on data reported by producers to the Bureau of Mines and do not include imported iron oxide pigments, except for possible minor amounts mixed

with domestic materials.

Consumption of iron oxide pigments in construction materials continued to be the largest end use. Use of domestically produced iron oxide pigments in construction material accounted for more than one-third of all shipments, the same as in 1988, and totaled 45,000 tons in 1989. In recent years construction use has been greater than the traditionally largest end use, paint and coatings, and was the end use with the most growth potential, because iron oxide pigment use in colored concrete blocks and roofing tiles was expanding. According to one study by F. W. Dodge, the Information Systems Div. of McGraw-Hill Co., newly started construction was valued at \$261.2

billion in 1989, remaining practically the same as that of 1988. Construction starts varied by region: the north-central and western regions had gains of 5% and 1%, respectively. Nonresidential building was the strongest sector during the year, increasing 3% to a value of \$93.1 billion; although the actual volume of work decreased 4%. Residential construction declined slightly to \$120.4 billion; single-family homes remained stable, and apartment and condominium construction was down 8%. Nonbuilding construction, including public works and utilities, also declined slightly to \$47.7 billion, principally owing to a large drop in highway and bridge construction.³

Coatings, the second largest use for iron oxide pigments, accounted for almost one-fourth of the iron oxide pigment consumption in 1989, decreasing slightly to 30,730 tons from 31,400 tons in 1988. Shipments for lacquer, paint, and varnish, as reported by the U.S. Department of Commerce, totaled about 1 billion gallons of coatings valued at \$11.6 billion, down slightly in volume but up 7% in value over those of 1988. Architectural coatings comprised 51% of all shipments and totaled 533 million gallons; product coatings (original equipment manufacture) was 33% of shipments, or 337 million gallons; and special purpose coatings

shipments were 16%, or 167 million gallons.⁴

Of all iron oxides, 17%, or 22,000 tons, were consumed as colorants for plastics, glass and ceramics, paper and textiles, and rubber, by order of rank. This was practically the same amount consumed in 1988. Iron oxide pigments were popular for these uses because of their low cost, coloring effectiveness in thermoplastics and thermosets, and acceptance by the Food and Drug Administration for food contact and medical applications.

The remaining 24% of reported iron oxide pigment consumption, in order of rank, was for use in foundry sands, industrial chemicals, ferrites, the manufacture of animal feed and fertilizers, and other end uses, including cosmetics, magnetic tape and magnetic ink, and polishing agents.

Regenerator oxides and steel-plant dust, not accounted for in table 4, were consumed mainly for use in the manufacture of ferrites, with lesser amounts used as colorants for cements and construction materials, industrial chemicals, foundry use, glass and ceramics, and fertilizers.

Magnetic iron oxides, also not included in table 4, were used mainly in the manufacture of ferromagnetic ceramics, magnetic media such as mag-

netic tapes and floppy disks, and in magnetic inks and toners.

PRICES

Domestic list prices for natural and synthetic grades of iron oxide pigments sold in 1989 by major producers remained practically unchanged from those of 1988. Although at least one major producer tried to increase prices beginning in the second quarter, competition from other producers discouraged this effort. The iron oxide pigment industry is an extremely competitive industry, and although some of the larger companies would like to increase prices to compensate for higher costs for labor, operations, and raw materials, competition from others makes this difficult. Synthetic iron oxides are the standard for the industry because they have the most consistent colors, highest tincture strength, and are easily dispersed. For these reasons, they command the highest prices and make up the greatest amount consumed. The competitive nature of the industry, however, has lowered the return for the companies involved and is one reason for the upheaval in ownership. Toward the end of the fourth quarter, prices were firming with little or no dis-

TABLE 4
ESTIMATED IRON OXIDE PIGMENT CONSUMPTION,¹ BY END USE,

⁶ Includes ferrite and animal feed and fertilizer iron oxide usage.

counting for bulk shipments. It was apparent that the new year would bring price increases of about 5 to 6 cents per pound for synthetic colors.⁵

Prices for imported iron oxide pigments also remained at 1988 levels. According to the American Paint and Coatings Journal, list prices for Italian burnt sienna were 50 to 78 cents per pound; for Turkish burnt umber, 47.5 to 56 cents per pound; and for Spanish red, 33.5 cents per pound.

FOREIGN TRADE

Trade statistics show that the United States imported 268% more iron oxide pigments than it exported in 1989. This apparently large trade imbalance was partly the result of the conversion of the U.S. foreign trade data system to the Harmonized Tariff Schedule on January 1, 1989, as required by Public

Law 100-418. This law changed the classification codes for both iron oxide pigment imports and exports. Therefore, an exact comparison could not be made.

U.S. exports of pigment-grade iron oxides and hydroxides decreased 55% in quantity and 52% in value when compared with those of 1988. However, because of the Harmonized Tariff Schedule classification changes, these data are not comparable. An analysis of the export data of the other grade iron oxide which increased 273% in quantity and 105% in value, indicated that pigment grade material was most likely included in this category. This analysis is based on the decrease in value of these other grades, which previously had a much greater average value, owing to the inclusion of magnetic materials in this category.

Exports of pigment-grade iron oxides went to 42 countries in 1989, principally in Asia, North America, and Europe. Chief destinations for iron oxide pigments were the Republic of Korea, Canada, and the Federal Republic of Germany. Exports of other grades of iron oxides and hydroxides were shipped mainly to the Federal Republic of Germany, Mexico, Japan, the Republic of Korea, and the United Kingdom, in order of rank.

U.S. imports for consumption of iron oxide pigments decreased 6% in quantity from those of 1988, but increased 13% in value. Imports were received from 19 countries in 1989, 1 more than in 1988. Imports of synthetic iron oxide pigments increased slightly in quantity and 17% in value. Synthetic iron oxides composed 86% of all imports received. Synthetic black, red, and yellow grades all increased in quantity, with the black grade showing a significant increase over that of 1988. The "other" category, including synthetic brown oxides, transparent oxides, and magnetic and precursor oxides, showed a sharp decrease. Synthetic iron oxides were received chiefly from Canada, the Federal Republic of Germany, Mexico, Japan, and the United Kingdom, in order of rank. Canada and the Federal Republic of Germany supplied 66% of the total synthetic iron oxides imported; Mexico, Japan, and the United Kingdom supplied 28%; and the remaining 6% were imported from other countries. Data on synthetic iron ox-

ides imported from Canada were as reported by the Bureau of the Census. It is likely, however, that a large portion of this material reported as a synthetic iron oxide pigment was misclassified, and was actually a regenerator iron oxide. This was apparent, because one of the two Canadian companies exporting iron oxide material into the United States was a steel-plant operator, not a pigment producer.

U.S. imports of natural iron oxide pigments decreased 36% for both quantity and value from those of 1988. Unit value for natural iron oxide pigment imports remained unchanged. Since the conversion to the Harmonized Tariff Schedule, there no longer exist classification codes for the natural iron oxide pigment grades. In order to remedy this situation, the Bureau of Mines submitted a request to the U.S. International Trade Commission to reinstate classifications for natural iron oxide pigment colors. The large quantity of the natural micaceous iron oxides imports reported by the Bureau of the Census in 1989 was most likely misclassified material, particularly those shown from Canada. The chief supplier of micaceous iron oxides to the United States was Austria, from which 92 tons were received in 1989. Canada, Cyprus, the Federal Republic of Germany, and Spain, in order of rank, supplied 97% of all imports of natural iron oxides, and the remaining 3% came from other countries. Imports received from Cyprus were primarily of crude and finished sienna and umber grades; from the Federal Republic of Germany, primarily Vandyke brown; and from Spain, natural red hematite and ocher. Minor amounts of natural and synthetic iron oxide pigments were received and stored in bonded warehouses for future consumption.

WORLD REVIEW

World mine production of natural iron oxide pigments for reporting countries increased slightly in 1989, totaling 283,000 tons, up from 276,000 tons in 1988. Of the reporting countries, India reported the greatest production, more than one-half of the world total. Other large producers of natural iron oxide pigments were the United States, Spain, France, and Cyprus, ranked in the or-

der named. Together with India, these countries produced 86% of the world total in 1989. In addition to the countries listed in table 9, other countries, including the centrally planned economy countries, produced natural iron oxide pigments in 1989. Production data for these countries, however, were not available. Natural red iron oxide was produced primarily by India and Spain; yellow ochre by Spain, the United States, Brazil, and the Republic of South Africa; and sienna by Cyprus and Italy. Cyprus was the major umber producer; Austria was the principal micaceous iron oxide producer; and the Federal Republic of Germany was the main Vandyke brown producer.

Synthetic iron oxides were one of the largest consumed colored inorganic pigments in the world. Their popularity was attributed to a favorable performance-price relationship. Iron oxides exhibit

high tinctorial strength and hiding power, chemical resistance, lightfastness, and weatherfastness at low pigmentation costs. Synthetic iron oxides have made continuous gains in total market share over natural iron oxides because of product consistency, higher tinting strengths, and more saturated color shades compared with natural grades. Principal world producers of synthetic iron oxides, in order of rank, included the Federal Republic of Germany, the United States, the United Kingdom, and Japan.

According to the Japan Inorganic Chemical (Pharmaceutical) Industry Association, shipments of iron oxides in Japan were expected to increase 3% in 1989, growing to 215,300 tons. This was an increase similar to that experienced in 1988. In 1989, iron oxides used for magnetic materials, the dominant end use in Japan, were estimated to be 154,000 tons. Iron oxide pigment con-

sumption in Japan in 1989 was estimated to be 30,000 tons, 42% of which was used in paints and the remainder in roads, construction materials, printing inks, synthetic resins, ceramics, paper-making, and other end uses, listed by order of rank. Another 31,000 tons of iron oxides was estimated to have been exported. Japan was producing more iron oxides from steel operations than it could consume in 1988, when it had iron oxide stocks of 25,000 tons. Iron oxide consumption in Japan is forecast to grow only slightly in the early 1990's. Japanese ferrite producers were operating at capacity, and increased ferrite production is expected in the United States.⁶

In the United Kingdom, the Cookson Group PLC and Magnesium International Corp. Ltd. formed a joint-venture company named Cookson Laminox Ltd. to manufacture synthetic

micaceous iron oxide (MIO). Based on a patented process developed by MPLC Laboratories Ltd., this technology will produce a synthetic iron oxide having the same lamellar characteristics as natural MIO, which impedes moisture penetration in paints and resists corrosion. The plant, having a capacity of 10,000 tons per year, was to be constructed at Peterlee near Durham. It was to ultimately create 40 jobs. Production was to begin in late 1989, and the pigment was to be marketed under the trade name Laminox.⁷

OUTLOOK

The outlook for the U.S. iron oxide pigment industry is expected to be one of continued growth despite a slight decrease in 1989. Domestic shipments of

finished iron oxide pigments are forecast to range from 141,000 tons to 153,000 tons by 1995. It is probable that shipments will reach the middle range of this forecast. Principal factors are the continued popularity of earth-toned colors, continued growth in construction activities, and continued growth in paint and coatings production. The low forecast of 141,000 tons would result principally from an increased demand for other pigment materials used as substitutes for iron oxide pigments, from a decrease in construction activities, or from a decrease in paint and coatings demand.

Shipments of domestic iron oxide pigments for use in construction materials are expected to continue increasing moderately and to help push probable iron oxide pigment requirements to the middle range of the forecast. Consumption for use in paint and coatings is expected to experience slower growth. Projected

growth rates indicate that the probable overall demand for domestic iron oxide pigments in the United States in 1995 will be 148,000 tons, representing an annual growth rate of 2.4%.

This forecast is based on the average annual growth rate of the gross national product (GNP) as prepared for the Bureau of Mines by DRI, a subsidiary of McGraw-Hill, which provides macroeconomic forecasting services. Iron oxide pigments used in construction materials in 1995 were forecast to range between 49,000 and 53,000 tons; end use for paint and coatings between 34,000 and 37,000 tons; and pigments used as colorants for ceramics, glass, paper, plastics, rubber, and textiles to range between 24,000 and 26,000 tons. Other end uses are expected to experience similar rates of growth, with the exception of ferrite use, which should reach the high end of the forecast of 3% per year or higher. A higher rate could also materialize if population growth increases at a higher rate than forecast or by changing trends in population movement.

IRON AND STEEL

By Anthony T. Peters

Mr. Peters, a physical scientist with 33 years industry and Bureau of Mines experience, has been the commodity specialist for Iron and Steel since 1988. International data tables were prepared by Virginia Woodson and Harold Willis, international data assistants.

The year 1989 was a good but not outstanding one for the industry. Raw steel production was 97.9 million tons, with 84.5% utilization of capacity reported to be 115.9 million tons. This was about 2% less than that of the previous year, when almost 100 million tons were produced by steel mills operating at 89.2% utilization of a capacity of 112.3 million tons. Imports were approximately 19% of demand, kept moderate by the relatively weak dollar and the strong demand for steel worldwide.

The profits of the top nine domestic steelmakers declined by about 22% in comparison with that of the previous year, to \$1.8 billion; by comparison, the profits in 1988 were actually eliminated by extraordinary expenses, and the \$2.3 billion profit became a \$559 million loss.

The year started very strongly, but by midyear steel demand, and thus production and prices, declined significantly. The first quarter capacity utilization of nearly 90% dropped to less than 80% near yearend. Table 1 summarizes the trends.

Worldwide, raw steel output reached another record high of 862.8 million tons. Increases of those of the previous year were registered by the European Community, which produced 154.1 million tons, an increase of more than 1%; Japan, 2% higher at 118.9 million tons; and the developing countries, most of which registered increases of 3% to 4%, to a total of 111.2 million tons.

Slight decreases occurred in the U.S.S.R. and Eastern Europe, but the People's Republic of China increased its production by approximately 3% over that of 1988.

industry was the extension of the Voluntary Restraint Agreement (VRA's) restricting steel imports into the United

States for an additional 2½ years, until March 31, 1992. The law's short title was Steel Trade Liberalization Program

Implementation Act of 1989. The industry preferred that the law cover 5 years, but the 2½ year extension easily passed both the House of Representatives and the Senate with hardly any objection. This compromise version did not contain some provisions requested by the steel industry. Additional details are presented in the Foreign Trade section.

The Department of Energy (DOE), as authorized by the Steel and Aluminum Energy Conservation and Technology Competitiveness Act of 1988, signed with the American Iron and Steel Institute (AISI) an agreement to finance up to 70% of a \$30 million cooperative program undertaken by eight member companies of AISI to develop a "direct steelmaking" process without coke ovens or blast furnaces. Details are discussed in the Technology section.

The DOE was also involved, under the terms of the Clean Coal Technology Act of 1987, in a development program for cleaning up coke plant emissions at the Sparrow's Point, MD, mill of Bethlehem Steel Corp. Also, the DOE financed part of a project to develop "superplastic" high-strength steels; two forges and a major minimill were involved.

The Environmental Protection Agency conditionally retained blast furnace slags, dusts, and sludges under the Bevill exemption for mineral processing wastes during 1989. These high-volume, low-hazard wastes from the extraction and beneficiation of ores and minerals were granted the exemption from subtitle C (hazardous) regulations under the Resource Conservation and Recovery Act, pending the evaluation of further hazard data. Slags, dusts, and sludges from the open-hearth and basic-oxygen furnaces were also conditionally retained during the same year. The Agency also extended the compliance time for the treatment of the electric arc furnace dust classified as hazardous until August 1990.

According to the Omnibus Trade and Competitiveness Act of 1988, the International Harmonized Customs Code System came into use on January 1, 1989. The act also mandated conversion of all governmental business to the metric system by 1992. Steel industry officials stated that the cost of the conversion, estimated at several billion dollars, would involve duplication and replacement of machinery, spare parts, tools, and rolling rolls. This rendered rapid adoption of the metric system impractical.

According to the requirements of the Comprehensive Anti-Apartheid Act of 1986, the President certified again that certain materials are "essential to the economy or defense of the United States" and must be excluded from sanctions against the Republic of South Africa. Exempted again from import controls were manganese, indispensable for all steels; chromium, the base of stainless steels; vanadium, essential for many tool steels; platinum group metals, irreplaceable in catalytic converters for automobile exhausts; and eight other materials.

The U.S. Department of Commerce determined that imports of new railroad rails from Canada were being subsidized and sold at 39% below fair trade value. Antidumping duties were assessed accordingly.

ISSUES

The raw materials of the steel industry are iron in the form of iron ore and scrap, coal in the form of coke, lime obtained from limestone, refractories, alloying materials, and coating metals. Adequacy of supply of some of these materials has been an issue in the steel industry.

The reserves of iron ore in North America are very large and are practically unlimited worldwide. (For details see the "Iron Ore" chapter.) Supplies of high-quality scrap, not contaminated with nonferrous metals, have been somewhat tight, but otherwise scrap supplies have been ample. The United States is a net exporter of scrap. These issues are discussed in the Iron and Steel Scrap chapter.

Coke represents a political problem. Although reserves of coking coals in the United States are very large, the coking industry is severely handicapped by harsh environmental rules. Fortunately, metallurgical coke, sometimes made from American coal, is obtainable from abroad, at a price. It does not appear that any new coke batteries will be built in the United States because of the uncertainty of environmental regulations. Possible changes in the Clean Air Act may cause the closure of several of the 40 existing coke plants. The reason is that there is either no technology available to meet the mandated limits or the large expenditures for compliance are not warranted by the

age of the existing installations. Most U.S. coke batteries are more than 20 years old, with perhaps 10 to 15 years life remaining. If no new coke ovens are built, the value of coke imports may reach \$3 billion per year if sufficient supplies from overseas are available. Availability of these supplies is uncertain.

Lime, the main refining flux, does not present any problems. Deposits of limestone are practically inexhaustible, and the lime burning kilns are under good ecological control. For details, consult the Lime chapter.

Ample sources of raw materials for furnace refractories are in existence, and the refractories industry, after some shakeouts in the 1980's, appears to be capable of supplying its primary customers, iron and steel plants, with all the goods needed.

Unfortunately, the country has ample supplies of only a few alloying elements, mainly silicon, and also the less important boron and molybdenum. The United States is totally dependent on imports for most others, including the irreplaceable and critical manganese and chromium mentioned earlier. The main reserve holder, producer, and supplier of these two metals is the Republic of South Africa. Shutting off the flows of manganese and chromium from the Republic of South Africa could grossly curtail steel production in the United States.

The two main coating metals, tin and zinc, were widely available, although their prices show strong variations. Some zinc was produced domestically, but most was imported. Apart from some recycled material, the United States is almost completely dependent on imports of tin. Fortunately, for many applications, chromized or aluminized steel could be used but, again, the country imports nearly all its chromium and some of its primary aluminum.

The other main issue confronting the steel industry was the question of the VRA's. The industry was skeptical that extension for only 2½ years was sufficient to complete the domestic modernization of plants and, especially, for negotiating free and fair trade in steel worldwide.

PRODUCTION

At yearend, there were 82 companies and independent subsidiaries producing

raw steel at 125 locations. Of these, 15 were integrated companies, organizations that produced raw iron by smelting iron ores and their concentrates and converting the iron to steel using the basic oxygen furnace refining process. This accounted for 60% of the production. The integrated mills also had several electric arc furnaces. The others were the mini-mills or nonintegrated operations that produce steel by remelting and refining iron and steel scrap, and some specialty steelmakers.

The State with the highest steel production again was Indiana, with 20.8 million tons; followed by Ohio, 16.4 million tons; and Pennsylvania, 11.9 million tons.

A summary of efficiency trends of the industry is presented in table 2.

There was an increase in the proportion of continuously cast steel for the year. This was probably due to some drop of production in the second half of the year—the less efficient ingot pouring operation would be suspended before any continuous casting operations were closed. The higher usage of work force reflects the tendency to hold on to skilled operators despite a drop in operations.

Integrated Mills

Armco Steel Corp. sold a 40% interest in its Eastern Division, producing flat products, to Kawasaki Steel Co. for \$350 million; the Japanese partner proposed to invest another \$350 million in rehabilitation of the Middletown, OH, and Ashland, KY, works in exchange for a further 10% ownership.

Inland Steel Co. culminated its long cooperation with the Japanese Nippon Steel Corp. by selling Nippon 13% of Inland's stock for \$185 million and buying 1% of Nippon Steel, the world's largest steelmaker. Because Inland had a number of profitable steel service subsidiaries, this was largely regarded as an antitake-over maneuver.

The LTV Steel Corp. completed the sale of its Bar Products Div. to its employees through an Employee Stock Ownership Plan. The new company was called Republic Engineered Steels, Inc.

United States Steel Corp. (USS) sold, for an undisclosed sum, a 50% interest in its only bar products integrated mill, the Lorain Works, to the Japanese Kobe Steel Corp. Kobe specializes in the production of high quality bar steels, and the announced purpose of the sale was the production of special bars for the

TABLE 2
EFFICIENCY TRENDS OF U.S. STEEL PRODUCTION

Year	Raw steel			Average steel ¹ product yield (percent)	Manpower ² input (hour per shipped ton)

Japanese-owned automotive companies in the United States. Major upgrading of the mill was planned.

An old rod mill from the South Works of USS at Chicago, IL, was sold to the Colombian Aceria del Rio Paz. Dismantling of this mill left only a wide flange mill operating.

USS also announced the construction of a third continuous caster at its Gary, IN, works. This will make Gary a 100% cast operation.

Minimills

For the first time in history, a nonintegrated steelmaker shipped more steel than an integrated company. North Star Steel Corp. shipped 2.26 million tons from its four mills whereas Wheeling-Pittsburgh Steel Corp. shipped 2.23 million tons. Nucor Steel Corp. was not far behind with shipments of 2.10 million tons. Once the two new mills of Nucor are producing at capacity, Nucor should be shipping in excess of 2½ million tons from its six operations. One, Nucor-Yamato Steel Corp., is 50% owned by the Japanese partner.

Nucor achieved a spectacular first in mid-1989 by starting the production of flat products using a new "thin slab casting" technique, developed in Germany. It appeared that by yearend the Crawfordsville, IN plant reached about 30% of its capacity of 800,000 tons of

hot-rolled coils. The entire greenfield mill cost \$265 million or \$331 per yearly product ton. This was considered low by integrated steel mill standards. Cold rolling was to be added within 1 or 2 years, but the width of only 52 inches (1,320 millimeters) makes the steel unsuitable for many applications, such as automotive use. Furthermore, electric furnace steel possesses some characteristics inherently undesirable for deep-formed flat products, mainly because of its relatively high contents of nitrogen and residual elements, such as chromium and copper.

Another first for Nucor was the mentioned Nucor-Yamato plant that makes large-size, wide-flange beams. This was a new product for minimills. This market had been occupied by the integrated majors.

Northwestern Steel Corp. was moving in the same direction, having bought the abandoned Houston, TX works of Armco Steel. This mill was to be converted to the production of large sections, including wide-flange beams. It was to be supplied by shaped cast blanks made on a continuous caster to be constructed at the main works in Sterling, IL. Like most minimills, Northwestern was also completing a ladle metallurgy station aimed at improved steel control. The heat size of this minimill was 380 tons, the largest electric furnace heat in the world, making this installation very unique.

Once this expansion is completed in 1990, Northwestern's capacity would be in excess of 2½ million tons per year.

Birmingham Steel Corp. announced that, in conjunction with Proler International Inc., a scrap processor, and Danieli S.P.A., an Italian mill machinery manufacturer, it would be building a flat products mill in Texas, to be named Buffalo Steel Corp. Proler owned 35% and Danieli 15% of the enterprise. The mill was to cast medium thickness slabs, 5 inches (127 millimeters) thick, and roll them on a hot strip mill reconditioned by Danieli. The abandoned Baytown Works of U.S. Steel Corp. was bought by Birmingham, and the environmental protection permits were transferred to the new owners. This made the startup of the new \$260 million, 1.2-million-ton hot strip mill possible as early as 1991.

The small New Jersey Steel Corp., a producer of reinforcing bars, announced a plan to build a flat products mill of 500,000-ton capacity using the thin slab casting technique, apparently the same as that utilized by Nucor.

Oregon Steel Corp., Portland, OR, bought an unused plate mill from California Steel Corp. for \$7.5 million. This mill, with a capacity in excess of 1 million tons of plate per year, was a part of the mills of the defunct Kaiser Steel Corp. in Fontana, CA, bought by California Steel in 1984. The mill was to stay in place and roll only about 150,000 tons per year of plate, which was needed for Oregon Steel's tube mill in Napa, CA. Enlargement of the melt shop in Portland would increase the tonnage at the Fontana mill.

A new minimill started production in 1989. This was the First Mississippi Corp. Inc., in Hollsopple, PA, with a capacity of 110,000 tons. Its two 40-ton furnaces were charged mostly with direct reduced iron and featured oxygen fuel burners and argon stirring from the bottom. This enabled the mill to make very low carbon low residuals clean steel. Once a ladle furnace and a horizontal caster are installed in 1990, this relatively small operation may be the most technologically advanced in the world. Until then, it makes ingots for sale.

Statistics regarding steel production and materials consumption are shown in tables 3 through 6.

Foreign Investments in the U.S. Steel Industry

Source: The WEFA Group, company reports

in 1980 did not cause much concern. Formation of California Steel Corp. in 1984 by a joint venture involving American, Brazilian, and Japanese interests was welcomed. This was the purchase and start-up of the rolling end of the defunct Kaiser Steel Corp. in Fontana, CA. Since then a number of major joint ventures came into being, mostly in 1989. Table 7 illustrates this trend.

Also, at least three small minimills, Auburn Steel Co., Auburn, NY, Razorback Steel Corp., Newport, AR, and Tamco,

Etiwanda, CA, are owned by Japanese interests. The bankrupt Phoenix Steel Corp. in Claymont, DE, was modernized by its new Chinese owners. It started again in 1989 to produce plates, working as Citisteel Corp.

The U.S. partners of foreign investors in domestic steel operations usually put up relatively small amounts of cash in joint ventures, totaling up to 1989 about \$450 million. The location itself and the local and marketing expertise were most critical. The foreign partner invariably

provided the majorities of the funds, totaling a little more than \$3 billion, plus technical expertise.

CONSUMPTION

Apparent consumption is the sum of steel mill shipments plus imports minus exports, with an adjustment, always small, for inventory change over the period in question. Before about 1960, the

United States was a net steel exporter, but thereafter it imported increasingly high amounts of steel. Imports in some months accounted for 30% of demand; consequently, correlation of demand with domestic production is poor, especially since the latter was affected by unpredictable occurrences such as steel or automotive strikes, introduction of the VRA's, etc.

The kind of demand is well known and fairly constant, judging from the extensive reports of shipments by the AISI and customs data for imports. Unfortunately, the categories are not identical, especially since the introduction of the Harmonized Tariff System in 1989. Thus, direct addition of categories is not possible. Furthermore, opinions vary as to the ferrous content of secondary steel imports, i.e., those of goods consisting mainly of iron and steel.

Eliminating from the AISI data the 10% to 15% of shipments classified as "other" or "unclassified" leaves data presented in table 8 divided in three groups.

The first group, distribution of shipments by steel type, indicates a shift from alloy to carbon steel. This is probably a reflection of the wide adoption of high-strength low-alloy steels, which are usually reported as carbon grades.

The second group, distribution of shipments by products, shows few changes over the past 5 years except for a growth of electrogalvanized steel. It is expected that this growth will continue, especially because of automakers' preference for this kind of steel for many applications.

The last group, distribution by markets, introduces a new variable—shipments to steel service centers and distributors. The final use of this steel is not known, but information from the Steel Service Centers Institute, with more than 400 members handling about 24 million tons of domestic and imported steel, indicates that up to one-half of this steel is ultimately used in construction, with about one-quarter used for replacement automobile parts and by machinery makers. The balance is spread over many applications.

It is remarkable that the distribution of steel by the main markets hardly changed over the past 20 years. The only major change was a drop of steel use by the canmakers in favor of aluminum. This trend seems to have stopped, as indicated by the numbers in the table. The

TABLE 8
DISTRIBUTION OF SHIPMENTS OF STEEL MILL PRODUCTS,
BY PERCENTAGE

		1985	1986	1987	1988	1989
Shipments by steel type:

Total shipments	thousand short tons	75,657	72,737	80,646	88,391	84,100

lowered shares of construction and of automotive and machinery markets in 1989 represent the weakness of these segments.

Castings

The actual consumption of iron and steel castings is difficult to estimate for two reasons: (1) a large part of the demand is satisfied by imports of castings or of assemblies not reported as castings but in which castings are a major part of the weight, and (2) many large industrial users, such as the General Motors Corp. and most integrated steelmakers, have their own foundries. These make castings for their own use but also sometimes for sale, with the sold tonnages usually classified with "other products."

The American Cast Metals Association made the following estimates of total demand in 1989 in short tons: Gray

iron.—7,210 million tons, with automobiles and trucks accounting for one-half of the total; Ductile iron.—3,300 million tons, pressure pipe and fittings consuming one-half of the total; Malleable iron.—320,000 tons; this is a decreasing commodity in favor of ductile iron; Plain carbon and low-alloy steel.—1,340 million tons; and high-alloy steel—130,000 tons, mainly stainless.

According to a survey by the U.S. Department of Commerce, ferrous foundries shipped the following amounts of castings: gray iron, 4,675 million tons; ductile iron, 2,815 million tons; malleable iron, 283,000 tons; and steel (carbon and alloy), 1,137 million tons. The differences between these numbers and the demand data shown previously probably represent imports.

The ferrous industry consists of about 1,200 foundries. Many use automated

production. A few also experiment with advanced melting methods; for example, General Motors was running an experimental electric plasma unit, with the goal of higher productivity, less melting loss, less pollution, and the ability to use low-grade feedstock such as turnings and borings.

STOCKS

There are no governmental stocks in existence. Steel mill inventories usually run to about 1 month's production, about 10 to 12 million tons, but one-half or more of this steel was earmarked for predictable future orders. Service centers typically carry about one-half of this amount, 6 to 7 million tons, representing 3 to 4 months of their shipments. Users' inventories are highly variable.

PRICES

Demand was strong and prices were firm at the beginning of 1989. This was true, except for the depressed oil country tubular goods market, and little if any discounting. Near yearend, the demand was low, especially from the automakers, and discounting was severe, up to 20% from list price and even more in stainless steels.

In the market, it is the discounting practice that determines a steel price. The nominal list prices are of no significance in a buyers market. The numerous quality and grade extras are enforced only in the infrequent periods of steel being on allocation for spot orders. Each steel sale is a negotiated transaction, not of any open market type. The traditional steel salesman's expression "steel is not sold, it is bought" is a characterization of steel as being demand driven, except for new specialty grades. Hence, determination of actual steel selling prices is not really possible. This is also due to the fact that at least 20 common grades and more than 100 specialties are traded every day in hundreds of sizes, shapes, gages, surface finishes, coatings, and qualities.

The Iron Age Magazine Finished Steel Base Index moved slightly during the year from \$495 per ton to \$512, a change of only about 3½%, which reflected the published list prices. The index appears

to be biased toward flat products made by the integrated steel producers and selling in the \$350 to \$700 range. The bars and structural shapes produced by the minimills and representing roughly 25% of all steel shipments cost much less and seem to be underreported in the index. In any case, the extent of discounting, even by minimills, made the published change of no practical significance.

The Iron Age Pig Iron Index was based on American-made foundry pig iron; because almost none was produced in the United States, the \$213 per ton, unchanged for several years, was only of historical interest. The actual prices of Canadian and Brazilian pig iron were in the range of \$170 to \$190 per ton.

FOREIGN TRADE

Exports

The relatively weak dollar helped several U.S. mills to export significant amounts of steel, varying from semifinished to electrogalvanized, to markets that seemed to be closed only a few years earlier. Most integrated steel producers such as U.S. Steel, which reactivated its closed export division, Bethlehem; LTV; Inland; Armco; and Geneva, reported shipments to the Far East, Europe, and South America. A number of minimills; such as Chaparral Steel Co. and Thomas Steel Corp., also reported such shipments.

Chaparral Steel was the first American steelmaker to obtain the quality approval from the Japan Institute of Standards, the Japanese standards organization, which is needed to participate in almost all Japanese construction projects. Other producers indicated that they were in the process of obtaining this certification.

Total exports in 1989 exceeded 4½ million tons, the best year since 1980. Table 9 shows the major shippers and recipients of U.S. steel; tables 10 and 11 list the exports by product categories.

Imports

The majority of steel imports entered the country under the terms of the VRA's. The VRA's 1 were originally established in 1984 when import penetration at times reached 30% of U.S. consumption. The purpose of the restrictions was to enable the U.S. industry to modernize its facilities. These VRA's, now called VRA 1, expired in late 1989.

In July 1989, President Bush announced a Steel Trade Liberalization Program extending the VRA for 2½ years. Overall, the steel import limit was set at 18.4%, the level of imports during the last year of operation of VRA 1. As a result of protracted negotiations, VRA's were signed with the European Community and 16 other countries. Instead of specifying tons, the agreements specified levels of participation as a percentage of U.S. consumption in 1989. Furthermore, all signatories agreed to work toward the elimination of steel trade distorting practices, such as refunds of taxes, subsidies, etc. On this basis, most countries had their quotas increased in the second and third part of the pact's duration. Table 12 appended the VRA's. Table 13 shows the imports of pig iron, mainly for foundry use. Tables 14 and 15 show the steel imports by product categories. Table 16 shows details of imports of stainless steels.

Distribution between individual steel products did not change much from the previous VRA except that quotas for semifinished steel imports were increased for countries owning rolling mills in the United States. The quotas for pipes and tubes were reduced from 38% to 24% of apparent consumption, reflecting the low demand level for the oil country tubular goods in the United States. Special steels were included in the overall VRA. The demand for semifinished steel, strong at the beginning of the year, tapered off to zero by midyear. Total imports were 17.3 million tons (disregarding castings) or approximately 19.5% of the total demand.

WORLD REVIEW

The production of pig iron, direct reduced iron, and raw steel (crude steel in Europe) in all countries is shown in tables 20 and 21. There are some minor discrepancies between the numbers published by the International Iron and Steel Institute and those obtained by the Bureau of Mines from individual inquiries; none appear to be significant.

Capacity

A precise estimate of steelmaking capacity is not possible. Not only is this number affected by normal operating conditions, such as variations of quality of raw materials and of product mix, but some countries count unused, obsolete

installations as capacity as long as the facilities exist, while other countries do not. Developing countries and centrally planned economies usually regard the best output of several past years as capacity but overstate the possibilities of new installations, etc.

It appears that the world's steelmaking capacity under normal conditions is on the order of 940 million short tons per year.

CURRENT RESEARCH

Some problems of technology not caused by political factors were diminished by two general developments.

The past 5 years saw a strong growth of cooperative research managed by AISI and involving member steel producing companies, universities, and also major supply and customer companies if the subject involved a raw material or properties of steel; for instance, a Refractories Research Center was established at the University of Missouri at Rolla. Although the original planning expected about 10 member companies to share the cost, no less than 23 members and suppliers signed up.

The flow of information became much more open than formerly. A good example was the wide variety of countries from which technical papers were presented at the annual Ironmaking and Steelmaking Conferences of the American Institute of Mining and Metallurgical Engineers. Papers originating abroad were uncommon before the 1980's, but in recent years about 20% of the presentations were from Japan, whereas another 20% or so came from other countries, including a few from the U.S.S.R.

An important development was initiation of the Direct Steelmaking Project, mostly funded by DOE and managed by AISI. This activity aimed at the development of a process to produce steel directly from iron ores or concentrates, bypassing the production of iron in blast furnaces and, thus, also the necessary coke ovens. Thus, pollution due to coke making and iron smelting is eliminated.

The process will be carried out in two connected vessels. The iron oxides, in whatever form, will be fed from the top along with coal, which will be the reducing agent. Oxygen for combustion will be blown in from the vessel's lower end. Partial refining of carbon-rich iron to crude steel is to take place there. Because this takes place in a closed system and the gases are returned to the first reduction vessel, pollution is eliminated or at least minimized.

The main differences between this process and the well-known methods of producing direct reduced iron are the use of coal instead of natural gas as a reductant and the production of crude liquid steel rather than solid, impure iron suitable as a scrap substitute.

An important development that occurred mainly in 1988 and 1989 was the wide adoption of flux pellets for the production of iron. Some details are discussed in the Iron Ore chapter.

Inland Steel Co. and the Research-Cottrell Corp. jointly developed a process for the reduction of sulfur levels in exhaust gases of coal-fired power stations and boilers. It involved controlled additions of limestone and lime powders into the flame. If widely adopted, it could reduce the acid rain problem.

The question of U.S. dependence on supplies of most alloying elements from foreign sources is discussed in the Issues section. The extent of possible substitutions was extensively studied, but not much progress can be expected in this area.

Other	10,701	6,252	26,078	10,273	13,307
Total	338,258	294,957	354,712	652,555	488,175

The consumption of alloying elements in various steel types is shown in table 17. Because many grades of various richness exist in most materials under discussion (e.g., three grades of ferromanganese, and some alloying practices involve scrap, oxides, and other materials), the reported totals tend to understate the actual demand. The consumption of silicomanganese is definitely understated because several minimills did not reply to repeated inquiries by the Bureau of Mines, and they are the main consumers of this alloy.

The sources of the alloying elements and the extent of imports are shown in tables 18 and 19.

OUTLOOK

Steel production in the United States is too strongly affected by non-recurring events with unpredictable outcomes to be amenable to normal forecasting

techniques. For instance, a major factor in the production level in 1991 will be a possible steel strike at U.S. Steel Corp. Strikes of up to 6-months duration occurred there in the past, and the corporation usually accounts for about 15% of U.S. steel production. In 1992, labor contracts expire at Bethlehem, National, and Inland Steel, and a prolonged strike or strikes could significantly affect the production level.

The costs of new clean air legislation should be known by 1991 or 1992, and these may have major impacts on steel-making policy in this country. If the restrictions result in compliance expenditures that are higher than acceptable to the industry, the "hot ends" of some mills will be closed, and the steel will be obtained from abroad in semifinished form.

A major question is the VRA's that expire in 1992. If the VRA's are retained, not much change should occur in the slow growth steel production pattern, assuming that other factors, such as the

value of the dollar, remain unchanged. However, if they are abandoned, the question becomes one of imports levels. If imports rise as high as those before the introduction of VRA in 1984, reaching up to 30% of consumption in individual months, U.S. steel production will contract sharply, and the shift to purchasing semifinished steel from abroad may be even more pronounced. If not, and the imports stay at 17% to 20% of consumption, production should not be severely affected.

As a very rough guess, it should be expected that in 1991–95, U.S. production in the case of combination of favorable factors could reach 115 million tons; if unfavorable factors predominated, raw steel production may be as low as 70 million tons.

One econometric model of steel production based on the actual production of 1982–89 assumes a steady growth with some shocks, such as a recession, assumed to occur in 1993–94. This model gives the following production numbers: 1991, 94.3 million tons; 1992, 93.6; 1993, 87.3; 1994, 78.5; followed by a recovery to 91.8 in 1995 and 100.7 in 1996.

BACKGROUND

Definition and Grades

Steel is probably the most versatile material known; its strength and hardness are proverbial. It can be cast into fairly intricate shapes, but its greatest advantage is the ability to deform without damage, at least within certain limits. Hence, large castings, called ingots, can be rolled into numerous sections used for structures, machines, and so forth, or into flat sheets and strips that can be formed into a multitude of products. They can also be drawn into wire, soft- or spring-quality.

Steel is by definition an alloy of iron with 0.02% to 1.7% carbon. Carbon is important because it is the chief controller of steel properties. Strength and hardness are directly proportional to the carbon content, as is heat treating, hardening by quenching from high temperature and subsequent tempering, toughening by reheating, or softening by annealing.

The soft steels containing less than 0.05% carbon are used for enameling sheets, for good atmospheric corrosion

^eEstimated.¹Product grouping based on U.S. Harmonized Tariff System.

resistance, and for electrical machines. Many are deep drawn, as into automotive bodies. Most stainless steels are low carbon.

The range of steels containing from 0.05% to about 0.15% carbon is mainly utilized for sheet and strip, where softness must ensure good formability; for example, a deep drawing steel used in flat products. Also, some alloy steels are made in this carbon range.

A carbon range from about 0.15% to 0.33% represents mainly structural steel for structures such as houses, bridges, and pipelines. Bars and plates are examples. Alloy grades exist.

From 0.34% to about 0.65% carbon, the steels are mainly rolled or forged into parts where high strength is the major requirement. Springs and plates are common in this range. Alloying elements are often used for critical requirements. Many products are heat treated.

Above 0.65% carbon, the steel becomes too hard, hence, too brittle for most uses. Some blades of agricultural implements, shafts, and tools not subject to shock loads are produced with up to about 1.0% carbon.

Steels containing more than 1.0% carbon are seldom if ever used. Equivalent strength level can be obtained by alloying and/or heat treatment without severe embrittlement. Special tool steels may have a higher carbon content.

Manganese is present in all steels. Although some manganese comes from the raw materials used—iron ore and scrap—more is usually added to liquid steel. It is required to combat the sharply embrittling effect of sulfur.

Sulfur is a common impurity, detrimental to steel properties except in resulfurized free-machining grades. Manganese acts as a strengthener and a weak hardener; but, because it does not impart brittleness to the steel, the steel retains its ductility. Therefore, manganese is often described as a promoter of toughness.

Most steels contain from 0.30% to 0.90% manganese. From 0.90% to 1.6% manganese is used to increase the strength and hardness of steels while retaining their toughness and, in steels with deliberate addition of sulfur (resulfurized grades), to minimize the resulting brittleness ("shortness") both when red hot and cold.

Many steels contain other alloying elements in addition to carbon. The purpose

²Consumption for High Strength, Low Alloy steels included in carbon steels.

³Including respective metal powders, oxides, and other forms converted to the ferroalloy.

⁴Underreported because of low response from minimills.

Note.—The steel production in 1988 was 99.99 metric tons, but presenting average alloy input per steel ton is technologically meaningless because of the large number of steel compositions.

Also, an estimated 30,000 tons of aluminum, mostly secondary, was used, most of it sacrificially for deoxidation, but some also for alloying; an estimated 15,000 tons of magnesium powder was used sacrificially for hot metal desulfurization and approximately 2,000 tons in the production of nodular cast iron.

Also, small amounts, under 500 tons, of bismuth, tellurium, and selenium were consumed in the production of free-cutting (free-machining) steels, approximately 5,000 tons of sulfur and less than 800 tons of calcium.

of alloying steels is to obtain specific properties or strengthen the steel to obtain weight savings for some particular design that otherwise would require a much heavier section of plain carbon steels.

High alloy steels, customarily regarded as those containing more than 5% of elements other than iron, include stainless steels based on chromium (12% to 30%) and high-speed tool steels, which retain their cutting edge at dull red heat,

thereby allowing fast machining. In decreasing order of importance, these always have tungsten, molybdenum, chromium, and vanadium in their composition, and, in the highest grades, there is also cobalt.

More than 80% of steel production is plain (unalloyed) carbon steels. A major part of these are the lower carbon grades, up to 0.10% carbon, causing another complication; in lower carbon ranges (up to 0.20% carbon), ingot steels of nominally identical composition can be made in several types—as unkilld (rimmed or mechanically capped), semikilled, or killed (deoxidized) steels. The properties of these steels differ drastically as do the costs of their production.

The importance of differentiation between steel types is, however, decreasing because of the wide adoption of the continuous casting method of solidifying liquid steel. This method is applicable to one type only, namely killed steels. Nevertheless, because about 35% of the U.S. output was still made using the old method of pouring in 1989, it is desirable to describe the properties of the steel types.

Rimmed or capped steels are characterized by a smooth, good surface that persists throughout processing and results in a product that easily takes almost any surface finish. However, the mechanical properties are rather low and not very uniform. Hence, although this type formerly was extensively produced for galvanizing, tinplating, painting, etc., it could not be used for stressed parts or be subjected to strong deformation, such as deep drawing.

Killed steels have uniform and reliable mechanical properties; this fact results in such steels always being selected, for example, by a machine designer or builder of heavily stressed structures. The surface quality is not as good as that of the rimmed grades but generally acceptable; it can be improved by careful steel conditioning. The production cost as ingots is fairly high.

An intermediate type, semikilled steel, falls between the two main classes; it has good and fairly uniform, but not outstanding, mechanical properties and a surface good enough for unexposed applications. It was the main type used for bars and plates and structural sections, especially for structures that are not critically stressed. The production cost is low.

Technology

Before World War I, the stress was on "country building" goods: rails, structural sections, and plates. After the 1920's, the demand for "population comfort" items, essentially formable "flat products" (sheet and strip), became increasingly important.

World War II introduced the concepts of steel and raw materials conservation; for instance, the substitution of molybdenum, freely available in the United States, for the imported tungsten in tool steels.

These trends culminated in the development of a new family of High-Strength Low-Alloy steels, based mainly on manganese with either columbium (niobium in Europe) or vanadium or both, often with molybdenum and other elements.

The push toward the development of the new, higher strength products, hence lower weight for equivalent mechanical performance, was given by two industries: line pipe, which had to be light but strong for constructional purposes, and automobiles. The clean air acts required greater fuel economy. Thus, if the performance were not to suffer, automobiles had to become lighter. Hence, the need for strong yet lightweight steel.

The following sums up the growth and decay of steelmaking processes in North America.

Crucible.—The only process known before Bessemer; very slow, very small scale, erratic product quality.

Bessemer.—Origin unknown, this process developed because of the possible realization that steelmaking is an oxidation process contrary to the relatively well-known blast furnace production of iron. Growth was caused by rapidly expanding markets in "country building" structural steels, known as "heavy products," plus the availability of low-sulfur and phosphorus ores. The production rate reached 40 tons per hour. Decay was due to the inability to remelt mill return scrap

¹Crude cast-iron from the blast furnace or cupola furnace.

²Direct reduced iron is obtained from ore by reduction of oxides to metal without melting. World direct reduced iron capacity is 27,680,000 short tons.

³Table excludes ferroalloy production except where otherwise noted. Table includes data available through June 20, 1990.

⁴In addition to the countries listed, Vietnam and Zaire have facilities to produce pig iron and may have produced limited quantities during 1985-89, but output is not reported and available information is inadequate to make reliable estimates of output levels. Production is pig iron unless otherwise specified.

⁵Reported figure.

⁶Includes blast furnace ferroalloys.

⁷Presumably from blast furnaces only. Although Iran has direct reduction iron plants attaining a reported 365,000 short tons per year capacity, no production data are available.

¹Steel formed in first solid state after melting, suitable for further processing or sale; for some countries, includes material reported as "liquid steel," presumably measured in the molten state prior to cooling in any specific form.

²Table includes data available through June 20, 1990.

³In addition to the countries listed, Burma, Ghana, Libya, and Mozambique are known to have steelmaking plants, but available information is inadequate to make reliable estimates of output levels.

⁴Reported figure.

⁵Data are for year ending June 30 of that stated.

⁶Includes steel castings.

⁷Revised to zero.

and customer scrap, to refine phosphorus and sulfur, and to produce alloy steels. The basic Bessemer process developed in Europe could not be utilized in the United States because it required high-phosphorus iron (more than 1.5% phosphorus), the phosphorus being the main internal fuel. Such ores do not occur in North America.

Open Hearth.—Developed from the need to remelt scrap as well as use iron from the blast furnaces and to produce low-alloy to medium-alloy steels (up to about 5% alloying elements). The process' moderate ability to refine sulfur and phosphorus out of raw materials later developed the basic lined version of the process. Because of the high capital and operating cost and low productivity in comparison with the basic oxygen process and the difficulty of intermittent operation, open hearth process began to decline.

Decay was slowed down by extensive use of oxygen and natural gas, but accelerated by stringent air pollution controls. Only about 3% to 5% of U.S. production comes from old open hearths.

Electric Arc.—Originated because of the availability of cheap power and the need for making high-alloy steels. The process is economical in a large range of furnace sizes (5 to 300 tons, per heat). Its independence of iron supplies, ease of startup and shutdown (for weekends in foundries), good reproducibility (leading to ease of computerized control), and ease of synchronization with a continuous caster have promoted growth. About 35% to 40% of U.S. production comes from arc furnaces.

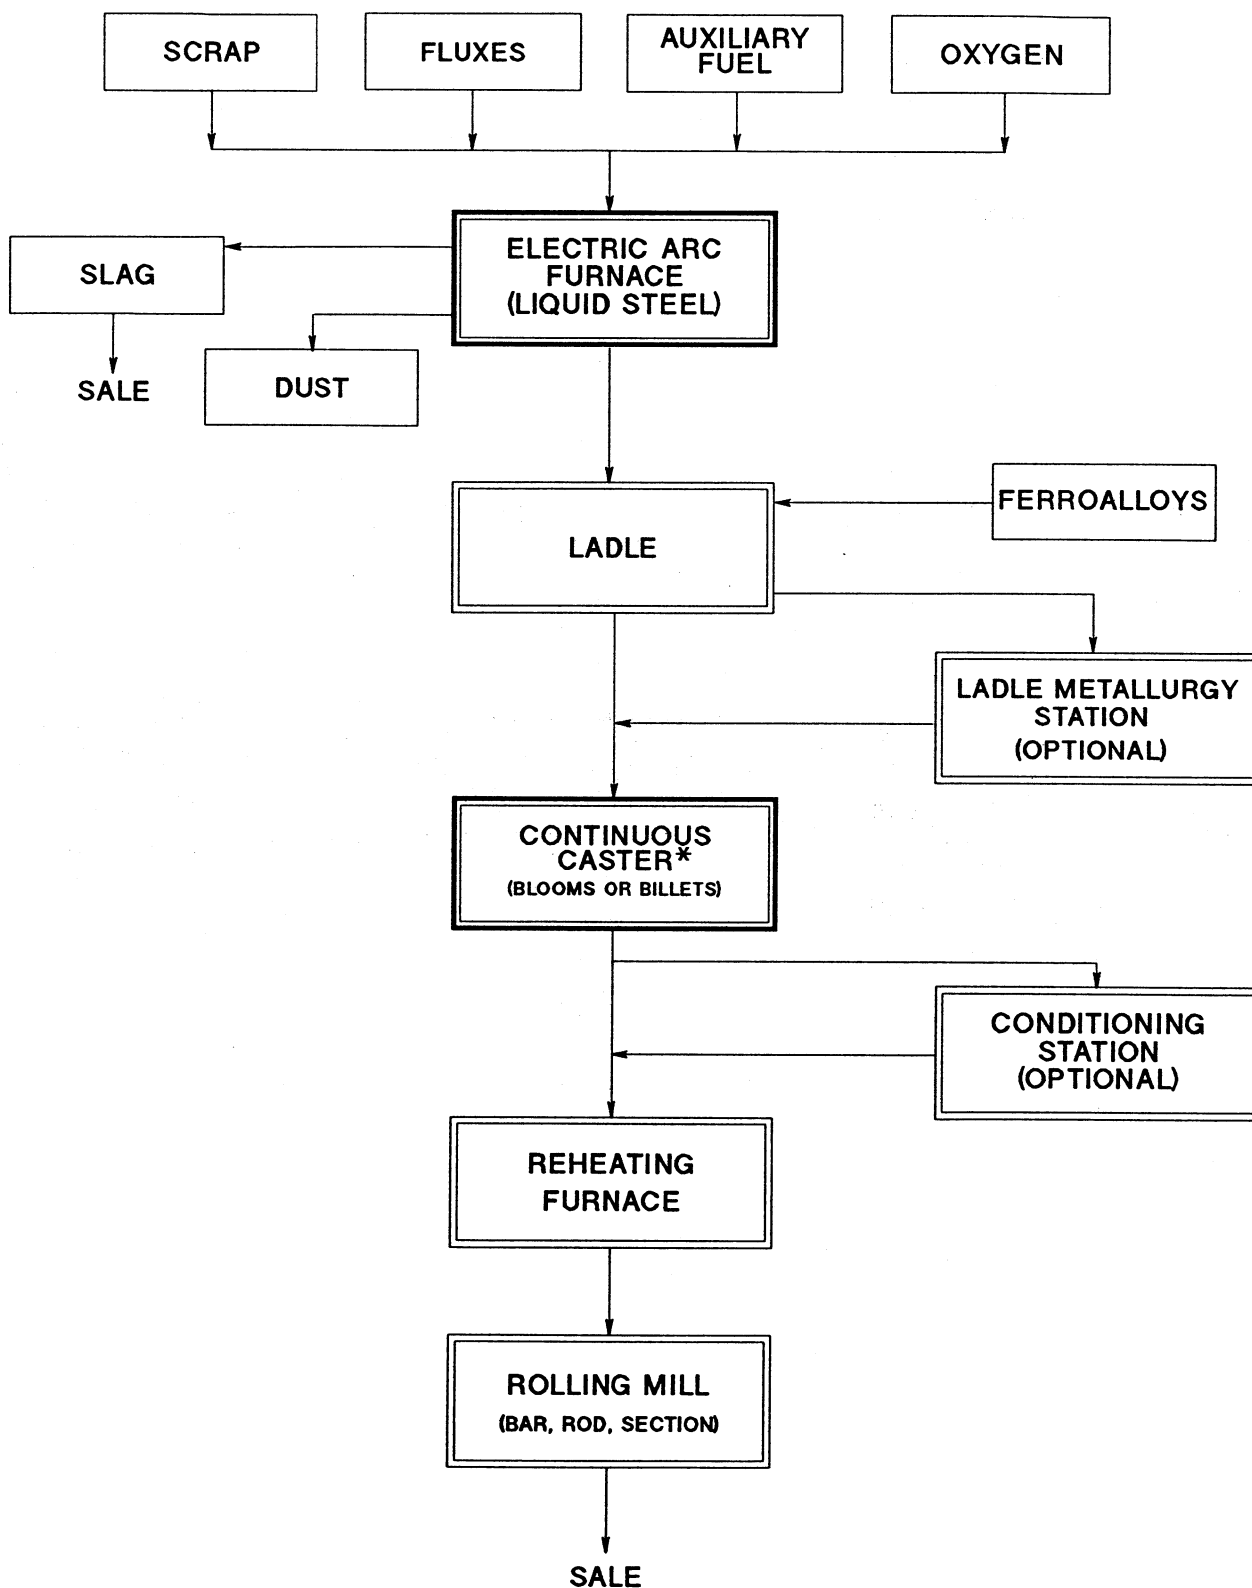

Basic Oxygen.—Originated from the unavailability of scrap in the country of its origin (Austria). It has high productivity and low capital cost of new installations,

but requires hot metal from blast furnaces. The basic oxygen process will continue to be used. Flowsheets illustrating these different ironmaking and steelmaking practices are shown in figures 1 through 4.

IRON AND STEEL SCRAP

By Raymond E. Brown

Mr. Brown, a physical scientist with 34 years of industry and Bureau of Mines experience, has been the commodity specialist for iron and steel scrap since 1986. Domestic survey data were prepared by Sarah P. Guerrino and Shirley M. Miller, Ferrous Data Section. International data tables were prepared by William L. Zajac, International Data Section. Tables 9 and 17 were prepared by the author.

DOMESTIC DATA COVERAGE

Brokers, dealers, and other outside sources supplied domestic consumers in 1989 with 43.6 million short tons¹ of all types of ferrous scrap at a delivered value of approximately \$4.63 billion, while exporting 12.3 million tons (excluding re-rolling material and ships, boats, and other vessels for scrapping) valued at \$1.75 billion. In 1988, domestic consumers received 47.1 million tons at a delivered value of approximately \$5.06 billion; exports totaled 10.1 million tons valued at \$1.35 billion. This represented a 7% decrease for received quantities and a 22% increase for exported quantities.

Domestic production data for ferrous scrap were developed by the Bureau of Mines from voluntary monthly or annual

surveys of U.S. operations. Of the operations to which a survey request was sent, 57% responded, representing an estimated 70% of the total consumption shown in table 2 for three types of scrap consumers. Consumption for the nonrespondents was estimated using prior reports adjusted by industry trends. An estimation error was also contained in the difference between the reported total consumption of purchased and home scrap and the sum of scrap receipts plus home scrap production, less scrap shipments and adjustments for stock changes. For scrap consumption data shown in table 2, this difference amounted to 0.3% for manufacturers of pig iron and raw steel and castings, 2% for manufacturers of steel castings, 5% for iron foundries and miscellaneous users, and 1% average for all types of manufacturers combined.

LEGISLATION AND GOVERNMENT PROGRAMS

In 1989, the United States generated about 160 million tons of municipal solid waste (MSW). About 9% of this solid-waste stream was composed of metals. A large percentage of the metal fraction in the waste stream consisted of ferrous components. A proposal by the Environmental Protection Agency (EPA) to reduce air emission levels from incinerators by at least 90% and to improve the recycling marketplace included a provision that would mandate a 25% source separation before incineration. The EPA's overall agenda for action indicated that by 1992, the MSW stream diverted by source reduction and recycling would be increased from 10% to 25%, landfilling would be decreased from 80% to 55%, and the amount of MSW combusted in municipal waste combustors would be increased from 10% to 20%. This would be the first time that the Federal Government has required recycling.²

In accordance with section 3004 (g) (5) of the Resource Conservation and Recovery Act (RCRA), the EPA was proposing to prohibit the land disposal of certain hazardous wastes listed in the U.S. Code of Federal Regulations (40 CFR 268.12).³ One comment by the American Foundrymen's Society Inc. on the proposal was that the proposed treatment standards for D006 (cadmium) and D008 (lead) were based on wastes that were dissimilar to those generated by foundries and should not be applied to foundry wastes.

As a result of an agreement between the Port Authority of New York and New Jersey and the New York State Legislative Commission on Solid Waste Management, the Port Authority conducted a study and published a report on export markets for post-consumer

secondary materials. The study was also designed to determine material composition and waste generation rates for these two States.⁴

On July 25, 1989, the President announced a steel trade liberalization program, under which the Voluntary Restraint Agreements (VRA's) would be extended for 2½ years, terminating on March 31, 1992. The President directed the U.S. Trade Representative to negotiate VRA's at an overall restraint level of 18.4%, which was the same as the 1988 VRA import penetration level.

The U.S. Office of Technology Assessment published a two-part report, including a summary, on MSW. The report examined the problems associated with MSW, which included increasing generation, declining landfill capacity, opposition to new management facilities, concerns about risks, and rising costs.⁵

The U.S. Department of Energy (DOE) signed final agreements in November for its part of a \$40 million project to reduce sulfur dioxide emissions from coke oven gases at Bethlehem Steel Corp.'s, Sparrows Point, MD, plant. DOE would contribute \$13.5 million to the project, announced in July, as part of a \$92 million overhaul of the Baltimore, MD, facility.

AVAILABLE SUPPLY, CONSUMPTION, AND STOCKS

Overall domestic demand for ferrous scrap by the iron and steel and the ferrous castings industries, the major consumers of this raw material, decreased about 6% in 1989 compared with that of 1988. Domestic demand for ferrous scrap by producers of pig iron and raw steel was down by both a larger quantity and a larger percentage than that for producers of ferrous castings. Because of continued strong worldwide demand for ferrous scrap in 1989, prices for most grades remained high.

International Mill Service (IMS), Philadelphia, PA, started engineering work for on-site electric furnace dust processing facilities at Atlantic Steel Co., Atlanta, GA, and Lake Ontario Steel Co. (Lasco Steel), Whitby, Ontario, Canada. IMS already operated Tetronics plasma dust processing facilities at two other domestic minimills:

Florida Steel Corp.'s mill in Jackson, TN, and the Nucor Corp. and Yamato Steel Co. joint venture in Blytheville, AR. IMS was one of only two domestic companies that operated facilities that used a thermal treatment process to remove zinc from electric arc furnace dust. Horsehead Resource Development Co., Palmerton, PA, was the other domestic company that performed thermal treatment of baghouse dust. Zinc recovered from baghouse dust by the IMS process was in metallic form, whereas that recovered by the Horsehead process was in oxide form. The EPA had given electric furnace (EF) operators a deadline of August 8, 1990, to treat EF dust to meet their standards. At that time, EF dust containing more than 15% zinc must be processed via thermal treatment.

The American Metal Market, New York, NY, and Recycling Times, Washington, DC, began quoting prices on clean used densified steel-bodied cans. Both of these publications provided prices per gross ton for various primary buying locations. A study by the Steel Can Recycling Institute, Pittsburgh, PA, revealed that steel food cans and steel beverage cans were recycled at a rate of 15% in 1988.

AMG Resources Corp., Pittsburgh, PA, planned to open a steel can recycling facility in St. Paul, MN. The plant would recycle 40,000 tons of steel cans annually from a five county area. Proler International, Houston, TX, had established a new satellite facility in Kansas City, KS. The facility would only serve as a collection point for post-consumer steel cans. The materials collected at the Kansas City location would be shipped by rail to Proler's plant in Houston, TX, for detinning.

Raytheon Service Co. (RSC), Burlington, MA, a wholly owned subsidiary of the Raytheon Co., Lexington, MA, has been the full service contractor for the Delaware Solid-Waste Authority resource recovery facility since March 1, 1984. Results from Bureau of Mines pilot-plant tests of MSW from approximately 1973 to 1981 were the basis for the design of two Raytheon commercial-scale reclamation plants. The Delaware Reclamation Plant (DRP) was one of these plants. An intensive cooperative effort was maintained between the Bureau of Mines and Raytheon during the MSW pilot-

plant testing period. RSC designed, built, and operated the DRP located at Pigeon Point near Wilmington, DE. From MSW, RSC recovered and marketed ferrous and nonferrous metals and glass at the DRP. This plant also recovered a refuse derived fuel (RDF) that was fired at an adjacent energy-generating facility and produced humus products suitable for many horticultural applications. MSW delivered to the DRP was first shredded to a nominal 4-inch particle size. Shredded waste was then air classified to remove RDF. Following air classification, the remaining waste was then processed to remove ferrous scrap through a series of magnetic separators. The recycled ferrous scrap was then shipped loose directly to Lukens Steel Co., Coatesville, PA, through a broker, The David J. Joseph Company, Cincinnati, OH. The DRP recovered between 6,000 to 7,000 tons of ferrous scrap annually. More than half of the ferrous fraction was comprised of steel cans.

Bayou Steel Corp., La Place, LA, was accepting post-consumer ferrous scrap for its minimill steelmaking process. Bayou used virtually 100% scrap in its two 65-ton electric arc furnaces, which had a combined annual capacity of 700,000 tons of raw steel.

Kobe Steel Ltd., Tokyo, Japan, invested an estimated \$300 to \$400 million in USX Corp.'s Lorain Works in Lorain, OH. The plant consumed significant quantities of scrap. Birmingham Steel Corp., Birmingham, AL, agreed to be bought out by a corporation headed by one of its outside directors for \$525 million. Harbert Corp., the purchaser, was a closely held Birmingham, AL, based company with interests in other areas. Birmingham Steel, a fast growing minimill chain, operated six plants in six states with a combined annual capacity of nearly 1.5 million tons.

North Star Steel Co., Minneapolis, MN, announced a tentative decision to discontinue operations at its Milton, PA, plant. North Star had negotiated for 6 months with union officials after buying the former Milton Manufacturing Co. minimill facility in February 1988. North Star's president was quoted as saying, "while the decision to close is not final, without acceptance of our final proposal to the union, we do not intend to continue operations at the Milton facility."

Razorback Steel Corp., Newport, AR, was sold for \$20 million to a partnership formed by Sumitomo Corp. of America (SCA). Razorback was a small independent minimill operation that produced 200,000 tons per year of steel in two 30-ton electric arc furnaces. The purchasers included SCA and its parent company, Sumitomo Metal Industries Ltd. of Osaka, Japan; Yamato Kogyo Co. Ltd. of Himeji, Japan; and Auburn Steel Co. of Auburn, NY, owned by Kyoei Steel Ltd. of Osaka, Japan. The partnership was named Arkansas Steel Associates.

Ford Motor Co., Dearborn, MI, announced it would sell its Rouge Steel Co. subsidiary in Detroit, MI, to Marico Acquisition Co. Marico, composed of a group of investors, was an organization formed specifically for the purchase. Rouge Steel, the Nation's ninth largest steel producer, had two 225-ton electric arc furnaces with a combined annual raw steelmaking capacity of 900,000 tons.

Auto dismantlers continued to play a vital role in the recycling chain as suppliers of auto parts and scrap. The dismantling industry was a major source of scrap in the United States,

handling seven to eight million vehicles each year. The Automotive Dismantlers and Recyclers Association (ADRA), Washington, DC, was supportive of legislation that promoted recycling to protect the environment and conserve natural resources.⁶

A symposium entitled "Steel Survival Strategies IV" was held in New York, NY, on June 27-28. Nearly 600 people attended the forum that was cosponsored by American Metal Market and Paine Webber Inc.'s World Steel Dynamics, both located in New York, NY.

Imports of metallurgical-grade coke decreased about 14% in 1989 to 2.31 million tons compared with that of 1988. Metallurgical coke imports represented 7% of domestic apparent consumption in 1989 compared with 8% in 1988. The United States continued as a net importer of metallurgical coke. Domestic coal consumption in coke plants decreased slightly more than 1% in 1989 to 41.4 million tons. However, domestic metallurgical coal exports increased 5% in 1989 to 65.1 million tons compared with those of 1988.

Raw steel production was 97.9 million tons in 1989 compared with 99.9

million tons in 1988. The shares of raw steel produced by electric, basic oxygen, and open-hearth furnaces were, respectively, 36%, 60%, and 5% in 1989 and 37%, 58%, and 5% in 1988. Continuous cast steel production represented 65% of total raw steel production in 1989 compared with 61% in 1988. Raw steel capacity utilization was 85% in 1989 and 89% in 1988. However, raw steel production capability was 115.9 million tons in 1989 compared with 112.0 million tons in 1988.

Net shipments of all grades of steel mill products were 84.3 million tons in 1989 and 83.8 million tons in 1988. Imports of steel mill products decreased from 20.9 million tons in 1988 to 17.3 million tons in 1989. Exports of steel mill products increased sharply from 2.07 million tons in 1988 to 4.58 million tons in 1989. The apparent supply of steel mill products decreased from 102.7 million tons in 1988 to 97.0 million tons in 1989. Imports of steel mill products, as a share of the U.S. market, decreased from 20% in 1988 to 18% in 1989. Steel mill processing yields increased from 84% in 1988 to 86% in 1989. Pig iron production increased slightly from 55.7 million tons

FIGURE 1

**RAW STEEL PRODUCTION (AIS), FOR ALL TYPES OF MFR'S COMBINED:
TOTAL IRON AND STEEL SCRAP CONSUMPTION, PIG IRON CONSUMPTION,
HOME SCRAP PRODUCTION, AND NET SCRAP RECEIPTS**

in 1988 to 55.9 million tons in 1989.

Iron castings shipments totaled 7.77 million tons in 1989 compared with 9.59 million tons (revised) in 1988. Steel castings shipments totaled 1.14 million tons in 1989 compared with 1.21 million tons (revised) in 1988.

Steel mills accounted for 72% of all scrap received from brokers, dealers, and other outside sources; steel foundries received 5%; and iron castings producers and miscellaneous users received 23%. The apparent total domestic consumption of ferrous scrap in 1989, in million tons, was composed of 45.9 net receipts (total receipts minus shipments), 25.4 home scrap, and a buildup of 0.1 stocks. The 1989 total was 71.2 million tons; the apparent total domestic consumption was 77.3 million tons in 1988. The total market for U.S. scrap (net receipts plus exports minus imports) was 57.3 million tons in 1989 compared with 59.0 million tons in 1988. Stocks of ferrous scrap held by steel mills and ferrous foundries increased in 1989.

The percentage of scrap consumed in the United States to produce a ton of raw steel was about 60% in 1989. Of the steel scrap consumed by domestic steel mills, about three-fourths was purchased from sources outside the steel plant in 1989.

PRICES

Based on average composite delivered prices per long ton quoted weekly and monthly by the American Metal Market (AMM), No. 1 heavy melting steel scrap cost \$107.30 in 1989, ranging from a low of \$96.67 in November to a high of \$116.07 in February. Based on Iron Age data, No. 1 heavy melting steel scrap cost \$107.66 in 1989, ranging from \$97.00 in December to \$116.08 in February. The average composite price for No. 1 heavy melting steel scrap in 1989 was lower compared with that of 1988, by 2% based on AMM data and by 1% based on Iron Age data. Continued strong demand, primarily from European consumers, propelled the price of nickel-bearing stainless steel scrap to a record high in 1989. In the Pittsburgh, PA, area, prices paid by consumers for the bellwether 18-8 grade peaked at \$1,675 to

\$1,700 per gross ton in March.

In 1989, the average price for total ferrous scrap exports increased 6% to \$142.42 per short ton compared with that of 1988 while that of total imports increased 3% to \$133.19 per short ton.

FOREIGN TRADE

For 1989, the foreign trade tables were based on the Harmonized Tariff Schedule (HTS) that became effective January 1, 1989. HTS increased the number of classes for both exports and imports (see the Bureau of Mines March 1989 Mineral Industry Surveys on Iron and Steel Scrap for more details). Additionally, valuation continued to be reported on a "f.a.s." basis for exports and on a "customs value" basis for imports.

The trade surplus in 1989 for all classes of ferrous scrap (including re-rolling material and ships, boats, and other vessels for scrapping) reached a record high of \$1.63 billion in value and 11.4 million tons in quantity. This was an increase of 28% in value and 20% in quantity compared with the 1988 surplus of \$1.27 billion in value and 9.43 million tons in quantity. The balance of trade for all U.S. merchandise [exports (f.a.s.) less imports (customs value)] showed a deficit of \$109 billion in 1989, down from a deficit of \$119 billion in 1988.

The quantity and value of both exports and imports reached record highs in 1989. Both the quantity and value of exports in 1989 increased by a larger percentage than imports compared with that of 1988.

Total U.S. exports of ferrous scrap (excluding re-rolling material; ships, boats, and other vessels for scrapping; stainless steel; and alloy steel) in 1989 went to 54 countries and totaled 11,435,701 tons valued at \$1,319,041,944, which averaged \$115.34 per ton. Six countries received 77% of the total quantity. The largest tonnages went to Turkey, 3,225,272 tons; the Republic of Korea, 2,779,185 tons; India, 943,828 tons; Canada, 936,626 tons; Mexico, 543,136 tons; and Japan, 357,539 tons. The value of scrap exports to these six countries was \$1,012,605,738; 77% of the total value.

Total U.S. exports of stainless steel

scrap in 1989 went to 30 countries and consisted of 291,609 tons valued at \$320,682,621 averaging \$1,099.70 per ton. Six countries received 83% of the total quantity. The largest tonnages went to Japan, 76,426 tons; the Republic of Korea, 58,537 tons; Spain, 51,492 tons; Canada, 23,929 tons; the Netherlands, 16,665 tons; and the Federal Republic of Germany, 15,293 tons. The value of stainless scrap exports to these six countries was \$275,874,190, 86% of the total value.

U.S. exports of alloy steel scrap (excluding stainless steel) in 1989 were shipped to 42 countries. The total comprised 562,921 tons valued at \$108,918,315, which averaged \$193.49 per ton. Six countries received 68% of the total quantity; the largest tonnages went to the Republic of Korea, 149,017 tons; Canada, 72,487 tons; Taiwan, 49,555 tons; Japan, 43,713 tons; Sweden, 33,991 tons; and Saudi Arabia, 33,120 tons. The value of alloy steel scrap to these six countries was \$64,812,644, 60% of the total value.

Total U.S. imports for consumption of iron and steel scrap were supplied by 31 countries in 1989. They contained 11,889 tons of tinplate waste or scrap valued at \$1,902,585.

WORLD REVIEW

World demand for iron and steel scrap increased slightly in 1989, but for the second consecutive year it reached a new alltime high. Demand for ferrous scrap, on a percentage basis, was higher in developing countries than in industrialized or western world countries. The largest increase in demand on a percentage basis came from the Republic of Korea.

The United States continued to be the leading exporting country of iron and steel scrap. France, the Federal Republic of Germany, the U.S.S.R., and the United Kingdom were also major exporters of ferrous scrap.

The International Iron and Steel Institute (IISI) estimated that the world steel industry achieved a 40% recycling rate in 1989. The estimated 300 million tons of secondary raw materials consumed represented significant energy savings and reduction in steel mill emissions and in wastes sent to landfills.

The recycling rate for steel production was much higher than that for other basic engineering materials.

Metal Bulletin, United Kingdom, held its first international scrap and secondary metals conference in Padua, Italy, in September. Also, the planning and building of direct reduction plants continued in areas such as India and Venezuela.

ISI published its third survey on cokemaking capacity in the western world. The report included details on plant ownership, location, number of batteries and ovens, age profile and physical dimensions, and the various processes employed in the production of coke in 35 countries.⁷

The total number of shredders in operation worldwide in 1989 was estimated at 601 (see table 17). The United States was the world's leading country in the total number of shredders, power, and tonnage capacity. Japan followed the United States in the total number of shredders in operation. The total number of shredders in the European Community was about equal to that in the United States. The most significant development was in the United Kingdom where 57 existing shredders would be augmented by an additional 3. Although not indicated in table 17, new shredders were reported also in Taiwan and Singapore.

CURRENT RESEARCH

Nucor Corp., Darlington, SC, began operating the world's first thin-slab caster for sheet steel production in June at its new minimill plant in Crawfordsville, IN. Other companies had been planning to open new plants or modify existing mills to take advantage of this new technology. They included Co-Steel Inc., Toronto, Ontario, Canada; Falck SpA, Sesto San Giovanni, Italy; Avesta AB, Stockholm, Sweden; Yieh United Steel Corp., Kaohsiung, Taiwan; and New Jersey Steel Corp., Sayreville, NJ. Additionally, Birmingham Steel Corp., Birmingham, AL, had announced earlier in the year that with the help of international partners, it would build a ministrip mill. However, that decision was being reviewed at yearend.

Development of processes to extract

iron from ore without the use of coke on a low economy-of-scale basis (500,000 tons per year), such as the Corex process and the iron carbide process, would likely result in a significant increase of "market-sized" flat-rolling steel mills throughout the world.⁸ Industrial-scale production of the Corex process began at Iscor Ltd.'s Pretoria Works in the Republic of South Africa in 1989, and the world's first commercial-scale iron carbide plant would likely be in production in the United States by midyear 1991.

In September, General Motors Corp.'s Central Foundry Div., Defiance, OH, held a dedication ceremony for the first plasma melter in the foundry industry. To construct the plasma melter, General Motors, in conjunction with Westinghouse Electric Corp. and Modern Equipment Co., modified an existing cupola furnace and added six 1.5-megawatt direct current plasma torches to the tuyere sections to provide the needed heat source.⁹

Schott Incorporated, the coowner of a proprietary hot metal technology, was using a recuperative hot blast cupola for producing steelmaking quality molten iron. Charge materials to the cupola consisted of carbon-bearing, iron oxide agglomerates that were both self-reducing and self-fluxing and charge carbon that consisted of anthracite coal briquettes. This technology could be used by ironmaking facilities having annual capacities ranging from 100,000 tons per year to those with no upper limit on output. One concept under consideration was combining (duplexing) the molten iron with purchased ferrous scrap as a metallic charge to electric furnaces.¹⁰

The American Iron and Steel Institute organized a forum to identify research opportunities. Direct steelmaking, near net shape casting, and intelligent processing were selected as the most important areas to address.

Carnegie Mellon's Center for Materials Production (CMP), Pittsburgh, PA, was developing a cofunded project to determine the cost effectiveness of the CONSTEEL process for the continuous feeding, preheating, melting, and refining of steel scrap in the electric arc furnace. The project, with Florida Steel Corp., Tampa, FL, and seven sponsors, sought to develop an economic and energy analysis of the process.¹¹ Also,

CMP held a symposium in Pittsburgh, PA, in November on commercially available processes and emerging technologies for treating electric arc furnace dust. The meeting included a thorough review of laws and regulations. Additionally, CMP sponsored a shredder residue planning meeting in Atlanta, GA, in October. The purpose of the meeting was to provide input to CMP and the Institute of Scrap Recycling Industries Inc., Washington, DC, so that an industry-wide meeting could be arranged to present and discuss solutions and useful research and development programs for the auto shredder residue (fluff) disposal problem.

In September, Tokyo Steel Manufacturing Co. Ltd., Tokyo, Japan, began operating what was believed to be the world's largest direct current (DC) arc furnace at its Kyushu Works. Initial monthly production of the 130-metric-ton DC arc furnace was 75,000 to 80,000 metric tons, tapping up to 23 heats per day.

OUTLOOK

The total market for U.S. ferrous scrap is affected by many factors. For example, major factors that impact the demand for domestic scrap include the quantities of domestic raw steel and ferrous castings produced, the level of scrap exports, and Government laws and regulations. To a lesser extent, other factors affecting the overall market for U.S. scrap include the production levels of U.S. industries that make ferroalloys, cement copper, and certain chemicals; the use of scrap substitutes; technological changes in steel mills and ferrous foundries; and the value of the U.S. dollar in relation to other world currencies. The health of the world's steel mills and ferrous foundries is of the utmost importance to the domestic scrap industry. The United States, the world's leading exporter of ferrous scrap, relies heavily on exports as a safety valve for the release of excess scrap when domestic demand slips.

The outlook for the total market for U.S. ferrous scrap is expected to be one of continued growth despite a slight decrease in 1989 to about 57 million short tons. The total market for U.S. scrap is forecast to range from 59 mil-

lion tons to 68 million tons by the year 1995, representing an average annual growth rate ranging from 0.6% to 3.0%, respectively. It is probable that by 1995 the total market for U.S. ferrous scrap will be closer to the mid-range of this forecast, reaching 64 million tons, which represents an average annual growth rate of 1.9%. This optimistic forecast is based predominantly on a combination of favorable factors affecting the market, which primarily include continued world growth in the quantity of steel produced in scrap-based electric arc furnaces; an increase in the percentage of steel that is continuously cast; and an absence of

excessive Government rules or restrictions on U.S. exports of scrap.

Total	^r 346,197	^r 351,719	^r 350,946	^r 356,967	380,086

^c Estimated. ^r Revised.

¹ Unless otherwise noted, figures represent reported consumption of iron and steel scrap utilized in the production of pig iron, ferroalloys, crude steel, foundry products, and rerolled steel, as well as other unspecified uses in the steel industry and by other unspecified industries as reported by the United Nations Economic Commission for Europe in its Annual Bulletin of Steel Statistics for Europe, 1988, v. 16, New York, 1989, 28 pp., which is the source of all reported data unless otherwise noted. All estimates are by the U.S. Bureau of Mines.

² Source: Canadian Foundry Association as reported by Energy, Mines, and Resources Canada.

³ Excludes scrap consumed by steel rerollers.

⁴ Excludes scrap consumed outside the steel industry.

⁵ Source: U.S. Bureau of Mines.

⁶ Reported data are from Instituto Latino Americano del Fierro y el Acero. Statistical Yearbook of Steel Making and Iron Ore Mining in Latin America, 1989, Santiago, 1990, 231 pp. Source does not provide details on what is included; presumably figures include total steel industry ferrous scrap consumption but exclude scrap used outside the steel industry.

⁷ Portugal and Spain became members of the European Community on Jan. 1, 1986.

⁸ Excludes scrap consumed in iron foundries.

⁹ Includes scrap used in production of steel castings in shipyards but excludes scrap, if any, used in production of pig iron and that used in iron foundries.

¹⁰ Excludes scrap consumed within the steel industry for purposes other than the manufacture of pig iron, ferroalloys, crude steel, foundry products, and rerolled steel (details on use not available).

¹¹ Source: Organization for Economic Cooperation and Development. The Iron and Steel Industry in 1985, Paris, 1987, 52 pp.; The Iron and Steel Industry in 1986, Paris, 1988, 52 pp.; The Iron and Steel Industry in 1987, Paris, 1988, 52 pp.; and The Iron and Steel Industry in 1988, Paris, 1989, 52 pp.

¹² Excludes a substantial tonnage derived from shipbreaking, possibly in the order of several million tons annually, for electric-furnace-equipped steel mills.

KYANITE AND RELATED MATERIALS

By Michael J. Potter

Mr. Potter, a physical scientist with 23 years industry and Bureau of Mines experience, has been the commodity specialist for kyanite since 1975. Domestic survey data were prepared by Joe Daniels, mineral data assistant; and international data table was prepared by Peter Roetzel, international data assistant.

U.S. kyanite production in 1989 was estimated to have decreased slightly compared with that of 1988 due to a drop in activity in the iron and steel industry, a major consumer of refractories.

Kyanite, andalusite, and sillimanite are a closely related trio of aluminum silicate minerals, differing slightly in physical properties and crystallographic characteristics, but sharing the same chemical composition, which can be represented as $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$. When heated, kyanite begins to break down to a noticeable extent at 1315°C (andalusite at $1,382^\circ\text{C}$ and sillimanite at $1,549^\circ\text{C}$) to form a mixture of mullite, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, and vitreous silica, SiO_2 . The mullite so produced usually consists of an aggregation of interlocking, acicular crystals and remains dimensionally and chemically stable until the temperature is raised to at least $1,810^\circ\text{C}$. These properties enable mullite to serve to advantage as a component in refractory shapes and furnace linings for a wide range of industrial applications. Above $1,810^\circ\text{C}$, mullite dissociates slowly with little change in volume into corundum (Al_2O_3) and silica, which recombine to form mullite at lower temperature.

Topaz, $\text{Al}_2\text{SiO}_4(\text{F},\text{OH})_2$, and dumortierite, $\text{Al}_7(\text{BO}_3)(\text{SiO}_4)_3\text{O}_3$, are also often classed as members of the kyanite group of minerals. Upon firing, topaz loses fluorine and dumortierite loses boron, yielding refractory residues consisting essentially of mullite. A number of other substances—fire clay, siliceous bauxite, and kaolin, for example—owe their ability to perform satisfactorily in some refractory applications to the fact that, when heated, at least part of the aluminum silicate they contain is converted to mullite.

There are three types of synthetic mullite. Low-temperature sintered synthetic mullite is made by sintering sili-

ceous bauxite or mixtures of bauxite and kaolin above 1549°C . High-temperature sintered synthetic mullite is prepared by sintering mixtures of alumina and kaolin, bauxite and kaolin, or alumina, kaolin, and kyanite above $1,749^\circ\text{C}$. Fused synthetic mullite is made by melting Bayer process alumina and silica, or bauxite and kaolin in an electric furnace at about $1,900^\circ\text{C}$.

All domestic kyanite ore is ground to permit separation and recovery by froth flotation of the mineral particles from accompanying gangue. The flotation-concentrate product is graded for sale to consumers in five particle-size ratings: 35, 48, 100, 200, and 325 mesh. Kyanite concentrates may contain from 56% to 60% alumina, from 38% to 44% silica, and from 0.2% to 0.9% iron oxide. Lump kyanite from India, ranging in size from pea size to boulders, was formerly imported into the United States. Indian reserves are limited, however, and material is no longer being exported.

DOMESTIC DATA COVERAGE

Domestic production data for kyanite and synthetic mullite were developed by the Bureau of Mines by means of two separate, voluntary, domestic surveys. The Bureau estimated kyanite production by using the last reported production levels adjusted by the trend of the iron and steel industry. In the synthetic mullite survey, all three canvassed operations responded, providing 100% of the total production tonnage data represented in table 1.

LEGISLATION

The allowable depletion rates for ky-

TABLE 1
U.S. PRODUCTION OF
SYNTHETIC MULLITE

1989	W	W

^eEstimated. W Withheld to avoid disclosing company proprietary data.

anite, established by the Tax Reform Act of 1969 and unchanged through 1989, were 22% for domestic production and 14% for foreign operations.

ISSUES

Andalusite continued to be imported into the United States in 1989 as one of several minerals and metals, which were exempt under a section of the Comprehensive Anti-Apartheid Act. The exemption list included strategic minerals for which the quantities essential for the economy or defense of the United States are unavailable from reliable and secure suppliers.

PRODUCTION

Kyanite was produced at two open pit mines by Kyanite Mining Corp., the Willis Mountain and East Ridge Mines in Buckingham County, VA. The company also operated beneficiation plants and calcining facilities for conversion of kyanite to mullite.

High-temperature sintered mullite

was produced by C-E Minerals Div. of Combustion Engineering Inc. at Americus, GA, and Didier Taylor Refractories Corp. at Greenup, KY. Electric-furnace-fused mullite was produced by Washington Mills Electro Minerals Corp. at Niagara Falls, NY.

CONSUMPTION AND USES

Domestic consumption of kyanite and synthetic mullite was mostly in the Eastern States. Utilization of the materials was limited west of the Mississippi by the expense of shipping from the existing production facilities in the East.

The Bureau of Mines does not collect data on end uses of kyanite and synthetic mullite. However, refractories for the iron and steel industries were probably the major end use of kyanite-mullite, consuming an estimated 55% of the quantity produced. Nonferrous metallurgical operations were believed to be the next largest use, estimated at 20%. A third category, estimated at 15%, consisted of glassmaking furnaces, ceramic kilns, boilers, petroleum-processing equipment, etc. Nonrefractory uses were estimated to comprise the remaining 10%.

In the iron and steel industries, mullite is important in critical areas of blast furnace stoves and stacks, reheat furnaces, steel degassing chambers and soaking pits, and many types of auxiliary pouring and handling equipment. In the nonferrous metal industry, an end-use example is in refractory linings of alumina reduction cells.

Other miscellaneous uses include kiln furniture, blown aluminum silicate high-temperature insulation, brake linings, foundry mold facings, glass additions for alumina contents, ceramic tile, pyrometer tubes, high-tension insulators, spinnable mullite fibers, shell castings, ceramic honeycomb, mortars, grinding media, whitewares, extrusion dies, and welding rod coatings.

Substitute and alternative materials for kyanite-group and mullite products in refractories include fire clay, calcined bauxite, and alumina. Other materials such as magnesite, chromite, silicon carbide, and zircon are interchangeable for specific end uses and conditions. Local availability of refractory raw materials is an important factor in choosing refrac-

tory products because transportation costs may prohibit use of alternative, technically superior materials.

PRICES

Prices at yearend 1989, in British pounds, from Industrial Minerals (London), were unchanged from the previous year. Price increases for 1989 in table 2 represent a stronger British pound against the U.S. dollar than in 1988.

FOREIGN TRADE

Shipments of U.S. kyanite, mullite, and synthetic mullite were believed to have been made to destinations in Europe and Asia. Imports of andalusite were approximately 10,300 metric tons from the Republic of South Africa, with a customs value of \$1,550,000.

WORLD REVIEW

Capacity

Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

The data in table 4 are rated capacity for mines and refineries as of December 31, 1989. Capacity data for Japan, the Republic of South Africa, and Sweden were obtained from literature sources. For other countries, recent peak production or estimated production was considered to be equal to rated capacity.

South Africa, Republic of

The country's andalusite industry was described in a journal article, including occurrence, properties, producers, uses, reserves, production, mining, beneficiation, and outlook.¹

CURRENT RESEARCH

The conversion of sillimanite to mullite was described in a paper entitled "Exploitation and Utilization of Sillimanite Minerals."² It was suggested that the temperature of initial decomposition and complete decomposition of sillimanite varies according to composition, impurity content, and grain size of the concentrate. When the grain size was less than 0.088 millimeter (mm), the sillimanite concentrate began to transform into mullite at 1,400° C and transformed into mullite com-

pletely at 1,700° C. When the grain size was larger than 0.088 mm, the initial conversion temperature of sillimanite concentrate became higher (approximately 1,500° C), and the complete conversion temperature was higher than 1,700° C.

OUTLOOK

Changes have taken place in iron-making and steelmaking and other high-temperature industries such as more intensive agitation, higher temperatures, and larger temperature fluctuations. More durable refractories have been required to meet these challenges. At the same time, consumption of refractories per ton of steel and other materials produced has gone down. Some lower duty refractories are being replaced by higher duty ones

¹ Owing to incomplete reporting, this table has not been totaled. Table includes data available through Mar. 30, 1990.

² In addition to the countries listed, a number of other nations produce kyanite and related materials, but output is not reported quantitatively, and no reliable basis is available for estimation of output levels.

³ In addition, about 7,000 metric tons of sillimanite clay (also called kaolinized sillimanite) is produced annually containing 40% to 48% Al₂O₃.

⁴ Revised to zero.

^s Reported figure.

based on kyanite-mullite. Raw or calcined kyanite provides needlelike blades in a refractory or ceramic body, which are interworked throughout and form a very mechanically strong product.³ Because of these unique properties, kyanite has maintained a stable consumption pattern and should continue to do so in the near future.

BACKGROUND

Products for Trade and Industry

Kyanite and related materials are consumed in the manufacture of high-alumina or mullite-class refractories and in lesser quantities as ingredients in ceramic compositions. U.S. kyanite is marketed either in raw form or after heat treatment as mullite. In the 35- to 48-mesh range, kyanite is used in monolithic refractory applications such as high-temperature mortars or cements, ramming mixes, and castable refractories, or with clays and other ingredients in refractory compositions for making kiln furniture, insulating brick, firebrick, and a wide variety of other articles. More finely ground material, minus 200 mesh, is used in body mixes for sanitary porcelains, wall tile, investment-casting molds, and miscellaneous special-purpose ceramics.

Data on the properties of finished refractory products are available from the producing firms. However, selection of the best refractory available for a specific application can sometimes be made only by testing under actual operating conditions. Load-bearing capacity, slag resistance, spalling characteristics, and other factors are often of prime importance.

Zircon sand containing some kyanite, sillimanite, and/or staurolite is used for foundry and refractory sand.

Industry Structure

Only a small number of countries world wide are currently producers of kyanite-group minerals. In France, the sole producer of andalusite is Denain-Anzin Mineraux Refractaire Ceramique (Damrec), a subsidiary of Mineraux Industrielle de Refractaire et Ceramique. Material is shipped to markets in Europe. India's reserves of lump kyanite are limited and material is not being

exported. In the Republic of South Africa, the world's largest supplier of andalusite, producing companies include Annesley Andalusite (Pty) Ltd., Cullinan Minerals Ltd., Hoogenoeg Andalusite (Pty) Ltd., Purity Minerals (Pty) Ltd., Verref Mining (Pty) Ltd., and Weedon's Minerals (Pty) Ltd. Material is exported to Europe, Japan, and the United States. In Sweden, kyanite output from the new and only producer, Svenska Kyanite AB, has been running below the plant capacity of 25,000 tons per year. Production in 1989 was estimated to be 5,000 tons.

Resources

There has been no comprehensive determination of domestic kyanite reserves, but a total of 30 million tons of kyanite content is a conservative estimate. In the category of kyanite resources, the quantities of that mineral existing in several States in deposits not currently or only marginally workable at a profit are known to be large, and kyanite makes up as much as 10% of the weight of a number of extensive formations of micaceous schists and gneisses.⁴

Established kyanite reserves in Brazil were given as 3.7 million tons. Large reserves of andalusite and sillimanite were reportedly discovered in China. Reserves of andalusite in France were approximately 4 to 5 million tons of contained andalusite. In the Republic of South Africa, reserves of andalusite are 50.5 million tons.

Information on foreign reserves of kyanite-group minerals is somewhat limited; however, kyanite deposits have been reported in several countries, including Austria, Bulgaria, Canada, India, Kenya, Liberia, Spain, the U.S.S.R., and Zimbabwe.⁵

Technology

Beneficiation.—Both mines of the one U.S. kyanite producer are open pit, hard-rock quarrying operations. Blasted material is reduced to manageable size by drop-ball breaking and trucked to the processing plants where it is crushed to minus 1-inch size in jaw and cone crushers and then ground in rod mills to minus 35 mesh or finer. Two stages of flotation with alkaline-fatty acid or acid-petroleum sulfonate collec-

tors produce an intermediate kyanite concentrate, which after being freed from iron by high-intensity magnetic treatment, becomes a salable product. Some kyanite is calcined at about 1,593° C and sold as mullite.

Byproducts and Coproducts

Quartzitic waste tailings from kyanite concentrators may be marketed locally as construction sand but transportation costs limit the areal scope of this byproduct.

Andalusite occurs in pyrophyllite ores that are mined by a company for ceramic and refractory purposes in North Carolina. A zircon-refractory heavy-mineral sand produced in Florida contains a small amount of aluminum silicates (kyanite, sillimanite, and staurolite) and is used for foundry and refractory sand.

LEAD

By William D. Woodbury

Mr. Woodbury is a physical scientist with the Branch of Nonferrous Metals. He had 25 years of geotechnical experience upon becoming the Bureau's lead specialist in 1982. Domestic survey data were prepared by P. Wiser and S. Hays, Nonferrous Data Section. International data tables were prepared by G. Jacarepaqua and A. Wilkes, International Data Section.

The year 1989 will be remembered within the lead industry, worldwide, as one of many records and accomplishments in several sectors. Most significantly, it was very profitable as the world price was sustained at high levels throughout the year, averaging the highest since

1981, and the fourth highest ever. Spot shortages of premium grades developed, and at yearend reported total metal stocks held by world producers, consumers, merchants, and the London Metal Exchange (LME) represented only about 3 weeks of demand.

In the United States, production at

secondary lead smelter-refineries and consumption of lead for storage batteries established record highs. Recovery from old scrap also set a new record. Total primary refinery production was about the same as that in 1988. However, the Nation's oldest and largest lead smelter-refinery established record

¹ Because of the implementation of the Harmonized Tariff System in Jan. 1989, import and export categories for 1989 are not necessarily comparable with those in previous years.

² American Bureau of Metal Statistics Inc.

³ Primary metal production only. Includes secondary metal production where inseparably included in country total.

production and output-per-worker levels, while simultaneously setting record-low injury rate and air pollutant emissions levels. Domestic mine production increased significantly, primarily because of a large mine coming on-stream in Alaska. As a result, the United States became a significant net exporter of lead concentrates for the first time, virtually all to Canada.

World mine production decreased marginally from that of 1988, and on a recoverable basis was 54% of demand. World secondary refinery production reached a record 2.65 million metric tons, and world demand increased for the seventh consecutive year, setting a record for the third consecutive year.

LEGISLATION AND GOVERNMENT PROGRAMS

In a major ruling by the Environmental Protection Agency (EPA) in September, in response to a court-ordered deadline, primary lead smelter slags were one of five mineral processing wastestreams conditionally retained in the Bevill exclusion from Federally regulated hazardous materials rules under the Resource Conservation and Recovery Act (RCRA), part B, as amended. This ruling was expected to be retained when final rules are promulgated, by court-ordered agreement, in January 1991. However, process wastewater was not retained in the exemption. The latter is only a fraction in volume of the former, however, and can be recycled effectively with best available technologies (BAT) at a cost estimated by EPA to be 0.1% to 0.2% of the 1988 value of refined metal shipments.

In a related matter, the EPA proposed in December that lead-acid batteries be prohibited from processing at Municipal Waste Combustors (MWC's) as part of an overall requirement that 25% of all recyclable materials entering the systems be salvaged. The regulation will be finalized in 12 months under MWC regulations.

At the state level, an historic occurrence with significant impact was the passage in Missouri of a new law, which, for the first time, regulates mine tailings. The industry-backed rules established a permit and fee system for lead, zinc, and iron ore tailings, set

forth reclamation standards for closure, and established a trust fund administered by the State for reclaiming the tails when currently active mines permanently close. The new law is known as the Metallic Minerals Waste Management Act of 1989. In Colorado, ASARCO Inc. reached an agreement with the State and EPA on a remediation program for a portion of the Leadville Superfund site.

STRATEGIC CONSIDERATIONS

Because of its pervasive worldwide use in the transportation, communications, and electronics industries, primarily for electric power storage, lead is a strategic and critical commodity. The National Defense Stockpile holds 525,000 metric tons of lead against a goal of 998,000 tons.

Except for mines in Missouri, Morocco, and the Republic of South Africa, primary supply of lead is closely interrelated, as a result of geologic occurrence, with zinc and silver. All of these metals are recovered from the same ore in most producing countries. A strategic consideration with potentially wide-ranging impact on domestic supply resulting from these coproduct-byproduct relationships arose in 1989. This was a result of emerging and innovative environmental control strategies that are discussed later. One aspect of the pollution prevention concept, known as source reduction, could entail severe reduced allowances for the use of virgin, i.e. primary, materials in the manufacture of potentially harmful or hazardous products. In the worst-case scenario, elimination of certain products from the market place could be considered.

Implementation of such a strategy on virgin lead use in the United States could impact the domestic supply of several other metals. An analysis of domestic mine production in 1988, before a large new base and precious metal mine opened in Alaska, indicates that 23% of U.S. total zinc mine production came from a coproduct relationship with lead. These same mines also produced 100% of the bismuth, 7% of the silver, and 23% of the cadmium. Because cadmium reports with

the zinc concentrates, the balance came from zinc mines in which lead is strictly a byproduct outside of Alaska. The zinc mines also were a small and only domestic source of germanium. Estimates for 1990, when the huge Red Dog zinc-lead-silver mine in Alaska is in production, are that the lead-zinc-silver coproduct relationship will supply 97% of the lead, 55% of the zinc and cadmium, and 30% of the silver. Also, as byproducts, these same mines are expected to supply all of the bismuth and indium, and about 80% of the germanium mined in the United States.

ISSUES

Because lead, its oxides, and some other lead compounds are highly toxic, especially to infants and children, whether inhaled or ingested, lead was selected during the year by the EPA for a comprehensive, highly publicized, study effort throughout the whole agency. This effort, known as The Lead Pollution Prevention Program (P4), was scheduled for completion in 1992, and involves almost all program offices in the EPA. The objective is to develop a comprehensive, cross-media (air-land-water) policy to minimize or eliminate human exposure to lead or its compounds where epidemiological evidence warrants. The new lead policy is to be framed in the context of pollution prevention rather than waste minimization, but still could utilize improved command-and-control techniques to achieve parts of the objective, including more timely, predictable, and realistic enforcement practices. The new lead policy, when finally determined, could serve as a model for tackling other major health risk problem areas as the Nation moves toward a uniform environmental code during the rest of this century. It is intended by EPA that the lead producing and consuming industries, as well as environmental and health organizations, be solicited for input and kept continuously apprised of developments during the information gathering, study, and policy framing periods. The Bureau of Mines was expected to be intimately involved with both the industrial sectors and EPA during development of the P4 program.

PRODUCTION

Mine Production

The increase in domestic mine output was exclusively from Missouri, Idaho, and a large new silver-zinc mine in Alaska. The reopening of The Doe Run Co.'s Brushy Creek Mine, closed since 1985, supplemented declining production elsewhere in Missouri. The Greens Creek Mine on Admiralty Island, AK, a joint venture of RTZ Corp. PLC (53%), Hecla Mining Co. (28%), CSX Corp. (12.6%), and Exalas Resources Inc. (6.3%), opened in February. Cominco Alaska Inc.'s planned November opening for the Red Dog Mine in the region of Kotzebue, AK, was delayed because of technical problems in the mill startup. Nine operating mines in Missouri, including Brushy Creek, plus six other mines shown on table 4, produced all but about 2,400 tons of the domestic recoverable mine output. The nine mines in Missouri accounted for 89% of the year's total. On the basis of lead in concentrates, the industry performed at only 62% of capacity (table 15) because of decreasing primary demand.

The Doe Run Co. of St. Louis, MO, the Nation's largest lead producer, operated three mine and mill divisions in Southeastern Missouri: Buick, Fletcher, and Viburnum. To take advantage of continuing high copper and zinc prices, Doe Run increased the total ore milled by 6% to 4.3 million tons, according to the annual report to stockholders of The Homestake Mining Corp., a 42.5% owner of Doe Run. This resulted in production levels of 228,000 tons of lead in concentrates, 49,000 tons of zinc concentrate, and 70,000 tons of copper concentrate. Average metal grades of the ore hoisted by Doe Run in 1989 were 5.6% lead, 0.9% zinc, and 0.6% copper. Total reserves at yearend were reported by Homestake to be 66.3 million tons, graded at 5.0% lead, 0.9% zinc, and 0.3% copper.

Asarco operated two mine and mill complexes in Southeastern Missouri, which together increased the ore milled by 40% compared with that of 1988, according to the company's annual report to stockholders. Contained lead increased by 20,700 tons, but declined by 2,000 tons at the Leadville, CO, mine operated by Asarco on a 50%

equity share basis. At yearend, Asarco had the captive domestic capacity to supply all the lead concentrates required by its Glover, MO, smelter, and about one-half of the company's overall requirements. In 1984, the company's mines supplied only 5% of the company's needs, according to Asarco.

The Magmont Mine at Bixby, MO, a joint venture of Dresser Industries Inc. and Cominco American Inc., the operator, was the Nation's third largest producing lead mine in 1989. However, because of dwindling reserves and lowered average ore grades, production declined nearly 10% from 1988 to 63,000 tons of contained lead in concentrates. According to Cominco Ltd.'s annual report to stockholders, the average concentrate grade actually increased from 77.5% to 77.9%. During the year, emphasis was on mining in the area of the large 1986 groundfall, and pillar extraction exceeded that in other areas of the mine. Surface drilling yielded no additional reserves, and planning for shutdown within the next 2 or 3 years was begun. The average grade of lead ore hoisted was 6.8% compared with 7.2% in 1988, although zinc and copper grades remained at 1.0% and 0.3%, respectively.

At Cominco Alaska Inc.'s Red Dog Mine in Alaska, final assembly of the mill modules, trial runs, and commissioning of the equipment continued

through December for official startup in early 1990. Construction of the port and storage facilities 52 miles away was also essentially completed. At yearend, Cominco had spent \$317 million on the mine and mill complex and \$170 million on the road and port facilities. The latter were financed by the State of Alaska through the Alaska Industrial Development and Export Authority. In addition, Cominco will pay an annual

toll fee to the State, as well as maintenance costs.

Primary Smelter-Refinery Production

According to Homestake's annual report, the Doe Run smelter-refinery at Herculaneum, MO, produced a record 216,758 tons of refined lead as a result of improved institutional and processing control systems, yielding a record high of 1.82 tons per manshift. This was accomplished simultaneously with setting a new safety performance record of a ratio of 1.1 lost-time injuries per 200,000 manhours, compared with a national average of 7.9, according to the

National Bureau of Labor Statistics. The facility, which includes a strip lead manufacturing plant, also achieved the lowest average employee blood levels ever recorded at the site, and for the first time achieved 1.1 micrograms (μg) of particulate lead emissions per cubic meter of air against the National Ambient Air Quality Standard (NAAQS) of 1.5 μg per cubic meter on an annual basis.

According to the Asarco annual report, the company produced 172,600 tons of refined lead in 1989, slightly less than in 1988 and 1987. Nearly two-thirds of the total was produced at the Glover, MO, smelter-refinery, and

the balance at the Omaha, NE, refinery, which received bullion from the East Helena, MT, smelter. The Omaha plant also produced lead from purchased old and new scrap in 1989. Construction of a completely enclosed unloading, handling, and ore storage facility to mitigate environmental problems continued throughout the year at East Helena.

Secondary Smelter-Refinery Production

Domestic secondary production increased appreciably for the fourth consecutive year, achieving the highest level ever, as the industry performed at 87% of capacity, the same rate as in 1988. In spite of two closures during the year, there was a net increase in capacity of 80,000 tons from yearend 1988, a net result of one large new plant coming on-stream late in the year, several expansions, and two downgradings. Total annual secondary rated capacity for refined lead and lead alloys at yearend was estimated by the Bureau of Mines to be 930,000 tons, representing 42 companies and 50 plants, with individual capacities ranging from less than 1,000 tons per year to 120,000 tons per year. The 10 largest operated 18 plants, representing 89% of the total capacity and accounting for 86% of the production. Twenty-three small producers, including Asarco, with annual capacities averaging 1,000 tons, produced mainly specialty alloys for such uses as solders, brass or bronze ingots, and bearing metals. The most significant event of the year relative to plants was the opening of the first large new secondary smelter-refinery since 1981, that of Exide Corp. at Muncie, IN, on the site of the former Bergsoe-Boliden plant, which closed in 1983. This was a major accomplishment in light of present day environmental requirements.

During the year, Doe Run entered the secondary market by purchasing scrap batteries and tolling them elsewhere. Except for the necessary RCRA part B permit to store hazardous materials, Doe Run acquired all the necessary environmental permits for building and operating a proposed Tonolli-Engitec CX "clean technology" plant at its Buick smelter in Boss, MO. However, it expected to move forward with the project in 1990. RSR Corp. also did not break ground on any of its three proposed new

¹ Includes remelt lead from cable sheathing plus other soft lead scrap processing.

"clean technology" plants announced in November 1988, but preliminary design and expansion details for the Indianapolis, IN, facility were completed by a consulting engineering firm.

In litigation actions, EPA officially declared the Nesquehoning, PA, plant site of Tonolli Corp., closed since 1985, a priority superfund site, and listed many U.S. battery manufacturers as potentially responsible parties (PRP's) liable for cleanup costs. In November, the Department of Labor proposed fines exceeding \$2 million for Interstate Lead Co. of Leeds, AL, for "blatant" blood lead and air level violations. If upheld, it would be the eighth stiffest Occupational Safety and Health Administration (OSHA) fine in history. The company was appealing at yearend.

CONSUMPTION

Domestic consumption of lead was the highest since 1979 as lead-acid storage battery manufacturers used more than 1 million tons for the first time. Automotive starting-lighting-ignition (SLI) battery shipments, including exports, exceeded 80 million units for the second consecutive year. The industrial-traction and specialty battery sectors also recorded significant gains. However, lead oxides used for glass, paint, ceramics, and other chemicals, which had been the second largest use for lead on a metal equivalent basis, declined for the fifth consecutive year. This was more than offset by a significant increase in lead use for bullets and shot, the latter including use at nuclear plants. Use of sheet lead in construction and cable lead sheathing in communications also increased, the latter by 40% compared with that of 1988.

Demand for lead in industrial and traction batteries, which includes uninterruptible power supply (UPS) designed to ensure constant voltage for large computer systems at hospitals, banks, communications networks, etc., and standby power supply (SBS) for emergency lighting and some telephone systems, was estimated by the Bureau of Mines to be 174,000 tons. This was an increase of 12% over that of 1988, and represents a record high. About one-third of that was for traction batteries, i.e., electric vehicles, including in-plant fork lifts and underground mine equipment. The UPS

market was expected to continue to increase as it is applied to smaller networked computer systems. There was also about 35,000 tons of lead used in 1989 for specialty batteries for aircraft and military applications.

STOCKS

Metal stocks at domestic primary refineries at yearend were essentially the same as a year ago, but those held by consumers declined nearly 10%. Therefore, total domestic metal stocks were at the lowest level since 1968, and reflected the worldwide tight supply-

demand situation as depicted in table 17. This worldwide sensitive balance kept the world price relatively high throughout the year, which essentially has been the case since May of 1987. Stocks of lead and antimonial lead metal in the market economy countries (MEC's) reporting to the International Lead and Zinc Study Group (ILZSG), including those on the LME, were approximately 378,000 tons at yearend, only about 6% of total world demand, and 60,000 tons lower than at yearend 1988.¹ Stocks in LME warehouses declined nearly 40,000 tons to only 23,000 tons at yearend. The centrally planned economy countries (CPE's) do not report lead stock levels.

PRICES

The North American producers' price quotations, including major secondaries, which were listed in a range of 42 to 42.5 cents per pound in early December 1988, dropped to 40 cents in early January 1989, and continued to drop through April, according to Metals Week. From a low of 35 cents per pound, which held from March 2 through April 27, quotes rose steadily through August before settling in a range of 42 to 44 cents from August 31 through October 31. The range broadened to 41 to 44 cents on November 1, before dropping to 38 to 40 cents during December. Monthly average cash prices on the LME paralleled the movement in the United States through April, but dropped more slowly, which

caused the spread with the U.S. average to decrease from 9.6 cents per pound in January to 7.2 cents in May. The price and spread then rose slowly through October to the year's high of 34 cents per pound, the spread again reaching 9.6 cents. The LME price then took a sharp dip in November, as it did in the United States, but more so, resulting in the high spread of the year of 9.9 cents per pound. However, in December the LME rose slightly, which reflected Asian and European spot shortages of premium metal, and the spread with the average U.S. price reached the lowest of the year, 6.7 cents per pound.

The North American producer price is a delivered price in the United States. Normally, a North American producer price of 5 cents per pound above the LME to cover the tariff, insurance, ocean freight, and delivery would stimulate importation. However, the worldwide tight supply-demand balance (table 17) and occasional spot shortages of premium metal (99.99% plus), resulted in the lowest net metal domestic imports since 1982, a recession year. The average U.S. and LME prices were the highest since 1980, when they were 42.5 and 41.2 cents per pound, respectively. The United States was a net pig metal exporter of 75,000 tons in that year.

W Withheld to avoid disclosing company proprietary data; included with "Miscellaneous."

¹ Includes lead that went directly from scrap to fabricated products.

The domestic prices for lead oxides were based on the selling price plus conversion charges for pig lead in a given period. Premium adjustments were also made by individual producers to reflect differences in manufacturing techniques, freight considerations, quality, and packaging requirements or other factors. According to American Metal Market, the quoted premiums for litharge ranged from 2 cents to 10 cents per pound in 1989, averaging about 6 cents for bags or drums in truckload lots, and 8 to 15 cents, averaging about 11 cents per pound, for 97% red lead. The premiums for leady litharge ("Bulk Battery") ranged from 1 cent to 4 cents per pound, and averaged about 2 cents.

WORLD REVIEW

According to the ILZSG statistics, consumption of soft lead and antimonial lead in the MEC's was a record 4.43 million tons in 1989, exceeding the previous high set in 1988 by about 70,000 tons.² Estimated world consumption of lead in all forms during 1989 increased for the seventh consecutive year to just under 6 million tons, and exceeded the 1988 previous record by more than 100,000 tons (table 17). The world demand growth since 1982 has averaged just over 2% per year, primarily because of steadily increasing SLI, UPS, SBS, traction, and load levelling battery systems. Estimated world total refinery production in 1989, including that from recycled scrap, increased only slightly from that of 1988. The production deficit shown in table 17 resulted in a continuing drawdown of world stocks, occasional spot shortages of premium metal, and sustained high prices worldwide. At yearend, supply and demand continued in delicate balance because of technical problems at smelters in Canada and Italy, mine production problems in Australia, and labor, political unrest, and sabotage in Peru.

Five new lead-producing mines came on-stream in 1989, and two small silver mines with byproduct lead were known to have closed during the year. As a result, there was 150,000 more tons of capacity operating at yearend than yearend 1988. This was the largest year-to-year increase in many years, accord-

ing to ILZSG, including reopenings and expansions. The largest of the new mines opened in 1989 were the Greens Creek silver-zinc mine in Alaska (12,000 tons of lead capacity) and the Hilton Mine in Australia (20,000 tons) which was integrated into the Mount Isa project in Queensland. The largest reopening was Doe Run's Brushy Creek Mine in Missouri, and the largest expansion (additional 38,000 tons) was at the Hellyer Mine on Tasmania. There were no permanent primary smelter-refinery closings in 1989. In Europe, a small rotary furnace was added to the Gaillitz plant in Austria, and in Italy, Nuova Samim expanded its refinery at San Gavino by 20,000 tons. In Canada,

Cominco Ltd. brought its new, larger, replacement QSL smelter on-stream.

Australia

The increase in mine production during 1989 was almost completely attributable to the new Hilton Mine coming on-stream, the Hellyer expansion project of Aberfoyle Ltd., and a full year's production from the Cadjebut open pit in Western Australia owned by BHP Minerals (58%) and Billiton Australia (42%). An expansion of the Cadjebut Mine, from 7,500 tons per year to 16,000 tons per year for lead, and from 41,000 tons per year to 65,000 tons per year for zinc, was started late in the year. Increased production from Hellyer began in March

and, when at capacity, was expected to produce a million tons of ore yielding 50,000 tons of lead and 110,000 tons of zinc per year. Reserves are 16.2 million tons grading 13.0% zinc and 6.8% lead, according to Aberfoyle.

Production from the integrated Mount Isa and Hilton operations of MIM Holdings Ltd. (MIM) will raise annual output from 180,000 to 200,000 tons of lead, and from 200,000 tons to 250,000 tons of zinc. The Hilton region 20 kilometers north of Mount Isa, Queensland, is envisaged as MIM's long-term source of lead-zinc-silver, gradually replacing the mine at Mount Isa. A resource of 100 million tons was indicated, including 49 million tons of proven and probable reserves, with grades similar to the Mount Isa Mine. Deposits of similar magnitude have been discovered nearby at North Hilton, making it one of the world's largest lead-zinc-silver regions.

Also in Queensland, a decision was announced early in 1989 to proceed with development of the Thalanga zinc-lead-copper-silver-gold deposit. The project is a joint venture between the operating company, Pancontinental Mining Ltd. (50%), Outokumpu Australia Pty. Ltd. (25%), and Agip Australia Pty. Ltd. (25%). The latter's share was secured from Outokumpu during a reorganization of the partnership. Reserves total 5.2 million tons grading 10.2% zinc, 3.1% lead, and 2.4% copper. At full production in 1991, when an underground decline is scheduled to replace the open pit, output is expected to reach 48,000 tons per year of zinc, 13,000 tons per year of lead, 10,000 tons per year of copper, and 33 tons per year of silver. This group continued study of a deposit at Lady Loretta near Mount Isa, publishing reserves of 6.5 million tons grading 18.8% zinc and 9.2% lead. Agip is a wholly owned subsidiary of Agip of Italy, owned by the state organization ENI, which also owns SAMIM, Italy's largest lead and zinc metal producer.

In exploration activity, MIM reached an agreement with the Northern Territory government for an 18-month drilling program, to be completed by the end of 1990, to establish the viability of mining the MacArthur River deposit. Resource estimates at yearend were 227 million tons of ore averaging 9.2% zinc and 4.1% lead. The company believes that technical problems with separating

the extremely fine-grained ore can be overcome with modern autogenous direct smelting techniques. Also in the Northern Territory, the Woodcutters Joint Venture operated by Nicron Resources Ltd. completed the first full year of underground operation. Proven and probable reserves were further extended to 1.27 million tons grading 13.8% zinc and 6.4% lead. Additional

drilling at depth outlined another 3 million tons of similar grades, and studies were undertaken to determine the viability of further development at the open pit-underground project.

Brazil

Companhia Paraibuna de Metais created a new subsidiary to produce high-grade lead for specialty batteries from

the lead and silver residues of their electrolytic primary zinc refinery in Minas Gerais. The new company, Companhia de Chumbo e Prata do Espirito Santo (CHESA), planned to produce 24,000 tons per year at a new plant in the State of Santo by 1991. The parent company also was expected to begin construction in 1990 of a new QSL lead smelter and electrolytic refinery. The project was expected to take 3 years to complete, have a capacity of 45,000 tons per year, and to process mostly imported Peruvian concentrates. The State of Parana closed the 19,000-tons-per-year primary lead refinery of Plumbum S.A. Mineração e Metalurgia in October until process effluent filtration equipment is installed at discharge points.

Canada

Mine production of lead declined significantly in 1989 through a combination of technical difficulties, natural events, and labor problems. Cutback in hoisting capacity at Brunswick Mining and Smelting Corp. Ltd.'s Number 12 Mine in New Brunswick was a result of a shaft-deepening project. Also in New

Source: International Lead Zinc Study Group, Bureau of Mines estimates, and other published sources.

Brunswick, East-West Caribou Mining Ltd. suspended production at the Caribou Mine in July to develop additional reserves, presently estimated at 15 million tons grading 11% lead and zinc combined. In July, Curragh Resources Inc. lost production temporarily at the Faro Mine, the nation's largest, in the Yukon Territory because of loss of power caused by forest fires. At Cominco Ltd.'s Sullivan Mine in British Columbia, the nation's second largest lead producer, production declined significantly because of increasing ore depth and processing problems, and cancellation of the miner's bonus formula, according to the Government's Mineral Policy Sector annual report.

In exploration and development during the year, Hudson Bay Mining and Smelting Co. Ltd. completed an expansion at its Chisel Lake Mine in Manitoba that was expected to increase lead output by 5,000 tons per year. In August, Noranda Inc. and Brunswick Mining and Smelting reopened their Heath Steel Mine near Bathurst, New Brunswick, which had been shut down since 1983. The three separate ore bodies contain 4 million tons of reserves grading 6.3% zinc and 2.5% lead. Also in New Brunswick, Marshall Minerals Corp. continued work on its Restigouche project in the north. East-West Caribou Mining planned to process the ore from the mine, which had about 1.1 million tons of reserves grading 7.71% zinc and 5.96% lead. In Nova Scotia, Westminer Canada Ltd. started work on reopening the Gays River Mine, closed by Esso Minerals Canada in 1982, at a production of 10,000 tons per year lead and 15,000 tons per year zinc. Reserves were about 1.5 million tons grading 10% zinc and 6.2% lead.

At midyear, Banco Español de Crédito de Spain agreed to sell a 20% interest in Asturiana de Zinc S.A. to Curragh in exchange for a 5% share of Curragh plus a 15% interest in their Cirque deposit in northern British Columbia. That project, with 30 million tons of reserves grading 8.6% zinc and 3.5% lead, was expected to come on-stream in 1992 at 25,000 tons per year of lead.

France

Peñarroya agreed to sell its remaining lead-zinc-silver leases in France and Belgium to Nicron Resources of Australia. Remaining reserves are about

350,000 tons grading 6.5% zinc and 3.5% lead with the potential of an additional 1 million tons. Nicron will exercise the options and start production pending confirmation by exploratory drilling.

Greece

Financial problems forced the state-owned Hellenic Mining and Metallurgical Co. of Laurium S.A. (EMMEL) to close the rebuilt 20,000-ton-per-year primary smelter-refinery in June. At yearend, EMMEL had no immediate plans to reopen the facility, but late in the year the Government formed a board to examine its options.

Italy

Nuova Samim and Metallgesellschaft (MG) of the Federal Republic of Germany (FRG) agreed to merge their secondary lead activities. The two Italian plants had a capacity of 80,000 tons per year, and the German plant at Braubach, which installed the Italian Tonolli CX process in 1988 with Tonolli, had a capacity of 40,000 to 50,000 tons-per-year. In September, Nuova Samim's large primary smelter at Porto Vesme, Sardinia, was shut down because of technical problems. The Russian designed Kivcet plant had been in operation since early 1987. A

planned expansion for 1990 was therefore accelerated to increase the capacity by 25% to 100,000 tons per year by midyear 1990, when the smelter was expected to reopen after correction of the problems.

Japan

Nippon Mining Co. Ltd. planned to develop a new mine on Hokkaido over the next 4 years. The deposit reportedly had reserves of 3 million tons grading 13% lead and 15% zinc with traces of indium.

Morocco

A large new underground zinc-lead-copper-silver mine was under development at Hajar by Compagnie Minière des Guemassa to be in full production by 1992 at about 16,000 tons per year for lead.

Saudi Arabia

The National Industrialization Corp. announced plans to construct the nation's first secondary lead smelter, capacity about 12,000 tons per year, near Jeddah. Startup is scheduled for early 1991. Late in the year, a group of Saudi private investors announced plans to construct a 25,000-ton-per-year plant near Riyadh, with MG of the FRG to be a 25% equity shareholder.

^c Estimated. ^P Preliminary.

¹ Recoverable content (95%) of mine production (lead in concentrates) divided by apparent consumption.

² Yearend stocks 1977 = 468; yearend stocks 1989 = 378 (estimated; producer, consumer, merchant, LME).

Spain

The nation's largest secondary lead producer, S.E. del Acumulador Tudor, doubled the capacity of its smelter at San Esteban de Gormaz from 20,000 tons per year to 40,000 tons per year to replace the yearend closing of its 15,000-tons-per-year plant at Zaragoza. Boliden Mineral AB of Sweden announced the significant discovery of a very large lead-zinc deposit, Los Frailes, near its Aznalcollar Mine, acquired from the Spanish company APIRSA in 1987. An estimated 50 million tons of ore grading 14% lead and zinc would make it one of Europe's largest base metal mines when developed. Pending further drilling, production could begin as early as mid-1992.

Tunisia

The Office National des Mines (ONM) and its partner, MG of the FRG, were studying the closed Bougrine Mine for possible reopening at depth. Deeper reserves are estimated to be 6 million tons grading 12% zinc and 6% lead. If approved, the mine could be on-stream within 3 years, producing 100,000 tons per year of lead and zinc concentrate. A lead-zinc deposit was discovered in the state of Kaf, estimated to contain 4 million tons of reserves, as a result of a joint-venture exploration program with BRGM of France.

United Kingdom

Britannia Refined Metals (BRM), a subsidiary of MIM of Australia, announced plans to acquire Chloride Metals' 30,000-tons-per-year secondary lead plant at Wakefield, West Yorkshire. In addition, BRM started to replace its 30,000-tons-per-year plant at Northfleet, Kent, utilizing MIM's revolutionary Isasmelt process, the first outside of Australia, and the first secondary application of the process. The process was developed with Australia's Commonwealth Scientific and Industrial Research Organization (CSIRO). The new smelter was scheduled for completion by mid-1991 at an increased capacity of 40,000 tons per year.

CURRENT RESEARCH

Recent and ongoing research relative to lead and its uses have focused

strongly on improvements in the lead-acid battery, through all its ranges of applications, in terms of safety, capacity, dependability, and manufacturing-marketing economics.

Research performed in 1989 by Fuji Electrochemical Co. of Japan (FDK) and Isuzu Motors Ltd. of Japan, which was 38% owned by General Motors Corp. of Detroit, led to the development of a quick-charging automotive "battery" with a storage capacity 30 to 50 times greater than conventional SLI's. Commercial production was targeted for 1992. The capacitor-structured "battery," with internal resistance as low as one-hundredth of a double layer capacitor in terms of power accumulation capacity per cubic volume, can recover electric power in less than 30 seconds, with accumulation potential 10,000 times that of conventional capacitors. Individual coin-size cells can be linked in series or parallel circuitry on any irregular area, such as a car roof or bumper, for solar charging as a "key-off" or accessory supply, or to recharge a dead SLI battery. Other potential applications would be electric cars, home and industrial supplemental or load-leveling power supply, and aerospace. A coin-size cell can store power of 1 volt and 30 watts.³

In contract work performed for NASA's Jet Propulsion Laboratory (JPL), tile-like positive electrode squares with improved adhesion were developed to reduce flaking on the positive faces of bipolar plates, common after repeated charge-discharge cycles in conventional lead plates. This new segmented structure prevents defects from spreading across the structure. The plate body is made of fiberglass coated with conductive fluoride-doped tin oxide in epoxy resin. Lead dioxide paste, reinforced with the same conductive fibers, is then applied to the formed recesses after conditioning the body surface to improve adhesion. The negative side of the plate is then built up from epoxy and graphite, lead foil, and lead paste supported by a glass scrim.⁴

Also for JPL, performance of a conventional lead and litharge positive plate was improved from 25% to 40% efficiency to 65% to 68% efficiency by increasing the porosity of the active paste material. This was accomplished by covering the conventional grid with lead

sulfate paste blended with tin oxide-coated glass fibers. The lead sulfate, which has a large molecular volume, increases in density during charging, opening additional pores. Ironically, lead sulfate buildup and subsequent sloughing is a cause for shorting out and failure in conventional lead-acid battery construction. In preliminary tests the new cell was deeply discharged and recharged more than 2,000 times without fading.⁵

A patent was issued during the year on a range of synthetic polymeric materials exhibiting an electrochemical ionic semiconductivity previously known only in living organisms. These materials greatly enhance ion selectivity with no change in resistivity when used as plate separators in a battery system. Because they also essentially eliminate nonionic transfer, they control the mobility within electrolytes of all metals, facilitating their use as electrodes in virtually all metal-metal secondary battery systems also. Known generically as EPM materials, they can be used as electrolytic cells for the extraction of metal ions from process effluents, as nonporous breathable coatings for protective clothing or bandages, or even as a synthetic skin in burn treatment.⁶

A comprehensive coverage of lead-related investigations and an extensive review of current world literature on the extraction and uses of lead and its products, including batteries, were published in quarterly issues of Leadscan, Lead Development Association, London, United Kingdom.

OUTLOOK

Although overall domestic consumption of lead has grown at an average rate of about 3% per year since 1985, this rate is not expected to be sustained, primarily because of institutional factors. As the Nation pays increased attention to pollution prevention mentality instead of the present strategy of waste minimization through command and control techniques, some end uses of lead will certainly be curtailed or eliminated entirely by legislation or regulation. One of the pollution prevention strategies known as source reduction will most likely reduce the use of lead in nongrowth markets such as solders; paints and coatings (already

eliminated in interior house paints); ceramics; gasoline additives; containers or other packaging, including inks or dyes, especially where food is concerned; and cosmetics. Some reduction of lead per battery unit can also be anticipated as the technology continues to advance. As a result, U.S. annual growth in lead demand will probably fall within an average range of 0.5% to 1.0% per year in the decade of the 90's as the storage battery sector becomes even more dominant. The lower average growth rate can certainly be expected if source reduction is applied to the ammunition sector, currently the second largest end use. The higher growth rate could be attained if lead-acid batteries for peak-power, load-leveling applications become widely accepted for households and commercial facilities.

World demand for lead, including the United States., has grown at an average rate of about 2% through 1989 since the low recession year of 1982 (table 17). Lower growth domestic demand, which is currently about 21% of the total, will undoubtedly lower the overall growth rate somewhat in the future. However, storage battery use in all applications will undoubtedly grow faster in the rest of the world than in the United States as some poorer nations increase their living standards as they grow with the world economy. It is estimated that currently about 60% of world demand is for batteries, compared with about 80% in the United States alone, and is forecast to reach about 70% by the end of the decade as the rest of the world's supply-demand pattern is rationalized by environmental concerns. Therefore, the most probable world growth until the end of the century is forecast to average about 1.5% per year.

The attendant worldwide production outlook is interrelated with anticipated structural changes discussed in the following section. Because of large capital demand and high costs associated with environmental concerns, large production surpluses in the near term are not likely. High realized producer prices are critical to profitably amortizing the large improvement expenditures anticipated over the next 10 years. However, this will continue to be partially subjected to developing situations in zinc and silver markets because of the geo-

^c Estimated. ^P Preliminary. ^r Revised.¹ Table includes data available through June 13, 1990. Data included represent the total output of refined lead by each country, whether derived from ores and concentrates (primary) or scrap (secondary), and include the lead content of antimonial lead, but exclude, to the extent possible, simple remelting of scrap.² Reported figure.³ Revised to zero.

logic relationships of the three metals in the primary production sector.

Complex multinational, multifaceted realignments and restructuring, including divestitures, among world lead producers and product manufacturers are expected to continue through the rest of the century. The reasons, whether market-driven, technology-driven, environmentally driven, or combinations thereof, are discussed in the following section.

BACKGROUND

Industry Structure

Since the development of the last major lead-producing region in 1968, the first year of significant production

from the Viburnum Trend in Southeast Missouri, large-scale structural changes have occurred worldwide in both the producing and consuming sectors of the lead industry. Most apparent, as illustrated in table 17, is the decline in primary demand, which has accelerated downward in recent years and is expected to continue this trend at a similar rate into the next century. The milestone year was 1984 when world mine production dropped to a 15-year low. As the world economy pulled out of recession, resource recycling was emphasized as world demand accelerated. A proliferation of new secondary plants has appeared together with expansion of capacity at older plants and environmental concerns for improved performance forcing technologic retrofitting. This was especially noticeable

by 1988 when world supply and demand were almost in balance (table 17). However, at yearend 1989, world metal stocks were extremely low relative to demand as world demand again outstripped production, as was the case in 1986. Although world secondary refinery production was an estimated record 2.65 million tons in 1989, mine production was estimated to be about the same level as 1978, in spite of significant increased production from new mines and increasing productivity at some old mines, especially in China.

Although increasing worldwide environmental awareness will continue to force an increasingly greater share of demand to be supplied from secondary sources, this will not alleviate the tight supply problem, regardless of the rate of recycling increase, without a considerable revolutionary (as opposed to evolutionary) technology shift. Basically, this will require electrowinning and/or electrorefining to obtain premium metal (99.99% plus), the occasional spot shortages of which have led to market "tightness" in the fourth quarters of 1988 and 1989. Conventional primary smelters fed by virgin ores can achieve this, especially with electrorefining (nearly 99.999%), but the best on average that conventional secondary smelter refineries can achieve is 99.985% purity. Premiums for the purer product have kept average prices artificially high the past 2 years. Eventually, a rationalization of worldwide environmental codes will alleviate this problem by forcing optimum recycling in conjunction with clean technology reprocessing.

Ironically, the demand for high-purity lead has been fed by evolutionary changes in the worldwide demand pattern itself and not simply the volume increase. Original equipment automotive batteries and some large UPS system batteries that are continuously on-line as voltage regulators and not subject to drawdown are more amenable to the use of high-purity calcium lead alloys. This is especially critical for the mass-production automobile industry. Replacement "hybrid" type low antimonial lead batteries, which are superior in electrical charge recovery cyclability but are more expensive to make, can carry a premium not associated with the cost of buying a new car. However, because of the greater volume

necessary (5 out of 6 in the United States) compared with the original equipment battery market, discounts can often offset this to the consumer, especially when the market is saturated.

What all this has led to in recent years is a massive worldwide restructuring and rationalization of the industry. In some cases retrenchment; in others vertical integration, often through multi-national mergers, especially on the primary side; in still others, lateral merging for more flexible marketing; and, in other cases, joint ventures, divestiture, or expansion depending on capital availability and its cost or simple conviction or lack thereof to remain competitive under continuously changing and evolving conditions.

One of the best examples of multinational restructuring through mergers on the primary side to increase vertical integration for some parties, facilitate cash-flow for investment for others, and ensure flexible marketing for all involved Asarco, one of the two remaining domestic primary lead metal producers. According to its 1989 annual report, Asarco, which is essentially a custom smelting company, has substantial interests in three of the world's major mining companies: an 18.7% stake in MIM of Australia, a 52.3% ownership of Southern Peru Copper Corp. (SPCC), and a 34% holding in Mexico Desaraollo Industrial Minero, S.A. de C.V. (MED-IMSA). MIM, which in return has a 24.9% interest in Asarco, is a partially integrated producer of copper, silver, gold, lead, zinc, and coal. SPCC operates two large copper mines and a copper smelter in Peru. MEDIMSA is a holding company for several, not necessarily integrated, companies in Mexico engaged in the mining, milling, smelting and refining of nonferrous metals, including the large integrated copper producer Mexicana de Cobre, S.A. de C.V. All these associated companies accounted for about 11% of the market economy countries' mine production of copper, 17% of silver, 14% of lead, and 10% of zinc in 1989, according to Asarco. In addition, MIM owns a secondary lead plant in Taiwan, and Asarco is presently considering re-entering that sector in the United States, representing lateral integration within one commodity, following the leadership of Doe Run. Other examples would be SAMIM's involvement in

both primary and secondary sectors in Italy, with MG of the FRG as previously discussed, and Britannia Metals in the United Kingdom, a subsidiary of MIM.

The total merger of Peñarroya of France with Preussag AG of the FRG in late 1987 into Metaleurop is an example of multilayer restructuring and merger on a grand scale. In late 1989, MG, in an attempt to expand its base production and raw material reserves on a global scale, hiked its share in MIM from 4% to 10.5%. MIM has a 3% interest in MG and a 9% interest in Cominco Ltd. of Canada, one of the world's leading base metal producers, in which MG has a 37% share through its Canadian holding company, Metall Mining Co. Ltd. Mitsubishi Mining and Smelting Co. Ltd. of Japan also has a small interest in Cominco, and they jointly own and operate a primary lead smelter that also utilizes secondary feed at Noashima called Mitsubishi Cominco Smelting Co. Ltd.

In the United States, there are two prime examples of divestiture in recent years, as both AMAX Inc. and Kennecott have gotten out of the lead business because of environmental risks and uncertain future markets. AMAX's interests, the Buick Mine and Boss Smelter-refinery, were eventually folded into The Doe Run Co. along with its partner, the Homestake Lead Mining Co. of Missouri. The interests of Kennecott's Ozark Lead Co. were acquired by Asarco.

Doe Run's pending lateral movement into the secondary sector utilizing "clean processing technology" will allow them market flexibility by, ironically, reopening the Buick conventional refinery only. Pyrometallurgical refineries can be made environmentally sound by retrofitting, not yet proven for conventional smelters, and extremely doubtful if stricter emission standards are applied. However, by combining the two processes, Doe Run will be better able to compete in the antimonial lead market, almost exclusively the domain of secondary producers in the United States. RSR Corp., which is about equal to Doe Run in lead production, on the other hand has chosen to convert to electrowinning with electrorefining of the metallic portion of the scrap to penetrate the premium market, now controlled by the primary producers in the United States.

On the consuming side, in the battery sector, multinational mergers and joint-producing ventures have also become common in recent years as new automated manufacturing technologies and new environmental codes spread rapidly, requiring increasing new capital investment. Recent examples of this in the United States have been Dunlop of Australia's acquisition of Chloride Inc., a former U.S. subsidiary of the Chloride Group of the United Kingdom, to form Pacific Chloride Inc., and then acquiring GNB Inc., the Nation's third largest battery company, renamed Pacific Dunlop Inc. Exide Corp., the Nation's largest battery manufacturer, has formed joint ventures with Yuasa Electric Storage Battery Co. Ltd., one of Japan's largest, to manufacture batteries for Japanese car manufacturers in the United States and also to manufacture replacement motorcycle batteries. The joint-venture plant at Reading, PA, adjacent to Exide's large secondary smelter-refinery-plastics complex, is the Nation's largest motorcycle battery plant, according to Exide.

Costs

In 1987 the Bureau of Mines investigated the domestic primary and secondary lead smelting and refining industries to determine the economic impacts of then existing and proposed environmental, health, and safety regulations. The impacts were assessed in terms of capital and operating costs for existing and alternative smelting-refining technologies. For the primary sector, the estimated capital cost to rehabilitate the three Missouri smelter-refineries by replacing the present sinter plant-blast furnace operations with dryers, flash smelting, continuous dressing, and double-contact acid plants was estimated to be \$1,000 per annual ton of capacity, or \$400 million 1987 dollars. The estimated capital expenditure for a single 400,000 ton replacement "green field" flash smelter in Missouri, optimally located, was estimated to be \$750 per annual ton of capacity, or \$300 million 1987 dollars. That plant would incorporate all BAT, including total ambient ventilation, and collection of airborne particulates from all plant areas. A second option analyzed was that for three QSL-type bath furnaces at a single location, estimated capital cost about the same as that for

rehabilitation of the existing three separate plants. Over 90% of the costs in all three scenarios were attributed to the requirements for improved airborne particulate (on-site and offsite) and SO₂ emission controls.

The average investment cost required for the 24 secondary plants processing batteries in 1987 to achieve existing regulatory compliance was estimated to average \$124 per annual ton of plant capacity for those studied. An average additional cost of about \$400 per annual ton of capacity was estimated and would be required to meet the most probable new lead NAAQS of 0.5 µg/m³. The latter cost was purely an estimate based on secondary industry responses to the Bureau of Mines for probable equipment requirements.

None of the foregoing estimates imply that investing the necessary capital expenditures would guarantee full compliance with all EPA, OSHA, or State requirements, in either the primary or secondary sectors.

With respect to basic operating costs only, the Bureau found that in 1987, these averaged 22 cents per pound for the secondary plants studied and 20.8 cents for the primary plants, allowing for 11.9 cents per pound byproduct credits in the latter case. After including taxes, capital recovery, and a 15% discounted cashflow return on investment, total costs were 23.1 cents and 23.8 cents, respectively.

Raw material feed costs, in recoverable metal terms, averaged 14.2 cents per pound for the primary plants and were assumed to be 9 cents for the secondary plants. Regulatory costs for these plants, on average, were 2.75 cents for primary and 3 cents for secondary at that time, but none of the plants in either sector were in full compliance with all EPA and OSHA or State regulations. An additional average cost per plant to meet the then existing regulations would have been 5.5 cents per pound for the primaries, only by complete rehabilitation, and

3.8 cents for the secondaries, requiring extensive retrofitting. The additional 5.5 cents for the primary case allowed for an additional (to 11.9 cents) estimated attendant 0.7 cent per pound increase in the deductible byproduct credit because of improved recovery (12.6 cents). Total required upgrading to meet the existing 1987 regulations, including taxes and return on investment, would have resulted in total average costs of 29.3 cents per pound for the primaries and 27.2 cents for the secondaries. Updating these costs to 1989 would require an additional average of 3 to 5 cents per pound in recoverable metal feed costs for secondary plants because of higher prices for battery scrap during 1988 and 1989. On the primary side, however, the mine and mill average costs have probably decreased at captive mines as a result of improved productivity, resulting in a slight reduction of raw material feed costs to the smelters. Some additional retrofitting costs at the smelters since 1987 were probably offset by improved productivity resulting primarily from institutional changes at Doe Run, discussed earlier.

It was estimated by the Bureau in 1987 that an additional average retrofit operating cost of at least 2 cents per pound on top of the capital requirements would be necessary for secondary plants to meet a probable NAAQS of 0.5 µg/m³. The proposed revised drinking water standard, which will directly impact plant discharges and process effluents, could double that additional cost or more. For primary plants, it is virtually certain that neither total rehabilitation nor new BAT plants, flash or bath, could meet such a NAAQS revision. It was estimated in 1987 that a new flash plant would operate at 28.2 cents per pound, including capital recovery and return on investment and discounting improved byproduct recovery credits of 12.8 cents per pound. The comparable figure estimated for a new bath plant (QSL-

type), was 29.4 cents. Although the latter has an inherent lower functional processing cost as the feedstock does not have to be dried, the capital recovery costs included are estimated to be 1.7 cents per pound greater than that for a flash plant (Outokumpu-type).⁷

LIME

By M. Michael Miller

Mr. Miller, a physical scientist with 12 years of minerals experience with the Department of the Interior, has been the commodity specialist for lime since 1989. Domestic survey data were prepared by Blanche S. Hughes, mineral data assistant; and the world production table was prepared by Harold D. Willis, international data assistant.

Total lime sold or used by domestic producers, including that from Puerto Rico, remained essentially unchanged at 17.2 million tons in 1989. These products, valued at over \$856 million, included quicklime and hydrated lime for commercial sale or captive consumption. Commercial sales increased for the third straight year and were at their highest level since 1979. Captive consumption decreased to the lowest level since the Bureau of Mines first collected accurate data on captive production in 1958.

DOMESTIC DATA COVERAGE

Domestic production data for lime are developed by the Bureau of Mines from two separate voluntary surveys of U.S. operations. The survey used to prepare this report is the annual "Lime" survey. Of the 116 operations to which the annual survey request was sent, 114 responded, representing 98% of the total sold or used by producers shown in table 2. Production for the two nonrespondents was estimated using reported prior-year production figures.

LEGISLATION AND GOVERNMENT PROGRAMS

Section 3001 of the Resource Conservation and Recovery Act (RCRA), enacted on October 21, 1976, mandated that the Environmental Protection Agency (EPA) "promulgate regulations identifying characteristics of hazardous waste, and listing particular hazardous wastes which shall be subject to the provisions of this subtitle." In 1980,

RCRA was amended (the Bevill Amendment) to exclude "solid waste from the extraction, beneficiation, and processing of ores and minerals" from regulation as hazardous waste under subtitle C of RCRA, pending completion of certain studies by EPA. In a 1988 reinterpretation of the Bevill exclusion, EPA proposed to include "air pollution control dust from lime kilns" within the exclusion, which would then be studied in a report to Congress and be subject to a subsequent regulatory determination pursuant to section 3001 of RCRA. However, on September 1, 1989, in response to a Federal Appeals Court directive, EPA published a final rule to narrow the exclusion as it ap-

plies to mineral processing wastes. Title 40 Code of Federal Regulations Part 261—Identification and Listing of Hazardous Wastes, § 261.4 Exclusions, was amended to include a revised definition of "beneficiation" in paragraph (b)(7): "Solid waste from the extraction, beneficiation, and processing of ores and minerals. . . ." The definition of "beneficiation" was revised to include the following activity: "calcining to remove water and/or carbon dioxide." Calcining at lime plants is designed to drive off carbon dioxide, and EPA has ruled that lime kiln dust now falls within the definition of solid waste from beneficiation and is therefore excluded from regulation under RCRA.¹

PRODUCTION

The term "lime," as used throughout this chapter, refers primarily to six chemicals produced by the calcination of high-purity calcitic or dolomitic limestone followed by hydration where necessary. They are: (1) quicklime, calcium oxide (CaO); (2) hydrated lime, calcium hydroxide (Ca(OH)₂); (3) dolomitic quicklime (CaO·MgO); two types of dolomitic hydrate, (4) type N (Ca(OH)₂·MgO) and (5) type S (Ca(OH)₂·Mg(OH)₂); and (6) dead-burned dolomite. Nondolomitic quicklime and hydrated lime are also called high-calcium lime. Lime can also be produced from a variety of calcareous materials such as aragonite, chalk, coral,

marble, and shell. Lime is also regenerated; that is, produced as a byproduct, by paper mills, carbide plants, and water treatment plants; however, regenerated lime is beyond the scope of this report.

Total U.S. lime production from limestone, including that of Puerto Rico, was essentially unchanged. Commercial lime sold by producers increased by 282,000 tons from the previous year. Captive lime used by producers decreased by 182,000 tons or nearly 8% compared with the previous year.

In 1989, 72 companies produced lime. Leading producing companies, in descending order, were Dravo Lime Co. with two plants in Kentucky, one plant in Alabama, and one plant in Texas (subsequently sold); Mississippi Lime

Co. in Missouri; Marblehead Lime Co. with two plants in Illinois and one each in Indiana and Michigan; Chemstar Inc. with two plants each in California and Nevada and one each in Arizona and Utah; Martin Marietta Corp. in Ohio; APG Lime Co. with one plant each in Texas and Virginia; Allied Lime Co. with two plants in Alabama; Chemical Lime Southwest with two plants in Texas; Continental Lime Inc. with one plant each in Montana, Nevada, Utah, and Washington; and Wimpey Minerals PA Inc. (formerly Broyhill and Associates) with two plants in Pennsylvania. These 10 companies operated 28 plants and accounted for 57% of total lime production.

Domestic lime plant capacity is based on 365 days minus the average

¹ Excludes regenerated lime. Includes Puerto Rico.

² Data may not add to totals shown because of independent rounding.

³ Includes data indicated by the symbol W.

⁴ Included with data for each individual State.

number of days for maintenance, times the average 24-hour capacity of quicklime production, including quicklime converted to hydrated lime, and reported in short tons per year. Specific plant capacity data were available for 75% of commercial lime plants. A weighted average for capacity utilization was calculated from specific plant capacity data and the percentage of capacity utilized at each plant. Based on these calculations, the domestic lime industry operated at 78% of capacity in 1989.

New Plants, Expansions, and Changes

Continental Lime Co., a wholly owned subsidiary of Continental Lime Ltd. of Canada, opened its new Pilot Peak lime plant at Wendover, NV. A used F.L. Smidth rotary kiln with a preheater of Continental design was installed. The plant has a capacity of 120,000 tons per year. St. Clair Lime Co. added a 10-ton-per-hour hydrating system to its Marble City plant in eastern Oklahoma. The system's major component is an Italian Cimprogetti three-stage hydrator, the first of its kind in North America. Germany Valley Limestone at Riverton, WV, announced plans to construct a new preheater lime kiln to replace two existing kilns. Startup was expected to be in the spring of 1990.

Allied Products Co. of Birmingham, AL, sold its lime division to Chemical Lime Co. of Fort Worth, TX. The Alabaster and Montevallo plants in Shelby County, AL, were renamed Allied Lime Co. Dravo Lime Co. sold its Round Rock division, located 60 miles southwest of Dallas, TX, to Texas Lime Co. of Cleburne, TX. The sale included the Blum lime plant and 1,200-acre limestone quarry. Broyhill and Associates was sold to George Wimpey Plc., a large construction company based in the United Kingdom. The sale included the limestone quarries and lime plants in Hanover and Annville, PA. USG Corp. sold its lime plant in Genoa, OH, to a management group from Bellefonte Lime Co. of Bellefonte, PA. Continental Lime Ltd. sold its precipitated calcium carbonate (PCC) plants in St. Helens, OR, and Prince Albert, Saskatchewan, to Georgia Kaolin Co., a subsidiary of Combustion Engineering Inc. Continental retained ownership of its PCC plant in Takoma, WA.

[†] Revised.

¹ Excludes regenerated lime. Includes Puerto Rico.

² Less than 1/2 unit.

³ Data may not add to totals shown because of independent rounding.

CONSUMPTION AND USES

Lime was consumed in every State. The breakdown of consumption by major end uses was as follows: 66% for chemical and industrial uses, 22% for environmental uses, 8% for construction uses, and less than 4% for refractory dolomite. Captive lime was used mainly in sugar refining and in the production of steel in basic oxygen furnaces.

In steel refining, quicklime was used as a flux to remove impurities such as phosphorus, silica, and sulfur. Dolomitic lime was often substituted for a fraction of the high-calcium lime to extend refractory life. Dead-burned dolomite, also called refractory lime, was used to line the bottom of open-hearth steel furnaces to extend the life of the brick lining. Dead-burned dolomite was a component in tar-bonded refractory brick used in basic oxygen furnaces. Lime consumption for raw steel production decreased 5% to 5.0 million tons and accounted for 29% of all lime consumed in the United States.

In nonferrous metallurgy, lime was used in the beneficiation of copper ores to neutralize the acidic effects of pyrite and other iron sulfides and maintain the proper pH in the flotation process. It was used to process alumina and magnesia, to extract uranium from gold slimes, to control pH and reduce cyanide loss in gold and silver leaching operations, and in the recovery of

nickel by precipitation.

Lime was used in the softening and clarification of municipal potable water. In sewage treatment, lime was used to control pH in the sludge digester, which removes dissolved and suspended solids that contain phosphates and nitrogen compounds. It also aided clarification and killing of bacteria. Lime was used to neutralize acid mine and industrial discharges. In flue gas desulfurization systems serving utility and industrial plants, lime was used to react with sulfur oxides in the flue gas. Lime was used to stabilize sludges from sewage and desulfurization plants before disposal.

The paper industry used lime as a causticizing agent and for bleaching paper pulp to the desired degree of whiteness. Lime was also used in the clarification and color removal of paper mill wastes and to make precipitated calcium carbonate, a specialty pigment used in premium-quality coated and uncoated papers.

The chemical industry used lime in the manufacture of alkalies. Quicklime was combined with coke to produce calcium carbide, which was used to make acetylene and calcium cyanide. Lime was used to make calcium hypochlorite, citric acid, petrochemicals, and other chemicals.

In sugar refining, milk of lime, a suspension of hydrated lime in water, was used to raise the pH of the product stream, precipitating colloidal impurities. The lime itself was then removed

by reaction with carbon dioxide to precipitate calcium carbonate. The carbon dioxide was obtained as a byproduct of lime production.

Dolomitic quicklime was used as a flux in the manufacture of glass. Quicklime was used to make calcium silicate building products; such as, sand-lime brick; hydrated lime was used to produce silica refractory brick.

In construction, lime was used for soil stabilization to upgrade clay soils into satisfactory base and subbase materials. Common applications included the construction of roads, airfields, building foundations, earthen dams, and parking areas. Hydrated lime was used with fly ash to make a base material, in asphalt mixes to act as an antistripping agent, and in plaster, stucco, and mortar to improve durability. Other applications of lime included agricultural uses, leather tanning, plastics manufacture, and pigments.

PRICES

The average value of lime sold or used by producers, as reported to the Bureau of Mines on an f.o.b. plant basis, increased to \$49.83 per ton (revised 1988 value was \$48.12). Average values were \$48.17 per ton for chemical and industrial lime (revised 1988 value was \$46.46), \$61.30 for construction lime, \$55.43 for lime used in agriculture, and \$65.10 for refractory dolomite.

The average value of quicklime sold increased to \$47.42 per ton. Average values per ton were \$47.01 for chemical lime (revised 1988 value was \$45.88), \$43.66 for construction lime, \$44.76 for lime used in agriculture, and \$60.99 for refractory dead-burned dolomite.

The average value of hydrated lime sold increased to \$62.16 per ton. Average values were \$56.60 for chemical lime (revised 1988 value was \$58.45), \$69.75 for lime used in construction, and \$59.66 for lime used in agriculture.

Traditionally lime has been a low-priced commodity. Its average annual price ranged from \$4 to \$15 per ton from 1910 to 1970. It was only in the 1970's, when energy prices escalated, that lime prices increased dramatically. This increase continued into the 1980's, although in recent years prices have

Grand total ²	14,516	2,560	17,077	14,691	2,488	17,178

[†] Revised.¹ Excludes regenerated lime.² Data may not add to totals shown because of independent rounding.³ Less than 1/2 unit.⁴ Includes U.S. possessions.

leveled off in the range of \$48 to \$50 per ton. When comparing prices over the past 20 years, based on constant 1989 dollars, two trends become evident. From 1970 to 1979 prices increased steadily, finishing the decade up 52%. From 1980 to 1989 prices decreased steadily, finishing the decade down 24%.

FOREIGN TRADE

Exports and imports of lime both increased in 1989. Exports increased by 116% to 32,241 tons, and imports increased by about 4% to 217,656 tons. Most U.S. trade was with Canada, which accounted for over 85% of the U.S. imports and exports of lime.

On September 11, 1984, the U.S. Department of Commerce published a countervailing duty order on lime from Mexico. The order established rates of 55.89% for Sonocal S.A. de C.V. and 1.21% for all others subject to the order. After the purchase of Sonocal by a private cooperative (Sociedad Cooperativa E.E.R.R. Bomintzha, S.C.L.) in 1986, Commerce initiated a changed circumstances administrative review of the countervailing duty order following

a request from the Government of Mexico on July 21, 1988. As a result of the review, on November 30, 1989, the Department of Commerce published a notice of final results revoking the 55.89% countervailing duty on imports of Mexican lime from Bomintzha, retroactive to August 24, 1986.²

WORLD REVIEW

In October 1989, the National Lime Association hosted the Executive Committee meeting of the International Lime Association in Williamsburg, VA. Final plans were discussed for the Seventh International Lime Association Congress, to be held in Rome, Italy, September 12-14, 1990. The Congress will include presentation of about 20 technical papers and an exhibit by lime and limestone equipment manufacturers.

Brazil³

It is estimated that Brazil produced over 6 million tons of lime in 1989. Over 75% of production came from the states of Minas Gerais, São Paulo, and Paraná. Although there were two to three hundred companies involved in

lime production in Brazil, roughly two-thirds of the total production came from 20 companies. The two largest producers were Ical-Indústria de Calcinação S.A. and Itaú N. Granja-Arcos, which together produced over 1 million tons of quicklime and hydrate. Lime was consumed by the domestic iron and steel industry, for construction, and in paper and pulp manufacture. These three markets accounted for over 70% of consumption.

Canada⁴

Energy, Mines and Resources Canada reported production in 1989 from 13 producers operating 18 plants. The major end uses for quicklime were steelmaking (53%), environmental uses (16%), pulp and paper manufacture (13%), and chemicals (8%). The major end uses of hydrate were environmental uses (60%) and in construction (11%).

The Canadian lime industry will grow significantly in the next few years. Plans have been announced for expansion projects or for new plant construction in New Brunswick, Quebec, Ontario, Alberta, and British Columbia. These projects will involve the following companies: the Havelock Lime division of Dickenson Mines Ltd. in New Brunswick, the Domlim and Jolichaux divisions of Graybeck Inc. in Quebec, the Société Dolo-Mine Inc. in Quebec, Beachvilime Ltd. in Ontario, Dymond Clay Products Ltd. in Ontario, Summit Lime Works Ltd. in Alberta, and the Texada Lime division of BP Resources Canada Ltd. in British Columbia. Most of this new capacity should come on-line during 1990 and 1991.

Germany, Federal Republic of

The West German lime industry continued to benefit from a strong economy. Expansion by the construction and iron and steel industries buoyed lime sales, despite increased competition from both Eastern and Western Europe. The Federal Republic of Germany ranked fifth in the world in lime production.

Sweden

The Swedish lime industry consisted of three commercial producers of quicklime and hydrate and three cap-

¹ Revised. W Withheld to avoid disclosing company proprietary data.

² Excludes regenerated lime. Includes Puerto Rico.

³ Data may not add to totals shown because of independent rounding.

⁴ Includes briquetting, brokers, calcium carbide, chrome, citric acid, commercial hydrators, desiccants, environmental uses, explosives, ferroalloys, fiberglass, glue, insecticides, ladle desulfurizing, magnesium metal, manganese, pelletizing, pharmaceuticals, petrochemicals, precipitated calcium carbonate, rubber, silica brick, soap, wire drawing, and uses indicated by symbol W in "Chemical and industrial" lime only.

⁵ Includes asphalt antistripping.

tive producers of quicklime. The major commercial uses were for steelmaking, paper and pulp manufacture, building materials, and environmental purposes. Annual commercial sales were about 465,000 tons and captive consumption about 275,000 tons. Two steel plants were to close down at the end of 1989, decreasing demand by 45,000 tons to 55,000 tons per year. In April 1989, a new lime kiln came on-

stream, intended to replace an older kiln. The new kiln, operated by Kalkproduktion Storugns AB and jointly owned by Swedish, Danish, and Finnish producers, will produce about 165,000 tons per year.

United Kingdom

Lime producers in the United Kingdom belonging to the trade association,

British Aggregate Construction Materials Industries (BACMI), formed the British Lime Association (BLA) in November 1989. The BLA will function within BACMI and be affiliated with the International Lime Association. Its major aims will be to promote the development of new applications in the United Kingdom and to represent the lime industry on matters concerning the Government.

^c Estimated. ^p Preliminary. ^r Revised.¹ Table includes data available through June 6, 1990.² Lime is produced in many other countries besides those listed. Argentina, Iraq, Pakistan, and Syria are among the more important countries for which official data are not available.³ Data are for years ending June 30 of that stated.⁴ Reported figure.⁵ Less than 1/2 unit.⁶ Revised to zero.⁷ Includes hydraulic lime.⁸ Data for year ending mid-July of that stated.

industry about the revised ASTM Standard Specification for Mortar for Unit Masonry (C-270-86) and Uniform Building Code, which allowed masonry cement to be used alone to produce any listed mortar type for either reinforced or unreinforced masonry. The concerns focused on whether mortars produced using masonry cements were equivalent to Portland cement lime mortars with respect to masonry assemblage characteristics such as masonry water tightness, masonry bond, masonry shear strength, and masonry compressive strength.

A testing program was developed to compare the two types of mortars. The program involved two phases: (1) tests on laboratory mortars and (2) tests on jobsite mortars. Eight masonry cement mortars and three Portland cement lime mortars were studied. The studies concluded that the properties of the mortars produced using either masonry cement or Portland cement lime were equivalent. However, the study also concluded that the masonry assemblage properties of Portland cement lime mortars were significantly better with respect to water tightness, flexural bond strength, and shear strength, and equivalent in compressive strength.

OUTLOOK

Lime has dozens of end uses in the chemical, industrial, and construction industries. Steelmaking is still the largest single end use for lime, although the total consumption by tonnage and percentage of total lime production has decreased. Over the past 20 years lime consumed for steelmaking averaged 6,790,000 tons per year or 39% of total consumption. In 1989, consumption dipped to 4,971,000 tons or 29% of total consumption. The dip in 1989 reflects a trend of decreasing consumption by the steel industry. This trend is a result of the decreasing consumption of fluxing agents, thus less lime is consumed per ton of steel.

The outlook for steel production in the U.S. is uncertain. Labor contracts will expire at major steel producers in 1991 and 1992, impacts of new clean air legislation are unknown, and Voluntary Restraint Agreements with foreign producers will expire in 1992.

These uncertainties make forecasting U.S. steel production extremely difficult. One econometric model, based on the actual production from 1982 through 1989, assumes production will decrease 1991 through 1994 and be followed by a strong recovery in 1995 and 1996. Based on this forecast and the decreasing trend in flux consumption, lime consumption for steelmaking could easily drop to 4.0 to 4.5 million tons per year by the early 1990's. This translates to a loss in consumption of up to 1.0 million tons per year, most of which would be in commercial sales.

Other sectors of the lime market are more difficult to analyze. No other single end use consumes more than 9% of total consumption, although environmental uses when grouped together account for 22%. It is in this sector of the lime market that growth potential exists. The four major environmental uses for lime are: (1) sulfur removal from stack gases or flue gas desulfurization (FGD), (2) water purification, (3) Sewage treatment, and (4) acid water treatment. According to Bureau of Mines statistics, during the 1980's the total consumption for these uses actually declined by nearly 12%, despite FGD use doubling. Other environmental uses consume over 600,000 tons per year.

New environmental legislation and a resurgence in environmental awareness and concern by the public will have an impact on environmental markets. Consumption for FGD should continue to increase, despite strong competition from limestone and other non-lime FGD systems. Consumption for stabilization of sewage sludge to tie up heavy metals and reduce odor should increase. Lime's ability to tie up heavy metals and neutralize acid water makes it useful in treating tailing ponds at active mining operations and in treating the runoff from abandoned mines. This should lead to increased consumption in the Western United States, where increased attention is being directed at the problems of acidification and heavy metal pollution of streams and rivers from past mining. Lime should be ideally situated to take advantage of a new emphasis on environmental cleanup. It is an important and economical component in the treatment of air, water, and solid wastes.

The outlook for lime consumption in

other chemical and industrial uses depends on the general health of the economy and the health of specific sectors, such as construction, paper and pulp, and mining. An attempt to address the problems in the Nation's transportation infrastructure could increase consumption in the construction sector, especially for soil stabilization in major projects such as airport and highway construction and as an antistripping agent in asphalt. Lime consumption in the pulping chemical market is forecast to grow by 6% per year. Lime consumption for precipitated calcium carbonate (PCC) production should increase dramatically as the push to build satellite PCC plants near paper mills continues. If base and precious metals prices remain steady or increase, lime consumption by the mining industry could increase. It is an important chemical in the recovery, smelting, and refining of copper, gold, silver, and other nonferrous metals.

BACKGROUND

Definitions and Specifications⁶

Lime is a manufactured product made by calcining limestone (calcium carbonate or a combination of calcium and magnesium carbonate) or other calcium carbonate materials at temperatures ranging from 1,800° F to 2,400° F. It is never found in a natural state. The calcination process drives off the carbon dioxide, forming calcium oxide (quicklime). The subsequent addition of water creates calcium hydroxide (hydrated or slaked lime). The term "lime" is a general term that includes the various chemical and physical forms of quicklime and hydrated lime. It may be high calcium, magnesian, or dolomitic. Quicklime is calcium oxide (CaO), with no water of crystallization. Hydrate is hydrated calcium oxide, or calcium hydroxide (Ca(OH)₂), and contains 24% combined water. Dead-burned refractory dolomite is dolomite that has been calcined at 2,800° F to 3,150° F. Refractory dolomite is another name for dead-burned dolomite. All of these products are called lime.

Quicklime is commercially available by the carload, in bulk, or in paper bags, in the following standard sizes:

1. *Lump lime*—the product is over 2.5 inches in diameter. Although sizes

can vary, the typical size is 5 x 8 inches. This largest size of quicklime is strictly a product of vertical kilns.

2. *Crushed or pebble lime*—the product ranges in size from 0.25 inches to 2.25 inches, but the specific product size is more precise. This size has traditionally been a product of rotary kilns, but is now available from vertical kilns as either a primary product or as a result of crushing lump lime.

3. *Ground lime*—the product is generally ground from larger size material. A typical product size passes nearly 100% through a No. 8 sieve and 40% to 60% through a No. 100 sieve.

4. *Pulverized lime*—the product is the result of further grinding. A typical product size passes nearly 100% through a No. 20 sieve and 85% to 95% through a No. 100 sieve. This is usually a secondary product and is produced by intense grinding and classification.

5. *Pelletized lime*—almond-shaped pellets or briquets of uniform 1-inch size, molded from quicklime fines.

Hydrated lime is shipped in bulk tank trucks, rail cars, and in 50-pound paper bags. As a result of the hydration process, it is of fine particle size. A typical product size passes 85% or more through a No. 200 sieve, and a few special applications may require a product passing 95% to 98% through a No. 325 sieve.

Because of the differences in limestones, a rigid standardization of lime material specifications is impossible. Few plants manufacture lime with exactly the same properties, as a result, lime specifications are by necessity quite general in their provisions. A typical analysis is shown in table 10.

Technology⁷

Lime manufacture involves three main processes: stone preparation, calcination, and hydration. Stone preparation involves quarrying or mining (including drilling, blasting, and conveying broken stone), crushing, and screening to provide the proper size kiln feed. Care is taken to avoid contamination with undesirable impurities, such as iron oxide, silica, and alumina. Although most lime manufacturers produce their own stone, some purchase the stone for kiln feed from commercial limestone producers.

Calcination is a simple chemical reaction. It is the addition of heat to

TABLE 10
TYPICAL ANALYSES OF
COMMERCIAL QUICKLIMES

Component	High Calcium quicklimes, range, ¹ percent	Dolomitic quicklimes, range, ¹ percent
CaO	93.25-98.00	55.50-57.50
MgO	.30- 2.50	37.60-40.80
SiO ₂	.20- 1.50	.10- 1.50
Fe ₂ O ₃	.10- .40	.05- .40
Al ₂ O ₃	.10- .50	.05- .50

limestone to cause thermal decomposition, in which the coproducts of CaO (quicklime) and CO₂ (carbon dioxide) are formed. This process is performed in a kiln, of which there are a wide variety of systems in use. The two basic kiln designs are rotary and vertical (or shaft). There are a few other miscellaneous designs, but the majority of commercial kilns are of rotary or vertical design.

A rotary kiln is a long cylindrical kiln with a refractory lining, inclined at a slight angle, rotated at a slow speed, and fired by fuel at the lower end. The calcareous raw material (kiln feed) is fed into the upper end and calcined at around 2,000° F during its travel through the kiln to form quicklime,

which is discharged at the lower end. The calcination temperature depends on size and composition of kiln feed and the type of desired product. The carbon dioxide is driven off as a gas and normally exits the system with the stack gas.

Vertical kilns are short, wide, vertical cylinders lined with refractory materials. They are usually circular in cross section, typically with a diameter of 9 to 14 feet and a height of 50 to 70 feet. They are the most widely employed in the world, especially in Europe. A vertical kiln is divided into four distinct zones where specific parts of the manufacturing process take place. They are, from top to bottom, (1) stone storage zone, (2) preheating zone, (3) calcining zone, and (4) cooling and discharge zone.

Examples of other kiln designs are the rotary hearth kiln and the fluosolids kiln. The rotary hearth design consists of a preheater, circular hearth, and cooler, all refractory lined. Stone is placed on the hearth and rotated through a heating chamber. In the fluosolids kiln, fine-sized stone is densely suspended by air and hot gases in the preheating and calcining zone of a vertical heated chamber. It can be operated at lower temperatures because of the fine stone size. The quicklime product is the most highly reactive of any commercial lime.

LITHIUM

By Joyce A. Ober

Mrs. Ober, a physical scientist with 12 years industry and Bureau of Mines experience, has been the commodity specialist for lithium since 1986. Domestic survey data were prepared by Carleen Militello, mineral data assistant, and international data tables were prepared by Peter J. Roetzel, international data assistant.

The United States led the world in lithium mineral and compound production and consumption. Estimated consumption increased slightly, and world production also grew. Sales increased for domestic producers, who announced price increases for the third consecutive year.

Because lithium is electrochemically reactive and has other unique properties, there are many commercial lithium products. Producers sold lithium as mineral concentrate, brine, compound, or metal, depending upon the end use. Most lithium compounds were consumed in the production of ceramics, glass, and primary aluminum.

DOMESTIC DATA COVERAGE

The Bureau of Mines collects domestic production data for lithium from a voluntary survey of U.S. operations. The two U.S. companies responded to the survey, representing 100% of total production. Production and stock data were withheld from publication to avoid disclosing company proprietary data. The metric system is the official system of measurement of most countries. The Bureau of Mines, in an effort to provide statistical data on lithium in units most consistent with international usage, will henceforth report data in kilograms and metric tons unless otherwise noted.

LEGISLATION AND GOVERNMENT PROGRAMS

The Department of Energy (DOE) planned to offer portions of its 36 million kilograms of lithium hydroxide monohydrate for sale. The DOE stocks

were excess from a weapons program that used the lithium to make tritium, a compound necessary for nuclear fission reactions. The stockpile originally contained about 42,000 tons of material, from which about 75% of the lithium 6 isotope had been removed. This material possibly contained 8 to 9 parts per million of mercury. Because of mercury contamination, DOE delayed the proposed disposal of lithium hydroxide until an environmental impact study was complete.

PRODUCTION

The two companies that produced lithium in the United States in 1989 did so from two different types of deposits. Both firms mined spodumene, (a lithium-aluminum-silicate ore) from large hard-rock deposits in North Carolina using open pit methods. Geothermal

brines were a source for lithium in Nevada. Pumps remove the brine from underground deposits into evaporation ponds. Extraction processes separate lithium from the concentrated brines.

Cyprus Foote Mineral Co. produced lithium carbonate at its brine deposit in Silver Peak, NV, and produced small quantities of spodumene concentrate at its mine in Kings Mountain, NC. It operated processing facilities for downstream lithium products and metal in Frazer, PA; Sunbright, VA; and New Johnsonville, TN. The company continued to maintain its lithium carbonate plant at Kings Mountain in a care-and-maintenance status as it had since mid-1986.

Lithium Corp. of America (Lithco), a subsidiary of FMC Corp., mined spodumene from pegmatite dikes near Bessemer City, NC. The company produced lithium carbonate and a full range of downstream compounds, including lithium metal and some organic lithium

CONSUMPTION AND USES

The aluminum, ceramics and glass, lubricating grease, and synthetic rubber industries consumed most of the lithium minerals and chemicals. These markets were primarily related to transportation, i.e., the aircraft and automotive industries. Industrial and consumer applications also used ceramics and glass. Estimated domestic consumption increased slightly in 1989. Ceramics and glass production and aluminum smelters were the largest consumers of lithium in the United States. Aluminum producers consume little lithium carbonate in other countries.

Lithium carbonate and mineral concentrate additions in ceramics and glass manufacturing processes lower process melting points, reduce the coefficient of thermal expansion and the viscosity, and eliminate the use of more toxic chemicals. The manufacture of thermal-shock-resistant cookware (pyroceramics) consumed the majority of lithium used in the ceramics and glass industry domestically. The manufacture of black and white television picture tubes consumed significant amounts of lithium concentrates overseas. Low-iron petalite and spodumene, two lithium ores, were a source of lithium used to improve the physical properties of container and bottle glass and as a source of alumina (Al_2O_3), another important component of the glass. Glass manufacturers used lithium in container and bottle glass, enabling them to produce lighter weight, thinner walled products.

Aluminum producers added lithium carbonate to cryolite baths in aluminum potlines. The chemistry of the potline converts it to lithium fluoride, lowering the melting point of the bath, allowing a lower operating temperature for the potline, and increasing the electrical conductivity of the bath. Operators used these factors to increase production, reduce power consumption, or increase current efficiency.

The multipurpose grease industry was the third largest end use for lithium in 1988. Lithium-based greases are favored for their retention of lubricating properties over a wide temperature

range; good resistance to water, oxidation, and hardening; and formation of a stable grease on cooling after melting. These greases continued to be utilized in military, industrial, automotive, aircraft, and marine applications.

Nearly all major battery manufacturers marketed lithium batteries in some configuration, and research and development continued for further substitution in applications that implement more conventional alkaline batteries. Although they represent a small percentage of total lithium consumption, sales of these batteries remained a favorable growth area for lithium consumption. Lithium batteries offer improved performance over alkaline batteries, at a slightly higher cost. Lithium batteries were used in watches, microcomputers, and cameras, and, more recently, in small appliances, electronic games, and toys. The military purchased large and small lithium batteries for a variety of military applications.

Aircraft manufacturers in several countries continued to test aluminum-lithium alloys for wing and fuselage skin and structural members of new aircraft. Use of aluminum-lithium alloys can reduce the weight of the aircraft by more than 10%, allowing significant fuel savings over the life of the aircraft. The alloys, which are 2% to 3% lithium by weight, are attractive to the aircraft and aerospace industry because of their reduced density and su-

perior corrosion resistance compared with those of conventional aluminum alloys. These alloys face direct competition, however, from composite materials consisting of boron, graphite, or aramid fibers imbedded in polymers.

Small quantities of other lithium compounds were important to many industries. Butyllithium was a catalyst in synthetic rubber production. Lithium chloride and lithium bromide were used in industrial air-conditioning systems, commercial dehumidification systems, and in the production of sophisticated textiles. Sanitizers for swimming pools, commercial glassware, and public restrooms contained lithium hypochlorite, as did dry bleach for commercial laundries. Patients diagnosed as suffering from manic-depressive mental disorders may take medication containing a pharmaceutical grade of lithium carbonate. Lithium metal was used as a scavenger to remove impurities from copper and bronze, and anhydrous lithium chloride was used as a component in fluxes for hard-to-weld metals such as steel alloys and aluminum.

PRICES

For the third consecutive year, both domestic companies increased prices for nearly all lithium products. Prices were about 6% higher in 1989 than the

previous year. The close balance between supply and demand worldwide has been instrumental in improving the price situation. Although installed production capacity remained in excess of demand, the chemical plant at Kings Mountain remained inactive, and supply and demand were balanced sufficiently to maintain strong prices.

FOREIGN TRADE

The Bureau of the Census began using the Harmonized Tariff Schedule in 1989 to identify material passing through U.S. Customs. This system makes classification codes for imports and exports consistent internationally. With the adoption of new codes, import and export categories for lithium and its chemicals changed, and some formerly listed details were no longer available. International trade information will no longer be available for lithium ore concentrates or lithium metal from the Bureau of the Census. Import categories identified as lithium carbonate and lithium oxides and hydroxides replaced lithium salts and compounds. For this reason, comparisons between 1988 and 1989 trade data are not valid.

The Federal Republic of Germany, Japan, and United Kingdom were the largest importers of lithium compounds from the United States. Imported lithium ore concentrates entered the United States, but no data were available. Reports from concentrate producers and consumers indicated that U.S. imports decreased in 1989.

WORLD REVIEW

A small number of countries throughout the world produced lithium ore and brine. The United States produced the most lithium; significant quantities also were produced in Australia, Canada, Chile, China, the U.S.S.R., and Zimbabwe. Argentina, Brazil, and Namibia produced smaller quantities; production primarily consisted of ore concentrates. Portugal and Zaire have produced lithium mineral concentrates in the past.

The U.S.S.R. and China produced significant quantities of lithium car-

bonate and other lithium compounds, but specific information on the operations was limited. Companies in the Federal Republic of Germany, France, Japan and the United Kingdom produced downstream lithium compounds from imported lithium carbonate, but no minerals or brines were produced in those countries.

Capacity

The data in table 5 are rated capacity for mines and refineries as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure. Any restrictions to capacity utilization related to legal, political, or environmental restraints have been footnoted.

Lithium presented special problems during compilation of production capacities for different operations. Ore concentrate products are not comparable to lithium carbonate. Lithium carbonate was the primary compound produced at lithium chemical plants and the compound from which all other lithium chemicals were produced. Because even high-grade ore products usually contained less than 4% lithium and lithium carbonate contains nearly 20% lithium, production capacities reported in tons per year represent large differences in the actual lithium content of the product. For that reason, capacities were reported based on the lithium content of the products also known as contained lithium.

Australia

Lithium Australia Ltd. (LAL), a subsidiary of Greenbushes Ltd., mined high-grade, low-iron spodumene at its mine in Greenbushes, Western Australia. LAL produced two ore concentrate products through a flotation process for sale to the ceramics and glass industry. The majority of the company's spodumene concentrate was used in the

manufacture of black and white television picture tube glass and pyroceramics in the Pacific rim countries and Europe. LAL sold to the same countries glass grade concentrate with lower lithium content for consumption in container glass. Sales and production continued to expand significantly, as they have every year since production began in 1982.¹

Bolivia

Industria Minera Tierra Ltda., a Bolivian company, and a U.S. company expressed interest in developing the Salar de Uyuni, the world's largest salt flat. Early in the year, Industria Minera Tierra requested permission from the Bolivian Government to build a pilot plant for the production of 40 tons of lithium carbonate per year. The Government showed interest in joint-venture arrangements by announcing plans to call for international bids. At yearend, the Government of Bolivia and Lithco were negotiating for a joint-venture operation in the Salar. Lithco's plans included an exploration program and, possibly, a 37,000-ton-per-year plant for recovery of lithium carbonate from the evaporated brines. Preliminary studies of the Salar de Uyuni, which is more than 3,600 meters above sea level, indicated reserves of 5.5 million tons of lithium, 110 million tons of potassium, and 3.2 million tons of boron.²

Canada

Tantalum Mining Corp. (Tanco) has been mining spodumene concentrates at its mine near Bernic Lake in southeastern Manitoba. Since mining began in 1984, Tanco has grown to become the largest supplier of lithium ore concentrates to the U.S. ceramics and glass industry. The Canadian spodumene was similar to the material mined in Australia (high-grade spodumene with very low iron content), making the concentrates ideal for direct application in the ceramics and glass industry.

Chile

Cyprus Foote Mineral Co. bought the remaining shares of its lithium brine operation at the Salar de Atacama, Sociedad Chilena de Litio Ltda. (SCL) to become the sole owner. Cyprus Foote, formerly Foote Mineral Co., has produced lithium carbonate

from the brines from this Salar since 1984. The project originated as a joint venture between Foote and Corporación de Fomento de la Producción (CORFO), a Chilean Government agency. Production capacity for lithium carbonate increased steadily from a 6,300-ton-per-year capacity to reach the current level of 9,100 tons per year. SCL expanded the evaporation ponds prior to another expansion at the carbonate plant. Further capacity expansion to 11,800 tons per year should be completed in 1990.³

Minera Salar de Atacama Ltda., the consortium formed by AMAX Exploration Inc. (United States), CORFO, and Molibdenos y Metales S.A. (Chile), completed studying the feasibility of developing another lithium operation on the Salar in 1988. Evaluations of the results were analyzed, and a decision from AMAX to pursue the project was expected in 1990.⁴

Namibia

Southwest Africa (SWA) Lithium Mines produced petalite concentrate at its Rubicon Mine near Karibib. Low-grade ores were beneficiated through a flotation process, while high-grade ores were hand picked. Small amounts of two other lithium ores, lepidolite and

amblygonite, were other products. The Federal Republic of Germany imported most of these ores. High-grade lepidolite was handpicked at the company's Helicon Mine for export to Western Europe and Japan.⁵

Zimbabwe

Bikita Minerals Ltd. mined petalite, another lithium ore, near Masvingos. Although the ore reserves were becom-

ing depleted, installation of a dense-media separator made it possible to recover lithium in the form of petalite averaging about 4.4% lithium oxide from a stockpile of previously rejected material. This extended the estimated mine life 30 years. Hand sorting, the method used since the mining began in 1916, amassed a stockpile of over 1 million tons that could be recovered with a significant savings in mining

costs after installation of the new device. Hand sorting continued to be used only for special small orders of minerals other than petalite.⁶

CURRENT RESEARCH

Research continued in areas believed to possess the greatest potential for the lithium industry. Martin Marietta Corp. of Baltimore, MD, developed a new family of aluminum-lithium (Al-Li) alloys, named Weldalite, targeted for use in aerospace applications, and, specifically, space launch systems. The alloys were the strongest known wrought aluminum products available, according to Martin Marietta. Reynolds Metals Co. received the license for exclusive production. During testing, Weldalite maintained superior

Output by China and the U.S.S.R. has never been reported.

rior strength over the wide range of temperatures required for space applications. The alloys were lightweight due to the lithium content, and weldable, making them attractive for use in fuel and oxidizer tanks for space vehicles. Reynolds planned to produce ingot, sheet, plate, and extrusions of Weldalite at its new casting facilities in McCook, IL. The McCook facilities were upgraded to prepare Reynolds to become a leading supplier to the aerospace industry.⁷

Because forged metal parts have been preferred to castings or machined parts due to superior tensile strength and toughness, techniques have been developed for forging Al-Li alloys. Boeing Commercial Aircraft Co. tested tow fittings forged from Al-Li 2090 alloy that should withstand the high load stress of towing and the extensive environmental exposure during takeoffs and landings on aircraft. Huntington Alloys International developed two powder metallurgy Al-Li alloys for

forgings. The company tested its 905XL hot-die forgings in aircraft components because of its low density and high strength. It considered its 9052 alloy for torpedo bodies and hulls because of its good corrosion resistance.⁸

Several organizations improved existing battery technology or developed new products. Long-life thermal batteries have powered weapons and spacecraft since World War II. These batteries can remain inactive for 30 years without discharge, and upon activation when the electrolyte melts, produce power for a few minutes to 1 hour. In the late 1970's, Sandia National Laboratories developed a lithium-silicon alloy and iron disulfide battery to replace the original calcium-calcium chromate thermal battery. The new design weighed 75% less than the calcium battery, but experienced troublesome voltage spikes. By addition of lithium oxide to the cathode material, control of heat input to the battery, and puri-

fication of the iron disulfide, the laboratory eliminated the voltage spikes.⁹

Researchers at the University of California at Berkeley developed a new battery that reportedly could make electric vehicles practical. The new battery, which could produce up to 30% more power per ounce than current systems and weighs significantly less, consisted of thin films of lithium, polyethylene film, and a disulfide polymer that are sandwiched together. A series of thin cells could be layered together to form larger batteries. The improved design reduced temperature requirements for electric vehicle batteries. The polymer battery could lower the operating temperature requirements from 700° F to between 176° F and 212° F. Coin cells like the ones found in watches and calculators should be available in 2 years using the new technology; larger size cylinders and vehicle batteries were expected to be available later.¹⁰

Sanyo Energy Corp. began offering a rechargeable lithium/manganese dioxide (Li/MnO₂) battery. The new product possessed a low self-discharge rate and high voltage in relation to size. One Li/MnO₂ battery should replace two nickel/cadmium batteries and provide two to three times the energy density.¹¹

Research continued in other areas, which, if developed, hold potential for requiring large amounts of lithium. Integrated, or waveguide, optics are the optical equivalent of the electronic integrated circuits. As more information is transported via optical fibers, devices will be developed to process that information through optical rather than electronic means. Lithium niobate has been identified as a prime material for integrated optic substrates.¹² Lithium should be an important material in the development and operation of nuclear fusion reactors. Westinghouse Hanford Co., in Richland, WA, developed a device called the Materials Open Test

Assembly (MOTA) to test different materials for use in fusion reactors. Samples of material would be placed in a reactor plant and irradiated for more than 1 year. Tests would determine tritium recovery rates from lithium oxide test canisters. Other fusion materials will be tested in other canisters.¹³

OUTLOOK

The aluminum industry experienced a slowdown in 1984, and, as a result, domestic lithium consumption decreased dramatically that year. Since that time, lithium consumption has expanded at an average of about 5% per year. This increase was due primarily to the recovery of the aluminum industry as well as increased demand for lithium compounds and minerals in the ceramics and glass industry. Similar increases are expected for the future.

Demand for lithium metal for batteries and alloys should increase, but total consumption of the metal will remain small in comparison to the demand for lithium chemicals. Markets should remain relatively stable with average growth, although new applications for mineral concentrates could increase demand for those materials significantly in the next few years. Lithium demand could increase dramatically if any of the new technology areas such as nuclear fusion were perfected. This is not expected to occur within the remainder of this century, and probably not within the next 25 years.

MAGNESIUM AND MAGNESIUM COMPOUNDS

By Deborah A. Kramer

Ms. Kramer is a physical scientist with the Branch of Nonferrous Metals. She has covered magnesium and magnesium compounds for 6 years. Domestic survey data were prepared by Lura Nightlinger, Nonferrous Metals Data Section. International data were prepared by Virginia Woodson and William Zajac, International Data Section.

MAGNESIUM

Domestic magnesium production hit its highest level since the beginning of the decade because strong demand continued for magnesium for aluminum alloying, casting applications, and iron and steel desulfurization. Because demand could not be completely met with primary production, particularly in the first half of the year, inventory levels dropped rapidly to reach a 20-year low by midyear. Demand slowed in the second half of 1989, and producers replenished their stocks. Magnesium exports increased significantly, and imports declined from the high level in 1988. The United States remained a net exporter of magnesium.

World production of magnesium reached a record-high level in 1989, and production capacity was expected to increase significantly within the next year. Two new plants in Canada planned to bring a total of 52,500 metric tons of annual capacity on-stream in 1990, and a small capacity expansion was planned in Brazil. Preliminary investigations were underway

to construct new primary magnesium plants in Australia, Colombia, India, Norway, and the Republic of South Africa.

Legislation and Government Programs

In September, the Environmental Protection Agency issued a final ruling on the criteria to evaluate mineral processing wastes for exclusion from regulation under subtitle C of the Resource Conservation and Recovery Act (RCRA). Wastewater from the anhydrous process for magnesium recovery was a candidate for exclusion under the original criteria in 1988. This waste passed the high-volume, low-toxicity criteria established in the final ruling and was conditionally excluded under RCRA. Final subtitle C regulation of the process wastewater was to be determined by January 1990.¹

Production

U.S. primary magnesium production was at the highest level since 1980 and was at 95% of rated yearend capacity. In April, AMAX Magnesium Corp. announced that it had sold its Rowley, UT, facility, but the sale was not final-

ized until September. Renco Group Inc. purchased the primary magnesium plant, which was renamed Magnesium Corp. of America (MagCorp). MagCorp planned to increase its capacity to 38,000 tons in 1990. The company also began drawing brine in 1989 from its new solar ponds in the west desert that replaced the solar ponds destroyed in a 1986 flood of the Great Salt Lake. MagCorp estimated that the new ponds have a 10- to 15-year supply of brine.

In May, Dow Chemical Co. announced that annual capacity at its Freeport, TX, magnesium plant was increased by 5,000 tons to 90,000 tons. This represented the fourth capacity increase at the facility since late 1987. The capacity increase was in response to low stock levels and growing demand in the automotive diecasting and desulfurization sectors. Dow's three previous capacity increases involved restarting idled electrolytic cells, but the fourth increase involved improvements in the production process.

Northwest Alloys Inc., a subsidiary of Aluminum Co. of America (Alcoa), planned to increase magnesium production at its Addy, WA, plant by

making proprietary improvements in its processing methods. Reportedly, two-thirds of Northwest Alloys' production is used by Alcoa for aluminum alloying. Alcoa used to purchase all of Northwest Alloys' production, but although aluminum can production has increased significantly, increased recycling rates have lowered Alcoa's consumption of primary magnesium.

Consumption

Spectrulite Consortium Inc. purchased Dow's magnesium rolled products business citing the need to strengthen the company's market position. In past years, Dow had purchased Spectrulite's rolled products, and Spectrulite also supplied Dow with extrusion billet for Dow's operations in Aurora, CO.

Frontier Foundries Inc. opened a new magnesium investment casting facility in its complex in Titusville, PA. The company's investment casting process can produce castings with precise size tolerance, smooth surface finish, and intricate detail. Also, Thompson Castings Inc. announced the develop-

ment of a new casting process that yields near-net-shape prototype components for automotive testing requirements. Components can be produced in a wide variety of shapes and in sizes from a few ounces to a few pounds. Castings can be produced by the new process with interlocking cores with thin-wall passages for pneumatic and hydraulic components.

Several new applications for die-cast magnesium in the automotive industry were announced. The Cadillac Motor Div. of General Motors Corp. planned to substitute magnesium valve covers for aluminum on the V-8 engines used in most of its cars. Also, magnesium was planned to be used for the main structural front seat parts in the 1989 Mercedes Benz SL Roadster, for Audi's V-8 die-cast instrument panel, and for wheels in some of Honda Motor Corp.'s automobiles. A review of magnesium applications in the automotive industry outlined additional uses.²

Usage of magnesium continued to increase in the computer industry for both die-cast and extruded components in housings and internal applications.

Because computer components change more quickly than those in other industries, extrusions may be preferable to castings. Extrusions have relatively low-cost tooling and economical short-run capabilities compared to diecasting, although the secondary costs may be higher.³

Stocks

Consumer stocks of primary magnesium declined from 6,860 tons at yearend 1988 to 5,350 tons at yearend 1989. Magnesium alloy ingot stocks increased slightly from 838 tons at yearend 1988 to 849 tons at yearend 1989.

Producers' primary magnesium stocks declined to their lowest level in nearly 20 years by the end of the second quarter. However, by the end of the year, stocks increased substantially to 20,133 tons and also increased from yearend 1988 stocks of 17,087 tons.

Prices

Producers' quoted magnesium prices were unchanged during 1989. Both Dow and MagCorp quoted a price for primary metal ingot at \$1.63 per pound

and diecasting alloy price at \$1.43 per pound throughout the year. A compilation of U.S. magnesium prices from 1915 to 1988 was published by the Bureau of Mines.⁴

Foreign Trade

Because of implementation of the Harmonized Tariff System (HTS) beginning in 1989, trade data for 1989 may not be comparable with those of previous years. Exports of magnesium increased significantly compared with those in 1988. The Netherlands, 27%; Canada, 24%; and Japan, 21%, were the principal destinations for U.S. exports. Magnesium imports declined from the high level in 1988. Norway was the source of 51% of domestic imports, mainly primary metal and alloy. Canada supplied 32%, mainly waste and scrap, and Mexico supplied 9% of U.S. imports.

World Review

World primary magnesium production reached a record-high level in 1989, and world inventory levels dropped significantly during the year. According to the International Magnesium Association, world inventories dropped to a 5-year low in June, but recovered to end the year at 35,000 tons. Yearend stocks represented 52 days of average daily demand during 1989 and were 7,800 tons above those at yearend 1988.

Australia.—Queensland Metals Corp. announced that it was seeking a partner to construct a 60,000-ton-per-year primary magnesium plant in Gladstone. The company was developing a magnesite mine and magnesia production plant nearby and expected to use magnesite for the metal plant feed material.

Brazil.—Cia. Brasileira do Magnesio S.A. (Brasmag) reportedly received a \$10 million loan from a pool of regional banks to increase its annual primary magnesium capacity to 10,600 tons in 1990. The expansion included installation of a series of electric-reduction vacuum furnaces. Brasmag planned to increase production capacity further in the mid-1990's if the Government approves the company's proposal to construct its own hydroelectric powerplant. When the initial expansion is completed, Brasmag plans to export one-fourth of its production

TABLE 5

Source: Bureau of the Census.

to Mexico and other Latin American countries; the bulk of the magnesium is planned for domestic consumption. Brazil's magnesium consumption, mostly from the automotive industry and estimated to be 9,600 tons in 1988, was partially met with imported metal.

Canada.—Small-scale magnesium production at Norsk Hydro A/S's Becancour, Quebec, plant began in November. The company planned to reach the plant's full production capacity of 40,000 tons per year by the first quarter of 1990. Total construction costs were about \$180 million greater than the \$340 million originally budgeted. Included in the total investment were the costs necessary to expand gradually the plant's annual capacity to 60,000 tons.

In November, Magnesium Co. of Canada Ltd. (MagCan) announced the startup of 12,500 tons of annual capacity at its new magnesium plant in High River, Alberta, would be delayed until January 1990. The company cited problems in getting the necessary labor to complete plant construction. MagCan planned to add two 25,000-ton-per-year capacity increments to reach a total annual capacity of 62,500 tons by 1994.

Colombia.—Industrial Minera de Colombia was seeking foreign partners to share the construction costs for a \$200 million magnesium complex in the Guajira peninsula. Annual production of the proposed electrolytic plant would be 30,000 tons. In addition to the electrolytic plant, the magnesium complex would include a desalination facility,

limestone mine, powerplant, and chlorine gas and caustic soda plant.

India.—Ispat Alloys Ltd. announced that it would construct a 4,000-ton-per-year primary magnesium plant near Agartala, Tripura, at a cost of about \$37.5 million. This area is rich in dolomite and natural gas, both necessary for operating a silicothermic plant. Annual demand for magnesium in India was estimated to be about 2,000 tons. No timetable was set for plant construction.

Japan.—In February, Nichiju A.M. announced an increase in its annual magnesium production by 1,200 tons to 4,800 tons at its plant in Takaoku, Toyama. In addition, Ube Industries Ltd. announced that it would increase magnesium production at its plant in Ube City to 8,000 tons per year by mid-1989. Ube planned to restart idled furnaces to achieve the additional production because all the company's operating furnaces were at capacity. With the closure of Furakawa Magnesium Co. Ltd.'s Oyama City, Tochigi, plant in March, total magnesium production capacity in Japan was 13,000 tons by yearend.⁵

Norway.—Norsk Hydro announced that it would close 10,000 tons of annual magnesium production capacity at its Porsgrunn complex when its Canadian plant comes on-stream. The closure was announced late in the year after Norsk Hydro reported that annual production capacity at the plant had been increased by 3,000 tons to

51,000 tons. The incremental increase was achieved by channeling additional electric power through existing facilities. Capacity that was closed in 1988 because of environmental problems was expected to remain closed for at least 5 years.

Elkem A/S planned to build a 20,000-ton-per-year primary magnesium plant if it could come to terms with the Government on electrical supplies. Elkem would take advantage of a power-rate cut offered to a new power-intensive industry. Two economically depressed cities, Fauske and Mo i Rana, were considered as possible plant sites.

South Africa, Republic of.—Anglo American Corp. reportedly began a feasibility study on recovering magnesium from a dolomite deposit in the Transvaal. The dolomite would be used to feed a 10,000-ton-per-year plant operated in a joint venture between Anglo American and Cape Lime Corp., the owner of the dolomite deposit.

United Kingdom.—Norsk Hydro reportedly acquired a majority share of Kirk Precision Ltd., a manufacturer of magnesium bicycle frames, and planned to establish a robotic facility capable of producing 200,000 frames annually. Kirk Precision was believed to have the largest hot-chamber, high-pressure diecasting machinery in existence. This machinery may be adaptable for production of large magnesium diecastings for other applications, particularly in the automotive industry.⁶

Current Research

Mintek, of the Republic of South Africa, patented a process to produce magnesium in a plasma-arc furnace. In the new process, a plasma-arc furnace replaced the submerged-electrode furnace normally used in the Magnetherm process, and the process was done at atmospheric pressure rather than under a vacuum. The reaction, in which magnesium vapor is generated from dolomite and ferrosilicon, was the same as that of the Magnetherm process. Min-

tek claimed that capital costs for the new process were less than those for the Magnetherm process, and it could be adapted to continuous or semicontinuous operation.⁷

Magnesium Elektron Ltd. introduced a magnesium casting alloy, designated WE43, a high-strength alloy containing yttrium for use at temperatures up to 300° C. The alloy was cast by a novel process called differential-pressure sand casting, which provides thin-walled castings with improved properties and in-

creases metal utilization. Corrosion resistance of WE43 was reported to be comparable with that of high-strength aluminum alloys. Potential applications for WE43 are aerospace engines, helicopter transmissions, and missiles. Allied-Signal Inc. also developed a new magnesium casting alloy suitable for applications in the aerospace and automotive industries. The magnesium-aluminum-zinc-neodymium alloy was reported to match the corrosion resistance of 2024 aluminum alloys. It also

showed superior resistance to pitting, compared with conventional magnesium casting alloys, while retaining equivalent mechanical properties. The new alloy can be formed by rapid-solidification-processing techniques.

A new company, Thixomat Inc., was formed to commercialize a process to fabricate near-net-shape metal and metal-matrix composite parts. The process, developed by Dow, combines elements of diecasting with injection molding, and developmental work was done with magnesium alloys and magnesium metal-matrix composites. In the one-step patented process, granules of magnesium alloy were fed into a reciprocating-screw-injection system, heated to 580° C to form a semisolid slurry, and injected quickly into a mold. Components produced from thixotropic magnesium were reported to have 50% lower porosity and greater dimensional stability than die-cast components.⁸

Outlook

The International Magnesium Association, in its annual review of magnesium supply and demand, projected an

average annual growth rate in consumption of 3% from 1989 to 1993 throughout market economy countries. Most of this growth was projected to occur in North American diecasting applications, with all other applications exhibiting small growth. Continued recycling of aluminum beverage cans, the largest market for magnesium, coupled with reduced can weight, contributed to a slow growth forecast in this application. But, if aluminum food cans are proven technically feasible and aluminum beverage cans are accepted in Europe, the slow growth forecast could change dramatically.

Worldwide magnesium production was expected to increase over the same period, but as significant additional capacity comes on-stream in Canada, capacity utilization was expected to de-

cline. As part of the decrease in capacity utilization, higher cost magnesium producers were expected to take small capacity increments offline when inventories increase to an acceptable level.⁹

MAGNESIUM COMPOUNDS

Overall U.S. magnesium compounds production decreased in 1989, although caustic-calcined magnesia production increased. Imports continued to supply a significant share of U.S. demand, but the dramatic annual increases in imports that occurred in the mid-1980's appeared to have stabilized.

Refractories were the principal use for dead-burned magnesia, and caustic-calcined magnesia was used primarily in

² Reported figure.

animal feed and chemicals. Seawater and brines were the main raw materials for magnesium compound production, accounting for more than 60%, with dolomite, magnesite, and olivine as the other source materials.

Many world producers of magnesia were upgrading their facilities to produce higher grade materials rather than increasing their capacity. Demand from the refractories users, such as the iron and steel industry, for better-quality, longer-lasting refractories resulted in this shift from higher quantity to higher quality.

Production

Caustic-calcined magnesia production increased for the third year in a row, and dead-burned magnesia production declined, reversing a 2-year trend. Production of olivine declined by 9%, and average value decreased by 16%.

Early in 1989, a partnership formed between managers of Merck & Co. Inc.'s magnesium chemicals business and C. P. Hall Co. purchased the assets of Merck's magnesium chemicals business. Although Merck sold the San Francisco, CA, plant to Genentech Inc. in 1988, the partnership, named Marine Magnesium Co., negotiated an open-ended lease with Genentech to continue operations at the plant for at least 3 years. C. P. Hall, a purchaser and reseller of specialty magnesias, was expected to continue to be Marine Magnesium's largest customer. National Refractories & Minerals Corp. announced in July that it completed an expansion of capacity for production of 50% magnesium hydroxide slurry. This expansion would triple magnesium hydroxide slurry capacity at its Moss Landing, CA, seawater plant to 400,000 tons per year.

Consumption and Uses

Refractories for use in iron and steel, nonferrous metals, glass, and cement production facilities were the dominant use for dead-burned magnesia. Caustic-calcined magnesia was used in a wide variety of applications. Animal feed, representing 27% of U.S. caustic-calcined magnesia shipments, was the largest consuming industry. Chemical uses accounted for 24% of domestic shipments. The following uses, in declining order, accounted for 24% of caustic calcined magnesia shipments: rayon manufacture, refractories, fertilizer, and fuel

additive. The remaining 25% of domestic shipments was consumed by the following industries, in declining order: stack-gas scrubbing, rubber, electrical, water treatment, ceramics, medicine and pharmaceuticals, oxychloride and oxy-sulfate cements, sugar, pulp and paper, uranium processing, insulation and wallboard, candies, foundry, and winemaking.

Magnesium carbonate and magnesium sulfate were used principally in

the pharmaceutical industry, with smaller use for chemicals and fertilizers. Magnesium carbonate also was used in the rubber industry, and magnesium sulfate was used for animal feed. Magnesium chloride brines were used primarily in chemical applications, with smaller uses in ceramics and dust control. Pulp and paper was the main consuming industry for magnesium hydroxide. Smaller quantities were used in the chemical and water

treatment industries. Magnesium chloride was used for chemicals and oxychloride and oxysulfate cements.

The bulk of U.S. olivine shipments, 68%, was used as foundry sands. Refractories represented 18% of olivine shipments, and the remaining 14% was used for slag control, soil conditioning, and unspecified applications.

Prices

Yearend magnesium compound prices, published in the Chemical Marketing Reporter, have remained unchanged since 1987. Yearend prices were as follows:

Magnesia, natural, technical, heavy, 85%, f.o.b. Nevada	per short ton	\$232
Magnesia, natural, technical, heavy, 90%, f.o.b. Nevada	do.	265
Magnesium chloride, hydrous, 99% flake	do.	290
Magnesium carbonate, light, technical (freight equalized)	per pound	\$0.73-.78
Magnesium hydroxide, National Formulary, powder (freight equalized)	do.	.78
Magnesium sulfate, technical	do.	.14

Foreign Trade

Because of the implementation of the HTS beginning in 1989, trade data for 1989 are not comparable with those of the previous years. For magnesium compounds, additional data on exports of crude magnesite and various magnesium compounds were separated that were previously included in categories containing other materials.

Trade data for olivine were combined with other trade data by the Bureau of the Census and could not be separately identified. According to the Journal of Commerce Port Import/Export Reporting Service, 205,090 tons of olivine was imported from Norway, and the United States exported 4,491 tons, mainly to Chile and Peru.

World Review

Australia.—After completing a feasibility study in June, the joint-venture partners in the Queensland Magnesite Project planned to begin construction

of a magnesite plant by yearend. The new plant, in Kunwarara, was expected to have an annual capacity of 150,000 tons of dead-burned magnesite and 25,000 tons of fused magnesite. Initial production was planned for mid-1991, with product shipments beginning in September. The magnesite deposit that will serve as the feed for the plant was estimated to contain 400 million tons of magnesite. Two areas, designated KG1 and KG2 and representing 13% of the total deposit, were targeted for initial mining operations at a rate of between 1.75 and 2 million tons per year.

Brazil.—Magnesita S.A., the largest magnesite producer in the country, also produces refractory brick and planned to install a new shaft kiln, with a capacity of 50,000 tons of brick per year at its plant in Minas Gerais. The new kiln,

expected to be operational by 1991, was designed to produce a high-density, 98% magnesite brick. In addition, one of Magnesita's subsidiaries, Refraterc-Productos Electrofundidos Ltd., planned to construct a 2,400-ton-per-year plant to produce a high-temperature grade of fused magnesite. Both of these new operations were part of Magnesita's program to develop new refractory products for basic-oxygen furnaces and electric arc furnaces.¹⁰

Canada.—Baymag officially opened a 14,000-ton-per-year fused magnesite plant in September in Exshaw, Alberta. Baymag produced caustic-calcined magnesite at its nearby plant as the raw material for the fused magnesite plant. To maintain feedstock supply, Baymag announced that it would construct a 50,000-ton-per-year facility for caustic-calcined magnesite at the new plant site. Because of the high degree of automation in the new plant, the entire operation reportedly could be run by six people. Depending on market strength, Baymag planned to double the plant's capacity by adding two electric arc furnaces.¹¹ In addition to its production of fused and caustic-calcined magnesite, Baymag was expected to supply magnesite for a new magnesium metal plant scheduled to begin operation in 1990.

India.—Tamilnadu Magnesite Products Ltd. reportedly was constructing a

30,000-ton-per-year plant to produce dead-burned magnesite. The new plant, scheduled to come on-stream in 1991, will use technology patented by Sulzer Brothers Ltd. of the Federal Republic of Germany to beneficiate low-grade magnesite to dead-burned magnesite containing greater than 99% magnesite. High-grade magnesite produced at the plant was expected to be used for refractory bricks in the country's growing steel industry. Tamilnadu Magnesite also produced caustic-calcined magnesite for export.

South Africa, Republic of.—Chamotte Holdings (Pty.) Ltd. installed kilns to produce caustic-calcined magnesite for use in animal feed and fertilizers at its operation in Malelane. The company has produced refractory magnesite, and installation of the new kilns was expected to reduce the Republic of South Africa's import dependence on caustic-calcined magnesite. Chamotte Holdings also completed a 6,000-ton-per-year magnesium sulfate plant, with the output destined primarily for paper, agricultural, and other smaller markets. A third project involved the installation of a plant to produce 75,000 tons per year of magnesium carbonate fines.

Outlook

Because the largest use for magnesium compounds is in the manufacture of refractories, this industry segment has had the greatest influence on overall magnesium compounds demand. Following the contraction of the iron and steel industry in the mid-1980's, magnesite refractories demand declined to historic lows. However, a combination of retrenchment and processing changes in the iron and steel industry led to stronger demand for magnesite refractories in the latter part of the 1980's. Growth for magnesite refractories in the early 1990's was expected to continue, but at a slower pace than in the late 1980's. Changes in steel furnace technology led to the substitution of magnesite refractories in place of other types of refractories. But at the same time, development of longer-lived magnesite refractories lengthened the amount of time between furnace relinings.

Although total demand for magnesium compounds has increased significantly from its low point in the mid-1980's, magnesite production in the

United States has not increased as significantly. When the industry was depressed, cheaper imports of magnesite, particularly from China and Greece, began to increase dramatically. Import reliance for magnesium compounds rose from 4% in 1982 to 25% in 1985 and has remained above 20% since then. Even though import reliance has leveled off somewhat, the United States was expected to continue to rely on imported material to supply about 20% of domestic magnesium compounds demand.

BACKGROUND

Definitions, Grades, and Specifications

Primary magnesium metal contains a minimum of 99.8% magnesium. Magnesium-base alloys are named by the composition of the two chief alloying elements, each designated by a letter, and the approximate percentage of each alloying element. For example, AZ91 contains about 9% aluminum (A) and 1% zinc (Z), and HK31 contains about 3% thorium (H) and 1% zirconium (K). Other letters used to specify magnesium alloys are E for rare-earth metals and M for manganese.

Although many minerals contain magnesium, magnesite, dolomite, brucite, and olivine are the only minerals from which magnesium is recovered commercially. Magnesite, or magnesium carbonate (MgCO_3), has a theoretical magnesite content of 47.6%. Dolomite is a calcium carbonate-magnesium carbonate mineral ($\text{CaCO}_3 \cdot \text{MgCO}_3$) that has a theoretical magnesite content of 22%. Brucite, magnesium hydroxide [$\text{Mg}(\text{OH})_2$] contains up to 69% magnesite, and olivine ($\text{Mg}_2\text{Fe}_2\text{SiO}_4$) contains up to 19% magnesite. Of these minerals, magnesite and dolomite are the largest sources of magnesite.

Seawater, brines, and bitterns represent vast sources of magnesium and magnesium compounds. In the United States, more than 60% of the magnesium compounds produced annually are recovered from seawater and brines, and 78% of the magnesium metal production capacity uses seawater or brines as a raw material.

Various magnesite products are made by calcining magnesite carbonate or

⁶ Revised to zero.

magnesium hydroxide at different temperatures. Caustic-calcined magnesia, which is readily reactive with water, is calcined at temperatures up to 890° C. Dead-burned magnesia, also called refractory or sintered magnesia, is calcined at temperatures up to 1,450° C and is unreactive with water. Fused magnesia is produced at temperatures greater than 3,000° C. Magnesia produced from magnesite is generally called natural magnesia, and magnesia recovered from seawater or brines is called synthetic magnesia.

Standards for magnesia generally are set by the consumer for a specific application. Refractory magnesia composition depends on the area of the furnace in which the material is to be used.

Magnesia produced from magnesite can contain between 88% and 98% magnesia, with varying quantities of silica, iron, calcium, and alumina impurities. Synthetic magnesia normally is purer than natural magnesia, containing between 92% and 99.5% magnesia, with smaller quantities of the same impurities found in natural magnesia. Most fused magnesia contains greater than 94% magnesia.

Products for Trade and Industry

The principal use for magnesium metal, averaging greater than 50% of domestic consumption annually, is as an alloying addition to aluminum. Magnesium improves the hardness and corrosion resistance of pure aluminum.

Aluminum-magnesium alloys are used in a wide variety of applications, including automobiles, trucks, aircraft, appliances, and home siding. Two-piece beverage cans, each containing about 2% magnesium, are the largest single use for these aluminum-magnesium alloys.

Magnesium and its alloys are used as structural components in automobiles, trucks, aircraft, computers, and power tools. Many of these applications use magnesium because of its light weight and its ease of machinability. Magnesium is used in the iron and steel industry for external hot-metal desulfurization and in the production of nodular iron. Production of the nonferrous metals beryllium, hafnium, titanium, uranium, and zirconium involves the

use of magnesium as a reducing agent. Anodes of magnesium are used for cathodic protection of iron and steel in underground pipe and water tanks. Small quantities of magnesium are used as a catalyst in producing organic compounds, as photoengraving plates, and in alloys other than aluminum.

Refractory magnesia represents the largest use of magnesium in compounds. Refractory magnesia is manufactured into bricks and other lining materials principally for use in the furnaces and auxiliary equipment used to produce iron and steel. Magnesia-base refractories also are used in furnaces in the cement, glass, and nonferrous metals industries.

Caustic-calcined magnesia is used in a myriad of applications in the agriculture, chemical, construction, and manufacturing industries. Caustic-calcined magnesia is an important component of animal feed and fertilizer, providing essential nutrients for livestock and plant growth. In construction, caustic-calcined magnesia is used in special cements for industrial flooring and in lightweight insulating wallboard. In the chemical industry, it is used as a starting point for the manufacture of other magnesium salts. Special grades of caustic-calcined magnesia are used for pharmaceuticals, including antacids, toothpaste, milk of magnesia, and cosmetics. Magnesia is used to remove sulfur from flue gases and boiler fuels and is used for acid neutralization in process wastewater and in lubricating oils. Caustic-calcined magnesia also is important in manufacturing paper, rayon, and rubber.¹²

Other magnesium compounds are used in place of, or in addition to, caustic-calcined magnesia in many of the above applications. Magnesium hydroxide is used in the pulp and paper industry; magnesium sulfate is used for pharmaceuticals, animal feed, and fertilizers; and magnesium carbonate is used in the chemical, pharmaceutical, and rubber industry. Fused magnesia is mainly used for electrical insulation.

The principal use for olivine is as a foundry sand used in casting iron and steel components and some nonferrous metals. Olivine is used in smaller quantities for refractories, slag control in blast furnaces, and soil conditioning. In Europe, olivine is used instead of sand for blasting debris from buildings and bridges and in incinerators.¹³

Industry Structure

U.S. producers of primary magnesium and magnesium compounds are shown in tables 18 and 19. Olivine is produced by two companies in the United States—Applied Industrial Minerals Corp. (AIMCOR) and Olivine Corp. AIMCOR operates two mines and processing plants in Indiana, North Carolina, and Washington. Olivine operates one mine and one processing plant in Washington.

Norway, the U.S.S.R., and the United States, with large electrolytic plants, represent 82% of the world's magnesium metal production capacity. Smaller thermal plants are located in Canada, China, France, Italy, Japan, and Yugoslavia. Canada is expected to replace Norway as the third largest producer in 1990 when two new electrolytic facilities come on-stream.

In the rest of the world, the largest magnesite production facilities are lo-

cated in the centrally planned economies of China, North Korea, and the U.S.S.R. Together, these three countries account for 53% of the world's magnesite production capacity. Japan and the United States account for nearly 64% of the capacity for magnesium compounds production from seawater and brines. Fused magnesia is produced in France, Israel, Japan, the United Kingdom, and the United States.

Norway is the world's largest producer of olivine, and, in addition to supplying domestic needs, Norway's production is exported throughout the world. Countries with smaller output are Austria, Italy, Japan, Mexico, Spain, and the United States.

Technology

Two thermal processes currently are in use to recover magnesium metal

from dolomite—the Pidgeon process and the Magnetherm process. Both utilize the same basic chemistry, but the Pidgeon process uses an external heat source, and the Magnetherm process uses heat generated by the electrical resistance of the reactants. In the Pidgeon process, dolomite and ferrosilicon are formed into briquettes and heated in a retort under a vacuum. Magnesium oxide in the dolomite reacts with the silicon to produce magnesium vapor, which is cooled and condensed in a separate section of the retort. Plants in Canada, Italy, and Japan use this process to recover magnesium.

In the Magnetherm process, calcined dolomite, ferrosilicon, and alumina are heated under a vacuum. Alumina reduces the melting point of the slag produced by the dolomite-ferrosilicon reaction to make resistance heating practical. Magnesium vapor is cooled and condensed in a condensing chamber. The Magnetherm process is used by plants in Brazil, France, Japan, the United States, and Yugoslavia.

Electrolytic recovery of magnesium requires a magnesium chloride feedstock that is prepared from seawater or brines. Two types of magnesium chloride can be prepared—hydrous and anhydrous. In the preparation of hydrous magnesium chloride, used by Dow, magnesium hydroxide is precipitated

from seawater by the addition of dolomitic limestone. Adding hydrochloric acid to the magnesium hydroxide produces a neutralized magnesium chloride solution. This solution is dehydrated until it contains about 25% water and fed directly to electrolytic cells.

MagCorp and Norsk Hydro use an anhydrous magnesium chloride feed for their electrolytic cells. MagCorp uses solar evaporation initially to concentrate magnesium chloride brines from the Great Salt Lake. After adding calcium chloride to precipitate sulfate impurities, the brine is further concentrated and dehydrated in a spray dryer. The resulting powder is melted and purified to yield an anhydrous material. Norsk Hydro starts with concentrated magnesium chloride brine. The brine is purified, concentrated, prilled, and dehydrated to produce anhydrous magnesium chloride.

Electrolytic cells used to recover magnesium from either hydrous or anhydrous magnesium chloride differ from company to company, and most information about cell design and operating conditions are usually not disclosed. Essentially, magnesium chloride fed to an electrolytic cell is broken down into magnesium metal and chlorine gas by direct current at 700° C. Magnesium is removed from the cell and cast into ingots, and the chlorine

gas is collected and recycled or sold.¹⁴

Mineral Process Licensing Corp. developed a one-step process for producing anhydrous magnesium chloride from magnesite that was expected to be used in the MagCan plant in Canada. Reacting magnesite with chlorine gas in the presence of carbon monoxide in a packed-bed reactor at 900° C produces magnesium chloride and carbon dioxide. Liquid magnesium chloride collects at the bottom of the reactor and is tapped periodically for transfer to the electrolytic cells.¹⁵

Preparing either caustic-calcined or dead-burned magnesia from magnesite involves crushing the magnesite to various sizes, depending on the type of material to be produced. After crushing, magnesite is beneficiated; the degree of beneficiation depends on the quality of the ore and the end use. Lower quality ore often requires heavy-media separation, magnetic separation, and flotation to remove impurities. High-quality ore may require only screening and hand sorting to produce a material of acceptable quality. Caustic-calcined magnesia is produced in shaft kilns, multiple-hearth furnaces, or rotary kilns. Dead-burned magnesia is produced in rotary kilns.

In producing synthetic magnesia, seawater or brines are treated either with a small quantity of lime or sulfuric

acid to remove dissolved carbon dioxide. Then calcium hydroxide, in the form of lime or dolime, is added to precipitate the dissolved magnesium as magnesium hydroxide. The resulting slurry is thickened and vacuum-filtered to yield a filter cake containing about 50% magnesium hydroxide. The filter cake can be directly calcined to produce caustic-calcined or dead-burned magnesia, or it can be calcined and pelletized before dead-burning to give specific size and density characteristics.

Fused magnesia is produced by fusion of high-grade magnesite or caustic-calcined synthetic magnesia in an electric arc furnace. After fusion, the material is crushed, inspected to remove any unfused magnesia, and crushed further in a ball mill.

Economic Factors

Costs to produce magnesium metal vary greatly, depending upon the feed material and the process used. Operating costs for magnesium production range from \$309 to \$2,283 per ton, with energy costs as the largest component of the total operating cost. Total production costs from seawater sources were lower than from brines or dolomite sources. Magnesium compound operating costs also vary depending upon source material and processing techniques. Operating costs range from \$24 to \$425 per ton for magnesium compound production, with seawater as the most costly source. Energy costs also represent the largest component of

operating costs.¹⁶

Tariffs for magnesium and magnesium compounds are shown in table 20. Depletion allowance for magnesium chloride from domestic or foreign sources is 5%. Magnesium carbonate and dolomite have depletion allowances of 14% from domestic and foreign ores. Depletion allowances for other ores are brucite, 10% (domestic and foreign); and olivine, 22% (domestic) and 14% (foreign).

⁵ U.S. demand for metal less U.S. recovery from secondary metal.

MANGANESE

By Thomas S. Jones

Dr. Jones, a physical scientist with 31 years industry and Bureau of Mines experience, has been the commodity specialist for manganese since 1982. Domestic survey data were prepared by Sherwood Jordan, mineral data assistant, and international data tables were prepared by Giovanni Jacarepaqua, international data assistant.

World production of manganese ore increased nominally, according to preliminary data.

The price of metallurgical-grade ore advanced about 60% on international markets to another record. Prices also rose significantly for manganese alloys.

Developments in the United States included a slight decline in usage rate for manganese in steelmaking. The total of contained manganese imported into the United States for the year was the greatest since 1981, and imports of silicomanganese again set a record. The Government's program of upgrading ore into high-carbon ferromanganese was extended through 1991.

LEGISLATION AND GOVERNMENT PROGRAMS

The Minerals Management Service of the U.S. Department of the Interior issued final regulations governing the second and third parts of a three-tiered regulatory program for marine mining on the U.S. Outer Continental Shelf of all leasable minerals other than oil, gas, and sulfur (54 FR 2042).

STRATEGIC CONSIDERATIONS

Security of Supply

Manganese, for which there is no economical substitute, is essential to steelmaking. Steel producers in the market economy countries (MEC's) of the United States, Japan, and Western Europe shared a common concern about lack of economically minable domestic manganese deposits. Also,

MEC ore supply was from relatively few sources, chiefly Australia, Brazil, Gabon, India, Mexico, and the Republic of South Africa, and from just one or two major ore mining companies in each of these countries. The United States was additionally concerned about supply of manganese ferroalloys because its domestic ferroalloy industry had declined well below self-sufficiency in manganese.

Stockpile

The sizable stockpile of manganese materials built up by the Government following World War II still represented a reserve of nearly 2 million tons¹ of contained manganese as of the end of 1989. On September 29, 1989, the De-

fense Logistics Agency (DLA) progressed with the latest phase of the program of upgrading metallurgical-grade ore in the National Defense Stockpile. A contract was made with Elkem Metals Co. to convert about 265,000 tons of ore into about 148,000 tons of high-carbon ferromanganese in 1990 and 1991 at a cost of approximately \$82.3 million. In March, DLA accepted into inventory 55,034 tons of high-carbon ferromanganese to bring its stocks of that ferroalloy to 812,157 tons. The only excess stockpile manganese materials sold in 1989 consisted of 336 tons of nonstockpile-grade metallurgical ore. These developments, plus a small accounting adjustment for natural battery ore, are summarized in the following table.

Material	Short tons, gross weight		
	Sales		Change in yearend inventory
	Stock- pile grade	Non- stock- pile grade	
Natural battery ore	—	—	+ 52
Metallurgical ore	—	336	- 78,198
High-carbon ferromanganese	—	—	+ 55,034

ISSUES

The United States has been lacking in reserves and significant production of manganese almost since the start of domestic steel production. Extensive efforts to discover worthwhile ore deposits or effective methods of using low-grade re-

sources, including steel slags, have resulted in little of commercial promise. In a 1985 report, the U.S. Congressional Office of Technology Assessment (OTA) concluded that improvements in steel production technology offered the best prospect for reducing U.S. manganese import vulnerability.² In so doing, OTA discounted ocean mining for the present.

The setting up and maintenance of a large stockpile has been the most tangible aspect of Government manganese programs. Management of this stockpile is a key part of Government policy. Current law limits use of the stockpile to emergency situations, but its mere presence has had economic implications. Questions that have arisen from time to time include what the makeup and size of the manganese stockpile should be and whether it should be

used for economic purposes, such as in the event sanctions disrupt supplies from the Republic of South Africa.

PRODUCTION

Ore and Concentrate

Production and shipments consisted only of manganiferous material having a natural manganese content of 5% to 15% mined in Cherokee County, SC, for use in coloring brick. Publication of shipments data was precluded to avoid disclosing proprietary data.

Ferroalloys and Metal

Publication of statistics was precluded to avoid disclosing proprietary data.

¹ FeMn, ferromanganese; SiMn, silicomanganese; Mn, electrolytic manganese metal; MnO₂, synthetic manganese dioxide.

CONSUMPTION, USES, AND STOCKS

Metallurgical applications accounted for most manganese consumption, about 90% for steelmaking. Relatively small quantities of manganese were used for alloying with nonferrous metals, chiefly aluminum. Nonmetallurgical applications included dry cell batteries, plant fertilizers, animal feed, brick coloring, and manganese chemicals.³

Ironmaking and Steelmaking

The average rate of consumption of manganese as manganese ore in making pig iron or equivalent hot metal stayed at 1.2 pounds per ton of raw steel, as calculated from a reported consumption of 135,000 tons of manganese ore in production of 97.9 million tons of raw steel.

For reported consumption in production of 99.1 million tons of raw steel and steel castings, the pounds of manganese consumed per ton of raw steel was 6.7 as ferromanganese, 1.3 as silicomanganese, and 0.1 for metal. The total of 8.1 was 6% less than in 1988.

Battery and Miscellaneous Industries

Production of alkaline batteries began in the latter part of the year at the Columbus, GA, plant of the joint venture between the Ultra Technologies Inc. subsidiary of Eastman Kodak Co. and Japan's Matsushita Battery Industrial Co. Ltd. In Wisconsin, Rayovac Corp. announced a major expansion of alkaline battery facilities at its Fennimore, WI, plant, to occur over a 4-year period.

² Includes estimates.

³ Approximately 90% of this subtotal was for consumption in aluminum alloys.

⁴ Internal evaluation indicates that silicomanganese consumption is considerably understated.

⁵ Estimated based on typical percent manganese content (rounded).

port, IL, once one of the larger domestic sources of carbon-zinc batteries, exemplified the trend for carbon-zinc cells, based on natural manganese dioxide, to decrease in popularity in favor

of alkaline cells, based on synthetic dioxide.

Through U.S. subsidiaries, Sweden's ESAB AB acquired the worldwide operations of L-TEC Welding and Cutting Systems. L-TEC's activities have included a plant at Niagara Falls, NY, where manganese materials are used in making welding fluxes.

PRICES

Manganese Ore

The price of metallurgical manganese ore rose by about 60%, an even bigger percentage increase than in 1988, to a new record high for price in commercial transactions. Factors cited as being behind ore price increases were increased demand and price for man-

TABLE 4

U.S. CONSUMPTION AND INDUSTRY STOCKS OF MANGANESE ORE,¹ BY USE

¹ Containing 35% or more manganese (natural).

² Natural ore, including that consumed in making synthetic manganese dioxide.

ganese ferroalloys, increased Japanese demand for ore for direct steelmaking, continued imports by East European countries and China that were estimated to total about 1 million tons, and limited international sourcing.

The average price, c.i.f. U.S. ports, for metallurgical ore containing 48% manganese was assessed as \$2.80 per long ton unit, compared with \$1.78 in 1988. Corresponding 1989 and 1988 prices were \$2.76 and \$1.75 per metric ton unit, and 12.5 and 7.9 cents per pound of manganese in ore. The price trend for manganese in metallurgical ore during the past two decades is given in the accompanying table.

1989	2.80	2.22

Manganese Ferroalloys

Based on quotations for imports, the general price trend for manganese ferroalloys was upward in the first part of 1989 and then downward, ending with a firming of prices in December. A relative advance in year-average price of nearly 40% for silicomanganese was almost double that of 21% for high-

carbon ferromanganese. Increasing ore costs and strong demand from steelmakers were credited for the ferroalloy price increases.

For high-carbon ferromanganese containing 78% manganese, the price of imported material, f.o.b. Pittsburgh or Chicago warehouse, continued in 1989 at \$600-\$615 per long ton of alloy, rose to a record peak of \$660-\$680, receded to \$570-\$595, and closed the year at \$620-\$645. The domestic producer price listed by Elkem Metals, f.o.b. plant or warehouse, followed a somewhat different course by carrying over from 1988 at \$615, increasing first to \$680 as of February and then to \$695 as of mid-June, and remaining at \$695 for the rest of 1989.

For silicomanganese with 2% carbon, the price in cents per pound of alloy, f.o.b. Pittsburgh or Chicago warehouse, started at yearend 1988's level of 35-36.25, advanced to 44-45.5, and then fell to 24-26 before closing at 26-28. The price for domestic material from Elkem Metals, similar basis, started the year at 36.5, increased to 45, and ended the year at 35.

Manganese Metal

For bulk shipments of domestic material, f.o.b. shipping point, trade journals listed a price range of 91-96 or 91-95 cents for all or the last three quarters of 1989, respectively.

FOREIGN TRADE

For ore, unit values indicated exports to Canada, the majority of exports to countries other than Canada and Mexico, and reexports of 1,384 tons (all to Canada) were metallurgical ore. Virtually all reported ore exports to Mexico appeared to have been transshipments of Gabonese ore.

The overall quantity of manganese units imported rose slightly to the greatest total since 1981. Average grade of imported ore decreased to 46.7%, the least since 1982. Imports of ore from Ghana were officially recorded for the first time since 1974. Average manganese content of all ferromanganese imports again declined, to 77.8%, the lowest average since 1981. Record imports of silicomanganese included shipments from China, the only such

during the 1980's. Reported imports of spiegeleisen were 276 tons.

Imports of manganese dioxide, all apparently synthetic except 10 tons from Morocco, dropped 70%. Receipts, total and from Japan, were the lowest since a separate tariff category was established in 1978. Imports of potassium permanganate advanced to a record, especially because of Chinese material. Listed under imports classified as "Other sulfates," which includes manganese sulfate, were 8,091 tons from Mexico valued at \$3.9 million.

Tariffs

Effective January 1, 1989, the Harmonized Tariff Schedule (HTS) replaced the Tariff Schedules of the United States as the basis of foreign trade categories and import duties. Duties that otherwise would have applied to imports from Canada under HTS were modified under the United States-Canada Free-Trade Agreement by Presidential Proclamation 5923 (53 FR 50638).

Imports on or after November 14, 1988, of electrolytic manganese dioxide (EMD) from Greece and Japan became liable for assessment of antidumping duties of 37% for EMD from Greece and ranging from 72% to 77% for EMD from Japan. The International Trade Administration of the U.S. Department of Commerce announced imposition of the antidumping duties on April 17 (54 FR 15243).

WORLD REVIEW

Capacity

The rated capacity data in table 9 are as of December 31, 1989, and are unchanged from those of the previous year. The data correspond to the manganese contents of ore and/or concentrates capable of being utilized, as in feed to a smelter. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate.

Reserves

Only a few of the world's many manganese concentrations have enough economic significance to be classed as reserves,⁴ no domestic deposits qualify.⁵

¹ Virtually all apparently transshipments from Gabon.

² Data may not add to totals shown because of independent rounding.

³ Unspecified group of countries differs from the 1988 Minerals Yearbook.

Source: Bureau of the Census; adjusted by the Bureau of Mines.

World reserves of manganese, on the same basis as capacity, are given in table 10 with no distinction between ore type or application. This table excludes perhaps 1% to 2% of total known reserves in nonlisted countries having only a small production.

Australia

Output from the manganese ore operations of Groote Eylandt Mining Co. Pty. Ltd. (GEMCO), a subsidiary of Broken Hill Pty. Co. Ltd. (BHP), advanced to a new record. GEMCO's exports and domestic shipments advanced slightly, to 1,754,000 tons and 440,000 tons, respectively, to give a shipments total of 2,194,000 tons.⁶

Brazil

Shipments of manganese ores from the Serra do Navio, Amapá Territory, operations of Indústria e Comércio de Minérios S.A. (ICOMI), plus 8,000 tons of sinter, totaled only 733,000 tons. Shipments, in tons, via Porto de Santana on the Amazon River, were 441,000 to European Community plus Comecon countries, 77,000 to South America, 43,000 to North America, and 172,000 to Brazilian consumers.⁷ The plant ICOMI previously operated in the port area for pelletizing manganese ore fines was converted into a unit for sintering such fines. Once the sinter plant was fully operational, annual output of about 50,000 tons of a high-

grade product was projected.

Total manganese ore shipments by Cia. Vale do Rio Doce (CVRD) from its Azul Mine in the Carajás region rose by about one-fifth to 594,000 tons. Exports were up about one-third to 393,000 tons while shipments to Brazilian consumers advanced just slightly to 201,000 tons.⁸

New record highs were set for production of manganese ferroalloys overall and for medium- and low-carbon ferromanganese and silicomanganese categories; the corresponding totals were 429,000 tons, 29,000 tons, and 230,000 tons.

At midyear, Cia. Paulista de Ferro-Ligas (Paulista) brought on-stream a plant at Conselheiro Lafaiete, Minas Gerais State, with annual capacities of 2,750 tons each for electrolytic manganese metal and EMD. The plant is close to where Paulista produces carbonate-type ore.

Canada

Wabush Mines developed the capability to produce, from its mine in Labrador, Newfoundland Province, fluxed or acid iron ore pellets having a manganese content of either 1% or 2%.⁹

China

China continued to import significant quantities of manganese ore, again from Australia and Gabon, and, according to the trade press, also the Republic of South Africa. A portion of these imports was barter and other types of arrangements in which Chinese ferroalloy plants smelted imported ore into products subsequently exported, mainly silicomanganese.

Gabon

Routing of shipments by Compagnie Minière de l'Ogooué S.A. (COMILOG) in 1989 was about evenly divided between railings to the new port at Owendo within Gabon and the established aerial tramway-railway system terminating at the port of Pointe-Noire in the Congo. USX Corp. of the United States reduced its holding in COMILOG to 15% in the fall of 1989, down from 36% at each yearend since 1983.

Ghana

Ore exports from the Nsuta Mine of Ghana National Manganese Corp. totaled 314,000 tons. Shipments were

made through the Port of Takoradi to Finland, Ireland, Italy, Norway, Portugal, and Spain in Western Europe; to Romania in Eastern Europe; to Japan and Singapore in the Far East; and to the United States.¹⁰

Japan

Production increased to 434,000 tons for ferromanganese overall and 135,000 tons for silicomanganese.

In foreign trade in manganese ferroalloys, imports of silicomanganese easily set a new record in rising to 302,000 tons. China was the source of over one-half of the total. Exports of silicomanganese advanced 2.5-fold to 2,750 tons. For ferromanganese, imports decreased 20% to 24,000 tons while exports increased 17% to 16,600 tons.

For EMD, production fell almost one-fifth to 61,300 tons, the least since 1985. Exports declined nearly 30%, from 49,800 tons in 1988 to 36,000 tons, the lowest level since 1982.

Production of electrolytic manganese metal advanced 14% to 4,960 tons. Imports of unwrought manga-

⁵ Free for products of Canada.

⁶ Not duty free for Mexico.

⁷ Not duty free for Brazil.

⁸ 12.6% ad valorem for products of Canada.

nese metal, including scrap, increased to 11,800 tons, most of which was from the Republic of South Africa. Exports were 1,080 tons, compared with 150 tons for 1988.

Mexico

Toward midyear, Nacional Financiera, a development bank of the Mexican Government, foreclosed on its controlling interest and took over management and operation of Cia. Minera Autlán S.A. de C.V. (Autlán). Production decreased at Autlán's operations in the Molango District of Hidalgo State. Respective 1989 and 1988 outputs were, in tons, 700,000 and 745,000 for carbonate ore, 388,000 and 434,000 for oxide nodules produced by calcining carbonate ore, and 19,700 and 29,300 for battery ore from the Nonoalco Mine.

Norway

The Government approved requests of Elkem A/S and Tinfos Jernverk A/S, the country's two manganese ferroalloy producers, and extended from July 20, 1989, until July 20, 1991, their exemption from sanctions against importing manganese ore from the Republic of South Africa.

South Africa, Republic of

Ore production increased 3%, attaining the highest level since 1986. Production in 1989 of the various categories of ore was as follows:

	Quantity (thousand short tons, gross weight) ¹
METALLURGICAL ORE	
30% to 40% Mn	1,205
Over 40% to 45% Mn	720
Over 45% to 48% Mn	726
Over 48% Mn	1,260
Total	3,910
CHEMICAL ORE	
35% MnO ₂ and less	—
Over 35% to 65% MnO ₂	82
Over 65% to 75% MnO ₂	2
Total	83

¹ Data may not add to totals shown because of independent rounding.

Manganese ore shipments by The Associated Manganese Mines of South Africa Ltd. (AMMOSAL) rose 17% to

1,965,000 tons, the greatest volume of shipments since 1979. USX of the United States sold its former equity interests of 21% in AMMOSAL and 45% in Feralloys Ltd., the ferromanganese-producing subsidiary of AMMOSAL.

Samancor Ltd. completed renovation of a 25-megavolt-ampere furnace for manganese ferroalloys at its Metalloys Works at Meyerton, Transvaal Province. Close to yearend, Samancor put into operation at its Mamatwan Mine a heavy-medium ore-beneficiating plant for producing concentrate containing about 43% manganese. This concentrate became feed for the mine's sinter plant, with which high-grade sinter containing a minimum of 48% manganese could now be obtained.

Also in the second half of 1989, Manganese Metal Co. (Pty.) Ltd. (MMC) began producing manganese oxide (Mn₃O₄) for ferrite manufacture. Annual capacity for oxide of MMC's new plant at Nelspruit, Transvaal Province, was 2,200 tons.

U.S.S.R.

Lack of the customary published reports implied production declines for both major ore-producing areas, the Nikopol' Basin in the Ukraine and the Chiatura Basin in Georgia.

Ore exports in 1988 were nearly 40% greater than those in 1987, and shipments to Poland increased over 70%. Even so, the total of 1,082,000 tons for 1988 was the lowest of any year since 1964. Principal destinations for 1988 exports, accounting for 90% of the total, were, in tons: Poland, 649,000; Czechoslovakia, 197,000; German Democratic Republic, 93,000; and Bulgaria, 40,000.

CURRENT RESEARCH

Recent trends have affected the manner of manganese usage in steelmaking.

¹ Table includes data available through May 16, 1990. Data pertain to concentrates or comparable shipping product, except that in a few instances the best data available appear to be for crude ore, possibly after some upgrading.

² In addition to the countries listed, Colombia, Cuba, Panama, Peru, and Sudan may have produced manganese ore and/or manganiferous ore, but available information is inadequate to make reliable estimates of output levels. Low-grade ore not included in this table has been reported as follows, in thousand short tons, gross weight: Argentina (19% to 30% Mn), 1985-8, 1986-11, 1987-11, 1988-11, and 1989-10 (estimated); and Czechoslovakia (about 17% Mn), an estimated 1 in each year.

³ May be for average content of each year's production rather than for content of typical products.

⁴ Metallurgical ore.

⁵ Reported figure.

⁶ Gross weight reported; metal content estimated. Estimated metal content figures have been revised as necessary.

⁷ Reported gross-weight figures are the sum of (1) sales of direct-shipping manganese ore and (2) production of beneficiated ore, both as reported in Anuário Mineral Brasileiro.

⁸ Includes manganiferous ore.

⁹ Calculated metal content includes allowance for assumed moisture content.

¹⁰ Much of India's production grades below 35% Mn; average content was reported as 38% Mn in 1985.

¹¹ Estimated product total, mostly oxide nodules; may include smaller quantities of direct-shipping carbonate and oxide ores for metallurgical and battery applications.

¹² Category represents the combined totals of Chile, Greece, Indonesia, Italy (from wastes), the Republic of Korea, Pakistan, the Philippines, and, beginning with 1988, Zambia.

¹³ Data may not add to totals shown because of independent rounding.

Differing circumstances have caused hot metal manganese contents as of 1989 to be relatively low in Japan, 0.2% to 0.4%; intermediate in Western Europe, 0.20% to 0.65%; and relatively high in the United States, 0.50% to 0.75%. At the Hoogovens IJmuiden BV plant in the Netherlands, a drop in hot metal manganese content from 0.70% to 0.50%, or below, was made to facilitate production of low-carbon, low-manganese steels, with some penalty of a lower converter lining life. Manganese ore addition to the blast furnace feed was still required to

achieve the 0.5% manganese content target. Recycling of converter slag, which would return some manganese to the blast furnace, was stopped to help control phosphorus to a low level.¹¹

A thermodynamic model of oxygen refining of high-carbon ferromanganese, developed on the basis of activities in the iron-manganese-carbon system, was used to predict limiting carbon and silicon contents during refining.¹²

In Japan, Mizushima Ferro Alloy Co. Ltd. developed technology for oxygen refining high-carbon ferromanganese into medium- and low-carbon fer-

romanganese to replace silicothermic methods, thereby reducing dependence on electrical energy. Key features of the new process included diluting the oxygen being top-blown with nitrogen or argon and stirring the bath by rotating the reaction vessel.¹³

Research clarified why ductility problems in hot working of steel, arising from sulfur impurity, are eliminated by an adequate manganese content. The affinity of manganese for sulfur greatly reduces a solid-state segregation of sulfur to the grain boundaries that would otherwise occur.¹⁴

OUTLOOK

The trend of manganese demand, domestically and globally, will continue to closely follow that of steel production. Nonmetallurgical components of manganese demand, especially batteries, may experience higher growth rates than for steel production, but will have only a minor effect on overall manganese demand.

U.S. apparent consumption of manganese was about 750,000 tons of contained manganese in 1988, as given in table 12. On the basis of 1982-88 data, the time trend value for 1988 is 733,000 tons; the projection for 1995 is 831,000 tons. The course of year-to-year steel production and, therefore, that of manganese demand between the present and 1995 is uncertain, particularly because of dependence on Government policy, as discussed in the "Iron and

Steel" chapter of this yearbook. U.S. apparent consumption of manganese in 1990-95 seems likely to range between 700,000 and 850,000 tons annually, assuming no further sizable decreases in manganese unit consumption in steel-making. The majority of U.S. demand will be met by imports.

BACKGROUND

Definitions, Grades, and Specifications

Ore.—The Bureau of Mines has compiled statistics on manganese-bearing ores, concentrates, nodules, and sinter, all referred to simply as "ore," by manganese content as follows: **manganese ore**, 35% or more manganese; **manganiferous ore**, less than 35% but not less than 5% man-

ganese; and within the latter, **ferruginous manganese ore**, 10% to 35% manganese; and **manganiferous iron ore**, 5% to 10% manganese.

Manganese ore may be considered as metallurgical, chemical, or battery grade. Metallurgical-grade material has an approximate manganese content range of 38% to 55% and may differ from chemical-grade ore only in physical form. Chemical- and battery-grade ores are often categorized by manganese dioxide (MnO₂) content, which typically is in the range of 70% to 85% (44% to 54% Mn). The U.S. Government maintains specifications for metallurgical, chemical, and battery grades of ore for stockpile purposes; industry has no corresponding standards.

Ferroalloys and Metal.—Ferromanganese is a manganese-iron-carbon alloy classified according to decreasing carbon content into standard or high-carbon

¹ Where available, data for manganese dioxide included beginning in 1984.

² Including manganiferous ore.

³ Includes miscellaneous nonmetallurgical uses of ore beginning in 1987.

⁴ Not specifically based on reported data; includes processing losses. Within this category, the distribution of components is approximately the same as for identified end uses above.

grades, medium-carbon grades, and low-carbon grades. Silicon is also specified in silicomanganese (such as 18%) and ferromanganese-silicon (about 30%). For U.S. tariff purposes, ferroalloys are required to have an iron content of 4% or greater; a material with less iron would be treated as metal.

Products for Trade and Industry

Metallurgical-grade ore is used primarily in making ferroalloys, pig iron, and steel. In making ferroalloys, ore with a relatively high manganese and low phosphorus content is particularly desirable.

The sulfur-fixing, deoxidizing, and alloying attributes of manganese are obtained mostly through use of intermediate forms such as ferromanganese. Manganese ferroalloys for use in steel-making are selected on the basis of cost per manganese unit, allowable steel carbon and silicon specifications, and steelmaking practice. For 1989, with the cost of manganese in metallurgical ore taken as 1.0, the corresponding approximate costs per manganese unit were 3.0 for high-carbon ferromanganese, 3.5 for silicomanganese, 4.9 for medium-carbon ferromanganese, and 7.4 for manganese metal. Metallic manganese is little used per se, as it is typically brittle and unworkable.

Manganese is added to aluminum using aluminum-manganese master alloys that typically contain 25% Mn, briquets of compacted aluminum and manganese powders that typically contain 75% Mn, and electrolytic manganese metal.

Various manganese dioxide-types of material, possibly ground, are used for batteries and other applications. These include natural mineral product (NMD) and synthetic dioxide produced either electrolytically (EMD) or chemically (CMD).

Other manganese materials and some of their uses include manganese sulfate and manganous oxide (MnO) for animal feed and soil conditioners, ground manganese ore for brick coloring, and potassium permanganate for water treatment.

Industry Structure

Makeup of the world's manganese ore producers is chiefly as follows: Australia, GEMCO; Brazil, CVRD and ICOMI, plus a number of rela-

tively small mines; China, apparently mostly small- to moderate-size operations in the eastern Provinces; Gabon, COMILOG; Ghana, Ghana National Manganese Corp.; India, over 200 mines, with Manganese Ore India Ltd. the most prominent company; Mexico, Autlán; Republic of South Africa, AMMOSAL and Samancor; and the U.S.S.R., two large complexes, mining the Chiatura Basin in Georgia and the Nikopol' Basin in the Ukraine. Most output is for metallurgical applications. Ore for nonmetallurgical uses generally is supplied by the large-scale producers mentioned plus smaller ones elsewhere.¹⁵

In recent years, the U.S.S.R. has been supplying over 1 million tons of ore annually to Eastern Europe, although such exports were notably lower in 1987 and appear likely to decline in the future. Otherwise, the principal source of ore to the international market has been an oligopolistic-like group of countries consisting of Australia (GEMCO), Brazil (ICOMI plus CVRD quite recently), Gabon (COMILOG), and the Republic of South Africa (AMMOSAL and Samancor).

Smelting of ore into manganese ferroalloys is much more diversified than ore production. Leading ferroalloy producers are as follows: Brazil, Paulista (a number of plants); China, many plants; France, Soc. du Ferromanganese de Paris-Outreau (SFPO); Federal Republic of Germany, Thyssen Stahl AG; Japan, Japan Metals & Chemicals Co. Ltd. and Mizushima Ferroalloy Co. Ltd.; Mexico, Autlán; Norway, Elkem A/S; Republic of South Africa, Metalloys Ltd., a subsidiary of Samancor; and the U.S.S.R., a number of plants. The U.S.S.R. is by far the largest producer.

Four MEC's currently produce metal, all electrolytically, in decreasing order of capacity: the Republic of South Africa, the United States, Japan, and, beginning in 1989, Brazil. China and the U.S.S.R. produce metal, including metallothermally in the U.S.S.R. World productive capacity for metal was given as 84,000 tons annually as of 1985,¹⁶ and was approximately the same in 1989.

Annual world capacity for EMD was assessed as 218,000 tons in 1989, including capacities of 78,000 tons for Japan and 39,000 tons for the United

States.¹⁷ The principal producer of CMD is Belgium's Sedema S.A., with annual capacity of about 40,000 tons.

Geology-Resources

The world's major land-based economic resources of manganese are of two principal types: marine chemical sediments and secondary enrichment deposits.¹⁸ Marine chemical deposits represent a majority of known resources. In 1985, the Manganese Centre (name changed in 1989 to International Manganese Institute) estimated that known relatively high-grade deposits (those with a manganese content of at least 44%) contained about 360 million tons of manganese.¹⁹ As given in the "World Review" section of this chapter, the reserve base for manganese can be considered more than ten times this size. The world's potential supply of manganese also includes extensive marine accumulations, such as oxide nodules on deep ocean floors and oxide crusts on midocean ridges, whose commercial future is indeterminate.

Technology

Exploration.—Highly selective methods of locating land manganese deposits do not exist, but interpretation of geologic environments can assist prospecting.²⁰

Mining.—Most manganese ore is produced by mechanized operations. Standard earth-moving equipment is used in surface mining. Underground mining generally is by room-and-pillar techniques.

Beneficiation.—Crushing, screening, washing, jigging, and tabling as well as flotation, heavy medium, and high-intensity magnetic separation are being or have been used to upgrade raw manganese ore into usable concentrates. Carbonate ore may be calcined. Ore fines are sintered into bulkier lumps at some ferroalloy plants, a practice which appears likely to be adopted increasingly by ore producers.

Smelting.—Electrothermy is the predominant method of manufacturing manganese ferroalloys, as by the submerged-arc-furnace process.²¹ Blast furnace-type operations are still used in a few foreign countries to make impor-

tant quantities of high-carbon ferromanganese. Recovery of metallics other than iron from manganese-bearing ore is rare.

Manganese metal and EMD commonly are produced by electrolyzing a solution of manganese sulfate prepared from ore that has been reduction roasted. Production of the dioxide is especially sensitive to minor ore impurities.²² Chemical manganese dioxide can be prepared by precipitating manganese carbonate from a sulfate solution and decomposing the carbonate to oxide.²³

Recycling.—Scrap recovery specifically for manganese is insignificant. Considerable manganese reenters processing as a minor component of steel scrap, steel slag, and nonferrous scrap.

Economic Factors

Costs.—As noted in a study of the Minerals Availability Program (MAP) of the Bureau of Mines, transportation is the most significant cost element in the production of manganese concentrates.²⁴ In a recent MAP assessment of costs for most major mines in MEC's, transportation accounted for about two-thirds of concentrate cost. Transportation costs were about equally divided between transportation to the port and transportation to the market. Also according to this assessment, the major mines for metallurgical-grade ore of the MEC's are quite competitive as to ore production cost. Of the considerable resources evaluated, about 80% had estimated production costs within 20% of the lowest cost.

Operating Factors

Environmental Requirements.—In 1988, the Environmental Protection Agency imposed an annual requirement of reporting releases to the environment of manganese metal and manganese chemical compounds (40 CFR 372). This requirement initially applied to annual manufacturing or processing of 75,000

pounds and annual use otherwise of 10,000 pounds.

Toxicity.—Manganese is an essential element for people, animals, and plants. In excess, it can be harmful to the respiratory and nervous systems.²⁵ Thus, manganese can be an industrial poison, but normally is not a hazard.

¹ Unless otherwise specified, the unit of weight in this report is the short ton of 2,000 pounds.

MERCURY

By Staff, Branch of Nonferrous Metals

Domestic survey data were prepared by Mr. Tony E. Morris, Nonferrous Data Section. International data tables were prepared by Ms. Virginia A. Woodson, International Data Section.

Mercury for use in domestic manufacturing in 1989 came from domestic mines, sales of surplus metal from Government stocks, imports, waste and scrap, and the drawdown of industry stocks. Industrial consumption was down 24% from the 1988 level. Mine production remained at about the same level. The United States was a net exporter of mercury in 1989. The average annual price of mercury fell 14% in 1989.

PRODUCTION

Mercury was produced as a principal product at one mine in Nevada, the McDermitt Mine, and as a byproduct

at nine gold mines in Nevada, California, and Utah. Nearly all of the newly mined mercury came from Nevada. Actual production figures were withheld by the Bureau of Mines to avoid disclosing company proprietary data.

Secondary mercury was recovered from scrapped mercury-containing products, from industrial waste and scrap, and from the sale of surplus Government stocks of scrap mercury. These source materials were processed by five companies: Adrow Chemical Co., Wanaque, NJ; Bethlehem Apparatus Co. Inc., Hellertown, PA; D. F. Goldsmith Chemical and Metals Corp., Evanston, IL; Mercury Refining Co. Inc., Latham, NY; and Wood Ridge Chemical Co., Newark, NJ. Total secondary production was down sharply in 1989.

CONSUMPTION AND USES

Two dozen plants, all but two in the eastern half of the Nation, accounted for 97% of the mercury consumed in 1989. About 90 other plants, laboratories, and other diverse organizations used much smaller quantities of mercury. Of the major quantities consumed, about 34% was used in chloralkali production, catalysis, and in various laboratory uses; 42% went into electrical products and instruments, of which batteries was the most important single category; and the remainder went into exterior paints, dental amalgams, catalysts, pigments, and pharmaceuticals. The substantial drop in overall consumption in 1989 was attributable principally to a further decline—for the sixth consecutive year—in the

1989	137	180	317

manufacture of mercury batteries, and to lower use in chloralkali production.

STOCKS

Stocks of refined mercury held by consumers and dealers fell by more than one-third in 1989, and at yearend were equivalent to about 2 month's industrial consumption. Figures on stocks held at mines were withheld to avoid disclosing company proprietary data.

³ Data may not add to totals shown because of independent rounding.

All of a large inventory of used (scrap) mercury held by the Department of Energy (DOE) at Oak Ridge, TN, was considered surplus, and limited quantities were offered for sale at monthly auctions by the Defense Logistics Agency (DLA), which acted as DOE's agent. One hundred and eighty metric tons was shipped during the year, leaving yearend stocks at 793 tons. DLA also held several monthly auctions of excess primary mercury from the National Defense Stockpile, and shipped 170 tons during the year, leaving a yearend inventory of 5,459 tons. Of this inventory, all but 362 tons was considered excess to Government needs.

PRICES

The New York dealer price for delivered primary mercury, reported in Metals Week as a range, was relatively stable in 1989, as compared with the price in most years. The price at the low end of the range began the year at \$280 per flask, rose to a high of \$320 from mid-February through most of March, then declined to a low of \$260 from mid-September through the first week of October, and ended the year at \$290. The price at the high end of the range tracked the movement of the low end price fairly closely, but was \$5 to \$25 per flask higher. The annual average of the weekly low end price was \$287.72, compared with \$335.52 in 1988. The low end price of Metals Week's European Dealer price range (c.i.f. Rotterdam) began the year at \$275 per flask and trended downwards irregularly during the year, ending the year at \$230. The high end price ran \$10 to \$20 above the low end price.

FOREIGN TRADE

the second consecutive year, to less than one-half the figure for 1988. Nearly all of the imported material was prime mercury from Spain, but none was imported from two important sources of the previous few years, China and Turkey. For the first time since 1977, data on exports of mercury became available, and showed that the United States was a net exporter in 1989. While imports came largely from 1 country, with much smaller quantities coming from 7 other countries, exports went to 24 countries, of which 3 received nearly three-fourths of the total. U.S. trade figures do not distinguish between primary mercury and scrap mercury.

WORLD REVIEW

Mercury was mined in at least 11 countries in 1989, with the U.S.S.R. and Spain together accounting for nearly two-thirds of production. Production capacity exceeded actual production by a considerable margin.

Contamination of the environment by mercury remained a concern. In Brazil, for example, where many of the

small gold mines in the Amazon basin recover gold by amalgamation with mercury, a method abandoned some years ago in most other countries, the State environmental agency, IBAMA, issued rules in mid-1989 governing the importation, sales, and use of mercury. It reportedly had been estimated that as much as 1,800 tons of mercury had entered the Amazon basin's environment in the period 1980-87. The new rules permitted less than 4% loss of mercury to the environment.

OUTLOOK

The world market for mercury was characterized, as it had been for at least two decades, by abundant supply and a slowly shrinking demand. The increasing recognition around the world of the danger posed by mercury's toxicity has led over the last quarter century to curtailment of its use in some applications and elimination from others. This trend is expected to continue.

MICA

By Lawrence L. Davis

Mr. Davis, a physical scientist with 34 years of industry and Bureau of Mines experience, has been the commodity specialist for mica since 1983. Domestic survey data were prepared by Linder Roberts, mineral data assistant; and international data tables were prepared by Audrey Wilkes, international data assistant.

Public Law 100-418 requires that U.S. Government agencies implement the use of metric units in their business activities by the end of Fiscal Year 1992. Consequently, all numbers in the text and tables are shown in metric units.

In 1989, about 119,000 metric tons of scrap and flake mica was produced in the United States, a decrease of 8% from 1988 production. Ground mica sales were 101,000 tons valued at \$22 million, a decrease in tonnage of about 7%.

Nearly all sheet mica supply continued to be imported. Consumption of muscovite block mica decreased 46% to 7.5 tons. Consumption of mica splittings increased slightly to 1,100 tons. The value of sheet mica exports increased 16% to \$7.4 million. The value of imports for consumption of sheet mica increased 13% to \$8.8 million.

DOMESTIC DATA COVERAGE

Domestic production and consumption data for mica are developed by the Bureau of Mines by means of three separate, voluntary surveys and one mandatory survey. Of the 18 operations to which the crude scrap and flake mica production form was sent, 17 operations, or 94%, responded, representing 95% of the production shown in table 1. Of the 17 operations to which the ground mica form was sent, all responded, representing 100% of the production in table 1. Of the seven canvassed operations to which the mica block and film consumption form was sent, six, or 86%, responded, representing 82% of the consumption shown in table 1. Of the nine canvassed

operations to which the mica splittings consumption form was sent, seven operations, or 78%, responded, representing 96% of the splittings consumption shown in table 1. Consumption for the nonrespondents was estimated using prior year production data.

LEGISLATION AND GOVERNMENT PROGRAMS

The Government inventory of stockpile-grade mica remained about the same at 10,000 tons. The Department of Defense sold 8 tons of phlogopite splittings.

STRATEGIC CONSIDERATIONS

Sheet mica and high-quality scrap mica used for making mica paper are important in the electronic and electrical industries. The United States is not self-sufficient in these materials and imports all its supplies, mostly from India. The U.S.S.R. and other countries with centrally planned economies are currently India's largest customers. The United States and other market economy countries compete for the remaining mica, and availability is sometimes limited, particularly for high-quality mica. Long delivery times and quality inconsistency also adversely affect sheet mica availability.

In a short-supply situation during an emergency, the National Defense Stockpile (NDS) would be able to meet short-term demand until substitutes could be made available. It is unlikely that domestic sheet mica production could replace or significantly reduce imports. Of the five strategic stockpile categories, only muscovite block mica has ever been produced domestically in sig-

nificant quantities, and then only under the stimulus of above-market prices paid by the Government. Domestic production in this century never provided more than a small fraction of domestic requirements.

The domestic supply of flake mica is adequate. Scrap and flake mica are not considered to be strategic materials. The United States is self-sufficient in flake mica but does rely on imports of high-quality scrap for the manufacture of mica paper.

PRODUCTION

Scrap and Flake Mica

North Carolina remained the major producing State with 61% of the total production. The remainder was produced in Connecticut, Georgia, New Mexico, Pennsylvania, South Carolina, and South Dakota. Most mica was recovered from mica schist, high-quality sericite schist, and as a byproduct of kaolin, feldspar, and lithium beneficiation.¹ The five largest producers were, in alphabetical order: The Feldspar Corp., Spruce Pine, NC; KMG Minerals Inc., Kings Mountain, NC; Lithium Corp. of America, Gastonia, NC; Pacer Corp., Custer, SD; and Unimin Corp., New Canaan, CT. These five companies produced 69% of the national total.

Ground Mica

Thirteen companies operated 16 grinding plants. Eleven plants produced dry-ground and five produced

wet-ground mica. The five largest producers accounted for 72% of the total. They were, in alphabetical order: KMG Minerals, Kings Mountain, NC; Mineral Mining Corp., Kershaw, SC; Pacer, Custer, SD; Unimin, New Canaan, CT; and USG Corp., Chicago, IL.

Low-quality sericite, used primarily in brick manufacturing, is excluded from tabulated data contained in this report. In 1989, four companies, one in North Carolina and three in South Carolina, mined low-quality sericite and reported an average value of \$3.75 per ton.

CONSUMPTION AND USES

Sheet Mica

Sheet mica is used principally in the electronic and electrical industries. Its usefulness in these applications stems from its unique electrical and thermal

SCRAP AND FLAKE MICA¹ SOLD OR USED BY PRODUCERS IN THE UNITED STATES, BY STATE

² Includes Connecticut, Georgia, New Mexico, Pennsylvania, South Carolina, and South Dakota.

insulating properties and its mechanical properties, which allow it to be cut, punched, or stamped to close tolerances.

The largest use of block mica is in vacuum tubes where fabricated mica spacers position, insulate, and support the tube elements. High-quality block mica is also used to line the gauge glasses of high-pressure steam boilers. Transparency, flexibility, resistance to heat and chemical attack are the properties that make mica suitable for this use. Other uses include diaphragms for oxygen-breathing equipment, marker dials for navigation compasses, optical filters, retardation plates in helium-neon lasers, pyrometers, thermal regulators, and stove windows. Block mica is also fabricated into washers of various sizes that act as insulators in electronic equipment.

1989	88	13,409	13	9,034	101	22,443

¹ Domestic and some imported scrap. Low-quality sericite is not included.

² Data do not add to total shown because of independent rounding.

Muscovite film mica is used as a dielectric in capacitors. Only high-quality mica, at or near the top of the quality scale, is used. The highest quality goes into capacitors that are to be used as standards. The next highest qualities are used for transmitting capacitors. Receiving capacitors use slightly lower quality film.

Consumption of muscovite block (ruby and nonruby) totaled 7.5 tons, a 46% decrease from that of 1988. Consumption of stained and lower-than-stained quality decreased 48%, but remained in greatest demand accounting for 88% of consumption. About one-half of the muscovite consumed was grade No. 5 or smaller. The decrease in consumption was the result of one more company ceasing fabrication operations. Five companies continued to consume muscovite block and film in five plants in four States: two in North Carolina and one each in New Jersey, Ohio, and Virginia.

Splittings represent the largest part of the sheet mica industry in the United States. Muscovite and phlogopite splittings are used to make built-up mica. Consumption of mica splittings increased slightly to 1,100 tons. Muscovite splittings from India accounted for 96% of the consumption. The remainder was phlogopite splittings from Madagascar. The splittings were fabricated into various built-up mica products by nine companies operating nine plants in seven States.

Built-up Mica

The primary use of this mica-base product, made by mechanical or hand setting of overlapping splittings and alternate layers of binders and splittings, was as electrical insulation material. Principal end uses of built-up mica are segment plate, molding plate, flexible plate, heater plate, and tape.

Segment plate acts as insulation between the copper commutator segments of direct-current universal motors and generators. Phlogopite built-up mica is preferred since it will wear at the same rate as the copper segments. Muscovite has a greater resistance to wear, causing uneven ridges which may interfere with the operation of the generator.

Molding plate is sheet from which V-rings are cut and stamped for use in insulating the copper segments from the steel shaft at the ends of a commu-

tator. Molding plate is also fabricated into tubes and rings for insulation in transformers, armatures, and motor starters.

Flexible plate is used in electric motor and generator armatures, field coil insulation, and magnet and commutator core insulation. Heater plate is used where high temperature insulation is required.

Some types of built-up mica have the bonded splittings reinforced with special paper, silk, linen, muslin, glass cloth, or plastic. These products are very flexible and are produced in wide continuous sheets that either are shipped in rolls or cut into ribbons, tapes, or any desired dimensions.

Total production, sold or used, of built-up mica decreased slightly from that of 1988. Segment plates and molding plates were the major end products, accounting respectively for 38% and 32% of the total. Other end products included flexible plates, heater plates, and tapes.

Reconstituted Mica (Mica Paper)

Primary end uses for mica paper are the same as those for built-up mica. Three companies consumed scrap mica to produce mica paper. The principal source of this scrap mica was India. Manufacturing companies in 1989 were: Corona Films Inc., West Townsend, MA; General Electric Co., Coshocton,

OH; and US Samica Corp., Rutland, VT. Kirkwood-Acim Corp.'s plant at Hempstead, NY was closed in 1988; the plant was absorbed by a sister company, Midwest Mica and Insulation Co., and relocated to Conway, AR. The plant might reopen in 1991.

Ground Mica

The largest domestic use of ground mica was in gypsum plasterboard cement. The mica acts as a filler and extender, provides a smooth consistency, improves the workability of the cement, and imparts resistance to cracking.

In the paint industry, ground mica is used as a pigment extender that also facilitates suspension, reduces checking and chalking, prevents shrinking and shearing of the paint film, increases resistance of the paint film to water penetration and weathering, and brightens

the tone of colored pigments.

Ground mica is used in the well drilling industry as an additive to drilling muds. The coarsely-ground mica flakes help prevent lost circulation by sealing porous sections of the drill hole.

The rubber industry uses ground mica as an inert filler and as a mold lubricant in the manufacture of molded rubber products such as tires. The plastics industry uses ground mica as an extender and also as a reinforcing agent.

Ground mica is used in the production of rolled roofing and asphalt shingles where it serves as an inert filler and surface coating to prevent sticking of adjacent surfaces. The coating is not absorbed by freshly made roofing because mica has a platy structure and is not affected by the acid in the asphalt or by weathering. Other uses include decorative coatings on wallpaper and on concrete, stucco, and tile surfaces; as an

ingredient in some special greases; as a coating for cores and molds in metal casting, and as a flux coating on welding rods.

In 1989, the major end uses were joint cement, 57%; paints, 10%; and well-drilling muds, 7%.

STOCKS

Reported yearend consumer stocks of sheet mica increased slightly to 542 tons; of this, mica splittings represented 93%, and mica block represented 7%.

PRICES

Prices for sheet mica vary with grade and quality and can range from less

than \$1 per kilogram for low-quality mica to more than \$2,000 per kilogram for the highest quality. The average values of muscovite sheet mica consumed in the United States in 1989 compared with 1988 were as follows: Block increased 76% to \$80 per kilogram; film remained at \$31 per kilogram; and splittings remained at \$1.36 per kilogram. The average value of phlogopite block increased 20% to \$22 per kilogram, while the value of phlogopite splittings increased 23% to \$5.53 per kilogram. The large changes in average value are more a reflection of the quality of mica consumed during the year than actual changes in price. The average value of crude flake mica, including high-quality sericite, was \$53 per ton. The average value per ton for North Carolina flake mica, predominantly a flotation product, was \$57.

FOREIGN TRADE

The United States continued to rely on imports, mostly from India, for nearly all of its sheet mica and paper-quality scrap mica. Imports for consumption of unmanufactured block, film, and splittings were about 1600 tons, about the same as in 1988 but considerably higher than in previous years. The high level of imports is a result of lower than average sales of mica from the NDS and continued

decrease in domestic fabrication of mica parts. Worked mica imports increased 50% to 1,100 tons. This increase is probably caused by reduced domestic production of mica paper. About 9,000 tons of ground mica was imported, mostly from Canada, while about 4,000 tons was exported to 32 countries. The combined value of all mica imports increased 13% to \$15.0 million, while the combined value of all mica exports increased 14% to \$9.6 million.

WORLD REVIEW

World production of mica decreased 3% to 265,000 tons. The United States continued to lead in the production of

flake mica. India continued to lead in the production of sheet mica.

Brazil

A mica and graphite mine in Minacu, Goias, is being developed by Cia Araguaia de Metais Nobres, and is expected to begin operating by mid-1990. The company recently opened a pilot plant in Sao Paulo to reduce the minerals to micron size.

India

The Mica Trading Corp. of India Ltd. (MITCO) instituted a policy whereby foreign purchasers of scrap mica may buy directly from private Indian suppliers, but only for orders under 1 million rupees (\$62,500). For larger orders the balance must be shared with MITCO.

MITCO's 600-ton-per-year-capacity mica paper plant has not reached the full production stage. The target production for the year, April 1989 through March 1990, was 150 tons.²

OUTLOOK

Demand for sheet mica has decreased dramatically over the last 30 years. For block and film mica the major cause of decreased demand was technological change, specifically the introduction of semi-conductor technology in electronics to the detriment of vacuum tube electronics that used large quantities of mica. Although the major impact of the technology change was felt in the 1960's and 1970's, con-

sumption of block and film mica continues to decrease, albeit more slowly. Substitute materials cause part of the decrease, and increased imports of finished electronic gear mean fewer mica parts are fabricated in the United States. Since 1979, consumption of block mica has decreased at an average annual rate of about 20%. This decline is expected to continue, and, by 1995, consumption will decrease to 2,500 kilograms. Consumption of mica splittings, the major type of sheet mica consumed in the United States, also decreased sharply through the 1960's and 1970's. During the 1980's, consumption leveled off to between 900 and 1,000 tons per year. Decreases were due to the development of substitute electrical insulating materials, miniaturization of electrical equipment, and increased imports of foreign-built products. Consumption of splittings is expected to decrease very slightly in the near future, reaching an annual consumption level of 1,000 tons by 1995.

Scrap and flake mica enters markets as ground mica, and demand tends to follow construction activity levels. For the major use of ground mica, a filler in wallboard joint compounds, consumption follows the macroeconomic indicator, New Construction Activities. Based on this indicator, annual consumption of mica in joint compounds is expected to increase to 75,000 tons in 1995, an average annual increase of 4.5%. Mica consumption in oil well drilling muds closely follows the Fed-

eral Reserve Board's Index of Production: Oil and Gas Drilling. Based on this index, annual consumption in well-drilling muds is expected to decrease to about 2,000 tons in 1995, an average annual decrease of about 20%. Mica consumption in other uses, such as paints, plastics, rubber, and roofing, etc., does not correlate well with any available indicators. Annual consumption has been relatively constant over the last decade and is expected to increase slightly by 1995.

BACKGROUND

Definitions, Grades, and Specifications

Mica is a group name for a number of complex, hydrous potassium silicate minerals with differing chemical compositions and physical properties. Crystals of mica have excellent basal cleavage and split easily into tough, flexible sheets. The important mica minerals are muscovite and phlogopite.

Commercial qualities of sheet mica are relatively free of defects and tough enough to be punched or stamped into specific shapes. Sheet mica is classified as block, film, or splittings. Block mica is not less than 0.018 centimeters thick and has a minimum usable area of 2.54 square centimeters. Film mica is split to specified thicknesses ranging from 0.0030 to 0.010 centimeters. Splittings

¹ Table includes data available through Apr. 25, 1990.

² In addition to the countries listed, China, Norway, Pakistan, Romania, and Sweden are known to produce mica, but available information is inadequate to make reliable estimates of output levels.

³ Data are for year beginning Mar. 21 of that stated.

⁴ Reported figure.

⁵ Less than 1/2 unit.

⁶ Excludes U.S. production of low-quality sericite and sheet mica, if any.

are sheets with a maximum thickness of 0.0030 centimeters and a minimum usable area of 1.9 square centimeters. Punch mica, which includes circle and washer mica, is low-quality, hand-trimmed mica up to about 5 centime-

ters in diameter. The American Society for Testing and Materials (ASTM) designates 13 quality groups for sheet mica, based on quantity of visible inclusions and structural imperfections, ranging from black- and red-stained to

perfectly clear. ASTM also designates 12 grades based on the maximum usable rectangle. The sizes range from grade 6 (with 2.54 usable square centimeters) to grade OOOE special (with 254 usable square centimeters).

Block and film mica products are small flat pieces of uniformly thin mica cut or stamped to close tolerances into a variety of shapes and sizes, depending on the use. Shapes can vary from simple circles, squares, or rectangles to very intricate patterns. Fabricators make their own dies in order to be able to cut the mica into any pattern desired.

Built-up mica, or micanite, consists of partly overlapped and irregularly shaped and arranged splittings cemented together with either an organic or inorganic binder. Large sheets of built-up mica are made by alternating layers of splittings and binder. Sheets of any thickness are made by pressing the layers at high temperatures. Built-up mica is sold in large, uncut sheets or is cut or molded to any size and shape specified by the customer. It is often bonded to another material such as fiberglass cloth to form a composite sheet.

Reconstituted mica or mica paper is a paperlike material made by depositing fine flakes of scrap mica as a continuous mat, which is then dried. The mica paper is sometimes impregnated with an organic binder.³

Scrap and flake mica is generally of a quality and size that is not suitable for use as sheet mica. Mine scrap varies greatly in quality but usually is a heterogeneous mixture that must be crushed, screened, and washed to yield the scrap mica in usable form. Mine scrap may be the sole product of mining a pegmatite or may be a byproduct of sheet mica production. Bench scrap or shop scrap is the mica discarded during the processing of handcobbled mica into sheet. Factory scrap is the waste that results from cutting and stamping sheet mica into pieces of definite size and shape. Factory scrap is usually the highest grade and quality material. Scrap mica that is recovered from schists and from the beneficiation of kaolin, feldspar, and lithium pegmatites is often referred to as flake.⁴

Industry Structure

The sheet mica industry in the United States is small, consisting of processors and fabricators of imported mica.

Worldwide, India dominates the production of muscovite sheet mica. Madagascar is an important producer of phlogopite sheet mica. Sheet mica mining, trimming, and splitting is very labor intensive, and producing countries have the advantage of low wages and a large labor force that is usually trained at an early age. India's sheet mica industry is characterized by a large number of small operations, most of which sell to larger companies or the Government's MITCO for further processing and export. India is putting more emphasis on exporting fabricated mica products. This is expected to reduce further the amount of mica that will be fabricated in the United States.

The U.S. flake mica industry ranks first in world production. Most production comes from surface mining of mica schists and as a byproduct of kaolin, feldspar, and lithium beneficiation. Nearly all flake mica is ground to final specifications depending on the use. Other countries producing significant amounts of flake mica are Canada, China, India, the Republic of Korea, and the U.S.S.R. Many other countries produce small amounts.

Geology-Resources

Sheet muscovite is obtained from coarse-grained igneous rocks called pegmatites. Pegmatites also contain quartz, feldspar, and various accessory minerals. Pegmatite dikes and veins range from a kilometer or more long and 100 meters wide to thin veins and veinlets of 2 centimeters or so in width.

The United States has no reserves of sheet mica. Small U.S. reserves were extensively worked in the past, and the high cost of labor has kept the mines shut down since the Government's purchase program ended in 1962. The primary sheet mica resources are in New England, the southeastern Piedmont

from Virginia to Alabama, the Blue Ridge Mountains in North Carolina, the Black Hills of South Dakota, and northern New Mexico. Other States with some sheet mica resources are Colorado, Wyoming, Idaho, Montana, and California.

No formal evaluation of world resources of sheet mica has been made, mainly because of the sporadic occurrence of this mineral. The most productive sheet mica districts in the world are in the States of Bihar, Andhra Pradesh, and Rajasthan in India. India's large reserves and resources of sheet mica have been the primary world sources for many years. Large reserves of sheet mica also are found in Brazil, and western Africa. In the U.S.S.R., sheet mica reserves are known in the Lake Baikal and Sayan upland areas as well as in the South Eniessy Range. Smaller but substantial reserves occur in Argentina, Australia, and Zimbabwe.

Phlogopite deposits are in areas of metamorphosed sedimentary rocks intruded by masses of pegmatite-rich granitic rocks. The phlogopite is found as veins or pockets in pyroxenite interlayered with or intersecting marble or gneiss. Canada and Madagascar have the world's major reserves of phlogopite. Additional reserves are known in the Sludyanka River district and Alden area of the U.S.S.R., Sri Lanka, and Mexico.

The primary domestic source of flake mica for grinding purposes is weathered alaskite bodies and pegmatites in North Carolina, where most domestic flake mica is produced. The mica is recovered as a coproduct of feldspar and kaolin beneficiation. Flake mica is also recovered from muscovite schists. These schist bodies range in size from 3 to more than 100 meters thick and several kilometers long. The mica content ranges up to 90%. Another form of flake mica is

fine-grained muscovite called sericite, which is an alteration product of various aluminosilicate minerals.

World reserves and resources of scrap and flake mica are not well known but are considered to be very large. All countries with sheet mica reserves or resources have even larger quantities of scrap mica because only a small fraction of the mica present is of sheet quality. Many other countries have reserves or resources of mica that, while not of sheet quality, are suitable for grinding.

¹ Production of high-quality sericite is included in the totals; however, figures for low-quality sericite, used principally for brick manufacturing, are not included.

MOLYBDENUM

By John W. Blossom

Mr. Blossom, a physical scientist/engineer with 42 years industry and Government experience, has been the commodity specialist for molybdenum since 1982. Survey and trade data were prepared by Cheryl M. Jackson, mineral data assistant; and the world production tables were prepared by Harold D. Willis, international data assistant.

Domestic and foreign molybdenum markets expanded in 1989, but mine production among market economy countries exceeded demand. Domestic producer and consumer stocks increased. U.S. mine output of molybdenum increased to 54% of world production. Reported end use consumption of molybdenum in raw materials increased. The reported U.S. consumption by end use remained about the same as in the previous year. Exports of all forms of molybdenum from the United States increased. Domestic producer stocks of molybdenum products increased to about 11 months of annual consumption.

DOMESTIC DATA COVERAGE

Domestic production data for molybdenum are developed by the Bureau of Mines by means of three separate, voluntary surveys. These surveys are Molybdenum Ore and Concentrate, Molybdenum Concentrate and Molybdenum Products, and Molybdenum Concentrates. Out of 15 operations to which surveys were sent, all responded, representing 100% of the total production shown in table 1.

PRODUCTION

Domestic mine production of molybdenum concentrate increased to a total of 139 million pounds of contained molybdenum, compared with 94 million pounds in 1988. The country's two largest suppliers, AMAX Inc. and Cyprus Minerals Co., produced sufficient material during 1989 to keep the molybdenum market stable.

CONSUMPTION AND USES

Consumption of molybdenum concentrate increased 13 million pounds in 1989. Domestic mine production of

molybdenum concentrate was either roasted, exported for conversion, or purified to lubrication-grade molybdenum disulfide. The quantity of concentrate roasted domestically to produce technical-grade molybdic oxide in-

creased over that of 1988. Oxide is the chief form of molybdenum utilized by industry, particularly steel, cast iron, and superalloy producers. However, some of the material is also converted to other molybdenum products, such

as ferromolybdenum, high-purity oxide, ammonium and sodium molybdate, and metal powder. Apparent U.S. consumption (defined as U.S. primary plus secondary production plus imports minus exports plus adjustments for Government and industry stock changes) was about 64 million pounds of molybdenum.

STOCKS

Total industry stocks, which include those of producers and consumers, increased to 33.5 million pounds of contained molybdenum. Inventories of molybdenum in concentrate at producer locations increased about 2.5 million pounds. Producer stocks of molybdenum in consumer products, such as oxide, ferromolybdenum, molybdate, metal powders, and other types, decreased about 1 million pounds. Compared with apparent consumption, yearend producer stocks of these materials represented about a 10-month supply. Domestic consumer inventories of about 6 million pounds, the same amount as at yearend 1988, representing approxi-

mately a 2-month supply as measured by average monthly reported consumption.

PRICES

The "Metals Week Dealer" (MWD) price of molybdic oxide (per pound of contained molybdenum) decreased from \$3.50 in January to \$2.55 at the end of December 1989. The average MWD price of oxide was \$3.39, or 8 cents less than the average MWD price in 1988.

The posted producer price for molybdic oxide was \$3.65 on January 1, 1989. Cyprus Minerals Co. increased its posted price to \$3.97 in February and returned to a posted price of \$3.65 on July 1. Both AMAX Inc. and Cyprus Minerals Co. reduced their posted prices to \$3.35 in October, where the price remained to the end of 1989.

FOREIGN TRADE

Exports

Exports of molybdenum in concentrate and of oxide increased compared

with those of 1988. Molybdenum concentrate exports were about 43% of domestic mine production. Approximately 98% of reported shipments of concentrate and oxides were to Belgium-Luxembourg, Canada, the Federal Republic of Germany, Japan, Mexico, the Netherlands, and the United Kingdom. The calculated molybdenum content of all exports was about 118 million pounds in 1989. Total value of exports increased from \$205 million in 1988 to \$327 million in 1989.

Imports

Approximately 5 million pounds of molybdenum in various forms were imported into the United States, 4.5 million pounds less than in 1988. Total value of all forms of molybdenum imported decreased from \$37 million in 1988 to \$30 million in 1989. In terms of both value and quantity, the major form imported was ferromolybdenum, principally from Chile and China.

WORLD REVIEW

World mine production of molybdenum was 257 million pounds, an increase of 49 million pounds from that in 1988. Canada, Chile, the U.S.S.R., and the United States accounted for more than 90% of the molybdenum produced worldwide.

Capacity

The data in table 10 are rated capacity for mines and mills as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that

can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure. Mine capacity for molybdenum is based on published reports, production statistics, and estimates.

Reserves

The definitions of reserves and reserve base are published in U.S. Geological Survey Circular 831, "Principles of a Resource/Reserve Classification For Minerals," which is reprinted in the introduction of the "Mineral Facts and Problems, 1985 Edition" and "Mineral Commodity Summaries, 1990."

Estimated world reserves and reserve base of molybdenum appear in table 12. Most of the world reserves of molybdenum occur in the western mountain regions of North and South America, extending from Alaska and British Columbia through the United States and Central America to the Andes Mountains of Chile. These regions, roughly bordering the eastern margin of the Pacific Basin, are also regarded as most promising for future discoveries and additions to reserves.

The United States, with a reserve base of molybdenum estimated at 11.8 billion pounds, has 47% of the world molybdenum reserve base. About 90% of U.S. reserves occurs in large porphyry or disseminated deposits mined, or anticipated to be mined, primarily for molybdenum. These deposits are located in Alaska, Colorado, Idaho, Nevada, New Mexico, and Utah. Other molybdenum sources contribute insignificantly to U.S. reserves.

Canadian reserves of primary molybdenum are located in British Columbia, including nearly 30% of the total in the Endako primary deposit. Other Canadian reserves are associated with molybdenum and copper-molybdenum porphyry deposits in British Columbia, and in relatively minor sources in Quebec and New Brunswick.

Molybdenum reserves in Central and South America are mainly in large copper porphyry deposits. Of several such

deposits in Chile, the Chuquicamata and El Teniente deposits are among the world's largest and account for 85% of total molybdenum reserves in Chile. Mexico and Peru have substantial reserves. The La Caridad deposit in Mexico is a large producer. Numerous other copper porphyries that may contain recoverable quantities of molybdenum have been identified in Central and South America. Many of these deposits are actively being explored and evaluated and could add substantially to reserves in the future.

Reserves of molybdenum in the U.S.S.R. and China are estimated to be substantial, but definitive information about the current sources of supply or prospects for future development in the two countries is lacking. Copper ores are being investigated on the islands of New Guinea and Bougainville in the Southwest Pacific, but it is not known whether these contain economically recoverable molybdenum.

OUTLOOK

Capital expenditures are expected to

decrease to a more normal growth rate over the next few years. Alloy and stainless steel demand is forecast to decline in 1990. Short-term molybdenum demand is expected to remain a little below the peak of 1989. Molybdenum demand appears to have ascended to a new level of usage. Molybdenum production must be adjusted to reduce inventories that have been built up in Western Europe during 1989. The long-term demand depends upon events in Eastern Europe and the U.S.S.R.'s ability to meet the needs of capital expenditures for environmental controls and to expand their manufacturing capacities.

BACKGROUND

Definitions, Grades, and Specifications

Molybdenum is a silver-white metallic element with an atomic number of 42, atomic weight of 95.95, and a density of 10.2 grams per cubic centimeter. The chemistry of molybdenum is complex; molybdenum exhibits oxidation states from -2 to 6, coordination num-

bers from 4 to 8, and forms compounds with most inorganic and organic liquids. Molybdenum is a strong carbide-forming element, and much of its alloying effect in steel is imparted through the formation of carbides. It has a melting point of about 2,610° C; among the metallic elements, only tungsten, rhenium, osmium, and tantalum have higher melting points. Other significant physical properties of molybdenum metal are good thermal conductivity (about one-half that of copper), the lowest coefficient of thermal expansion of the pure metals, high strength at elevated temperatures, and resistance to corrosion in a wide variety of mediums. Molybdenum metal is stable in air or water at moderate temperatures, but oxidizes readily above 500° C.

Molybdenite is the principal mineral from which molybdenum is obtained. Crude ore containing molybdenite is beneficiated to produce molybdenite concentrate. The concentrate generally contains about 90% molybdenite; the grade may be somewhat lower, particularly if produced at copper byproduct concentrating plants. Typically, "tech-oxide" has a molybdic-oxide content of 85% to 90%, or a minimum of 57% contained molybdenum. Other raw materials, including ferromolybdenum, purified molybdic oxide, ammonium and sodium molybdate, and molybdenum metal powder are produced from technical-grade oxide. The production of these materials is described in the next section, "Products for Trade and Industry."

The American Society for Testing and Materials (ASTM) has developed standards for the chemical composition of molybdenum oxide products (Specification A 146-64, reapproved 1979), and ferromolybdenum (Specification A 132-74, reapproved 1979). These standards specify minimums for molybdenum content and maximums for impurity content as an aid to producers and purchasers. Material marketed by the major domestic producers generally meet or exceed ASTM standards.

Products for Trade and Industry

Some commercial-grade molybdenite concentrate is treated with additional grinding and flotation steps to produce lubricant-grade 99% molybdenum disulfide.

Molybdenite concentrate is con-

verted to technical-grade 90% molybdic oxide having a maximum sulfur content of 0.1%. This oxide is the major form of molybdenum used by industry and the base material for production of ferromolybdenum, chemicals, and molybdenum metal powder. The technical-grade oxide is produced by roasting molybdenite concentrate in the multiple-hearth furnace at temperatures of up to 650° C. Technical-grade oxide or ferromolybdenum is used to add molybdenum to steels, cast irons, and nonferrous alloys.

Ferromolybdenum is typically produced by reduction of a mix of technical-grade oxide and iron oxide in a conventional metallothermic process, using silicon and/or aluminum as the reductant. The molybdenum content ranges from 58% to 64%.

Ammonium molybdate is produced by reacting pure molybdic oxide with ammonium hydroxide and crystallizing out the pure molybdate. Sodium and calcium molybdate are made similarly using sodium hydroxide and calcium chloride.

Molybdenum metal powder is manufactured by reducing pure molybdic oxide or ammonium molybdate with hydrogen. The purest metal powder (99.95% molybdenum minimum) is produced from ammonium molybdate. Metal powder is pressed and sintered into small metal ingots, which are converted into rod, wire, or sheet by hot rolling, swaging, or forging. Large ingots are produced by arc-casting powder under a vacuum or inert gas atmosphere.

Geology

Mineralogy.—The average crustal abundance of molybdenum is 1 to 2 parts per million (ppm). The molybdenum content of igneous rocks tends to increase with increasing silica content. Molybdenum does not occur in nature in its free or native state but is found only chemically combined with other elements. Small deposits of molybdenum-bearing minerals occur throughout the world, but the only molybdenum mineral of commercial importance is molybdenite. Wulfenite, powellite, and ferri-molybdite are common but have supplied very little molybdenum. Other molybdenum minerals include chillagite, ilsemannite, koechlinite, lindgrenite, eosite, and jordisite.

MOLYBDENUM MINERALS YEARBOOK—1989

Types of Deposits.—Molybdenum deposits are of five geological types: (1) porphyry or disseminated deposits, including stockworks and breccia pipes in which metallic sulfides are dispersed through relatively large volumes of altered and fractured rock, (2) contact-metamorphic zones and tactite bodies of silicated limestone adjacent to intrusive granitic rocks, (3) quartz veins, (4) pegmatites and aplite dikes, and (5) bedded deposits in sedimentary rocks. The first three genetic-type deposits are hydrothermal in origin and, as such, represent nearly all the known molybdenum resources currently mined in the world. The remaining types do not represent a great volume of molybdenum and are economically important only when molybdenum is associated with other high-valued minerals.

Technology

Exploration.—Prospecting and exploration for molybdenum is basically the same as that for deposits of other metals. Areas generally considered favorable for molybdenite mineralization are in metallogenic provinces encompassing known occurrences of molyb-

denum stockworked deposits and copper-molybdenum porphyry deposits. An understanding of regional geology, mineral associations, and known patterns of molybdenite mineralization is essential to identify potential sites for field investigation. Sites for detailed study may be selected on the basis of geologic mapping of rock units and structures, geochemical analyses of sediments and soils, and ground geophysical surveys. An intensive drilling and sampling program is then required to estimate the size, grade, and continuity of the discovery. Exploration drifts may be driven into the ore body to provide more specific geologic information and bulk samples for metallurgical testing.

Mining.—Molybdenum ore is mined by underground and open pit methods, the choice of method being determined by the size, configuration, grade, and depth of the ore body.

Recycling.—Some secondary molybdenum metal is recovered in the production of alloy steels, superalloys, and the metal, but data on quantities are incomplete and inconclusive. Most of

this recycled material is generated and reused directly at metal-forming or fabricating plants (runaround scrap) or shipped to plants that reclaim it (prompt industrial scrap). Very little molybdenum-containing obsolete scrap is processed for its molybdenum content. Although some molybdenum is recycled as a minor constituent of scrap alloy steels, the use of such scrap does not generally depend on its molybdenum content. An increasing quantity of molybdenum is being reclaimed from spent catalysts and chemical residues.

Byproducts and Coproducts

Tin, tungsten, and a very minor quantity of pyrite are recovered as byproducts from molybdenum ore at the Climax, CO deposit. Rhenium is extracted from flue gases and dust produced during roasting of molybdenite concentrate produced as a byproduct of copper mining.

Molybdenum is recovered as a byproduct primarily from copper ores. A very small amount is also obtained from tungsten and uranium ores. At the Sierrita Mine of Cyprus Minerals, copper and molybdenum are considered coproduct values.

Operating Factors

The mining and milling of both primary molybdenum ore and copper ore containing molybdenum are high-tonnage operations. The largest domestic molybdenum mine has an ore-processing capacity of about 48,000 tons per day; processing capacity at the largest copper-molybdenum surface mine exceeds 100,000 tons per day of ore. Ore grade is low; therefore, open pit and underground block caving methods are required to extract ore profitably.

Costs involved in producing molybdenite concentrate vary according to mining methods used (underground or surface), physical characteristics of the ore body, and difficulty in ore benefi-

ciation. In mining, the principal nonlabor operating expenses involve consumption of explosives, utilization of fuel, and electricity for operating equipment. Costs of ore beneficiation are dependent on use of grinding materials, flotation reagents, electricity to operate milling and concentrating equipment, and general plant maintenance. Operating variables are monitored, and adjustments are made when necessary to maximize efficiency and economy of operation.

The mining of primary molybdenum ore and disposal of ore tailings disturb land areas. Land reclamation will become increasingly necessary as mines become inactive. Copper mining that yields byproduct molybdenum entails

the disturbance of significantly larger land areas. Development of new mine-mill complexes presents local socioeconomic and land-use problems. Because new potentially economic sources are likely to be found in relatively unpopulated regions with little other industry, development of a major mine can have a significant impact on established occupational patterns. Interaction between mining firms and local and state agencies has increased to ensure that mine development proceeds in as orderly and environmentally sound a manner as possible.

The conversion of molybdenite concentrate to technical-grade molybdic oxide involves roasting. Producing firms have modified roasting facilities or in-

stalled sulfuric acid recovery equipment to reduce emissions and thereby comply with more stringent pollution restrictions. Because the molybdenum-processing industry is relatively small, raw materials and energy needs generally are not critical concerns, although increasing energy costs will add to overall production costs.

Compared to other industrial metals, molybdenum exhibits low or negligible toxicity. No significant toxic effects in human beings have been identified in the mining and processing of molybdenum materials. As an environmental trace element, molybdenum is an essential micronutrient and has been shown to be related to copper metabolism in certain animal species. Deficiencies or excesses of molybdenum can affect the normal growth and development of numerous plant and animal species.

NICKEL

By William S. Kirk

Mr. Kirk, a physical scientist with 24 years of Government experience, has been the commodity specialist for nickel since 1987. Domestic survey data were prepared by Barbara J. McNair, Ferrous Data Section. International data tables were prepared by William Zajac and Audrey Wilkes, International Data Section.

Western World consumption rose while domestic demand fell. Prices fell, as demand fell in the second half of the year. The Riddle, OR, ferronickel facility was recommissioned. Falconbridge Ltd., a large Canadian producer, was sold.

LEGISLATION AND GOVERNMENT PROGRAMS

The Agency for Toxic Substances and Disease Registry issued a Toxicological Profile for Nickel, which identified health effects and levels of human exposure to nickel and nickel compounds that may be toxicologically significant.

STRATEGIC CONSIDERATIONS

Nickel is an essential ingredient in austenitic stainless steels and superalloys. As such, its availability is important to the national security. Domestic production capacity is less than 1% of apparent consumption. Canada, however, a close ally and a geographically secure source, is capable of supplying U.S. needs under normal circumstances.

ISSUES

The primary environmental problem associated with nickel production is the emission of sulfur dioxide (SO₂) from nickel smelters processing sulfide ore. The SO₂ emitted from smelter smokestacks combines with atmospheric water to form sulfuric acid (H₂SO₄), a major component of acid rain. Inco

Ltd., the world's largest nickel producer, must reduce SO₂ emissions by two-thirds to 290,000 short tons per year by 1994 at its Sudbury complex to meet Ontario Provincial Government imposed limits. The company has embarked on a \$410 million program to install new technology to meet those limits. The alternative would be to reduce its production by two-thirds from 1989 levels.

PRODUCTION

The Riddle, OR, ferronickel smelter in Douglas County reopened, becoming the sole domestic source of nickel. The facility, formerly owned by M. A. Hanna Co., closed in 1985 because of the then prevailing low nickel prices. In April 1989, the smelter property was purchased by the Glenbrook Nickel Co., Spokane, WA, which was owned by Cominco American Resources Inc. (CARI), Spokane. CARI was 100% owned by Cominco Resources International Ltd. (CRIL), Vancouver, British Columbia, Canada. CRIL was about 60% owned by Cominco Ltd., Vancouver, BC. The land at the mine was owned by a separate group of individuals and Glenbrook was trying to lease the property from these groups, although no decision had been made at yearend on whether to reopen the mine. After extensive rehabilitation, the smelter was restarted in August, using ore from a reject pile accumulated by Hannah over a 30-year period. The reject pile was at the smelter, rather than the mine, and was considered adequate for about 2 years of smelter feed. Glenbrook produced 382 tons of nickel contained in ferronickel in 1989.

CONSUMPTION

Western World consumption reached record levels for the third consecutive year, although it fell sharply in the second half of the year. U.S. consumption followed a similar pattern; domestic stainless steel production was 24% lower in the second half than in the first, according to data from the American Iron and Steel Institute. Demand by the stainless steel sector slackened

first in the United States, then in Europe, and finally in Japan.

STOCKS

The combined stocks of primary nickel maintained in the United States by foreign producers with U.S. sales offices, and by metal-trading companies with U.S. sales offices, decreased 11% during the year. At yearend, these stocks represented 14 days of domestic

apparent consumption. The decrease in stocks took place in the first half of the year. As consumption dropped in the second half, producers began to rebuild inventories.

PRICES

The London Metal Exchange (LME) cash price for nickel fell by 55% through the year. Prices began the year on the rise, reached their peak for the

year in March, and, except for a brief rise in late June, declined steadily thereafter. Changes in price levels in 1989, as in recent years, were almost entirely driven by stainless steel demand, the largest end use for nickel (48% of domestic reported consumption in 1989).

The primary reasons for the rise in the first quarter were low stock levels and concerns about actual and potential significant production losses (see World Review). At the end of the first quarter, the service centers began to realize the long boom in stainless steel consumption could be coming to an end. Service centers, which buy stainless steel from the mills for resale to stainless users, handle more than 50% of the stainless steel sold in the United States and are a major factor in Europe as well. The service centers began to sell off their inventories and reduce their purchases from the mills. The drop in orders meant that the stainless steel mills needed less nickel. This coincided with increased availability of stainless steel scrap, a major constituent of stainless steel production. The increased availability occurred because scrap exports were down as a result of decreased foreign demand from Europe and Japan, the major recipients of

FIGURE 2
MAJOR SOURCES OF U.S. PRIMARY NICKEL IMPORTS IN 1989

stainless steel scrap exports. The LME price declined steadily until the third quarter when lower than expected shipments of Soviet nickel caused a brief rally. Stainless steel demand and nickel prices then experienced a steady decline throughout the remainder of the third quarter and through the fourth quarter.

FOREIGN TRADE

The net import reliance was 65% because there was little domestic primary production and virtually all primary nickel consumed in the United States was imported. Canada, as usual, supplied most of the imported nickel, including most of the nickel imported from Norway. This nickel was mined and smelted in Canada before being refined in Norway and shipped to the United States. The high level of demand for primary nickel also meant high demand for nickel-bearing scrap, both domestically and abroad. As a result, U.S. stainless steel scrap exports in 1989 increased considerably. Assuming a nickel content of 7.5%, 21,863 tons of nickel contained in stainless steel scrap were exported in 1989 compared to 18,251 tons in 1988 and an average of about 14,000 tons per year for the 5 years preceding 1989.

WORLD REVIEW

Industry Structure

Nickel was produced in at least 26 countries in 1989. Nickel-producing countries and companies can be grouped by deposit type; production within a country is generally from laterite or sulfide deposits. Exceptions include Australia, Brazil, and the U.S.S.R. Usually ferronickel is produced from laterite ores because of their high iron content and because these ores are more easily smelted than concentrated and refined hydrometallurgically, whereas refined metal is most often produced from sulfide ores. From 1985 through 1989, those countries producing from laterite ore accounted for about 35% of world mine production, with the balance coming from sulfide ores. Inco Ltd., of Canada, is the largest single producing company. From 1985 through 1989, the

five largest producing countries and their share of world mine production were: the U.S.S.R. (24%), Canada (22%), Australia (9%), New Caledonia (9%), Indonesia (6%), and Cuba (4%).

The Sudbury area of Canada has remained one of the principal sources of nickel in the world. This area is mined by Inco and Falconbridge Ltd. Other very important nickel mining districts are the Noril'sk in the U.S.S.R. and the Kambalda district of Western Australia. The only U.S. producer at present is the Glenbrook Nickel Co., which operates the ferronickel smelter at Riddle, OR. Some nickel is also produced in the United States as a byproduct of copper refining and recycling.

Capacity

The data in table 9 are rated capacity for mines, smelters and refineries as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long term operation rate, based on the physical equipment of the plant, and given acceptable operating procedures involving labor, energy, materials, and maintenance.

The major corporate event of the year was the sale of Falconbridge Ltd., of Canada. As a result of unprecedentedly high nickel demand in recent years, there was a spate of exploration and development activity, most of which took place in Australia.

Australia

Australian Consolidated Minerals Ltd. (ACM) and Outokumpu were planning to form a 50-50 joint venture to exploit ACM's wholly owned Mt. Keith deposit in Western Australia. Preliminary feasibility studies indicated an initial reserve of 110 million tons of ore grading 0.63% nickel. One purpose of the joint venture was to provide Outokumpu with an additional source of feed for its nickel facilities in Finland by shipping concentrates to the company's facility in Kokkola, Finland. There, the concentrate was to be roasted in existing facilities, and an electric furnace was to be built to produce ferronickel. The companies indicated that, although the project was planned to have a capacity of 22,000 short tons per year, the deposit had the capacity to supply a much larger operation. The joint venture was to hold discussions with other users of nickel

concentrate to identify potential purchasers. The project was subject to approval on completion of a final feasibility study in 1990.

Outokumpu was also reported to be planning to begin a \$27 million nickel project in Forrestania in Western Australia. The company bought a 55% interest in the project from Metals Exploration Ltd. Forrestania was comprised of two properties, Digger Rocks and Cosmic Bay. Outokumpu planned to complete the development of the open pit Digger Rocks and underground Cosmic Bay properties and build a 440,000-short-ton-per-year concentrator by early 1991. Digger Rocks reportedly had reserves of 1.3 million tons of ore grading 1.76% nickel, and Cosmic Bay had 2.5 million tons grading 2.82% nickel. The project was expected to have a lifetime of 7 years based on forecast production. The concentrate from the facility was to be sent to Outokumpu's smelter and refinery in Finland. Outokumpu was also reported to be considering developing the richer Flying Fox and New Morning nickel deposits in the region. The Forrestania purchase was part of Outokumpu's efforts to obtain a long-term

¹ Because matte is an intermediate product that must be refined before the nickel it contains can be used in making alloys or other products, smelter capacity for matte is not listed to avoid double counting.

² Includes Austria, Czechoslovakia, the Federal Republic of Germany, the German Democratic Republic, Poland, and Yugoslavia.

³ Standby or partially standby capacity.

supply of feed, because its own reserves have been diminished.

Queensland Nickel Pty. Ltd. was considering a plan that would permit the company to increase the production rate of its nickel refinery near Townsville, Australia, by 50%. This was to be accomplished by increasing the production capacity by 20% and processing higher grade ore. Reserves at the refinery's source of feed, the Greenvale Mine, were expected to be depleted in 1992. Queensland Nickel signed an agreement with P.T. Aneka Tambang to supply nickel ore to the plant. The Indonesian Government-owned mining concern was to supply as much as 1.1 million short tons of ore per year for 8 years. This was enough feedstock to satisfy about one-third of the Yabulu plant's requirements at the time, and was expected to decrease to about one-quarter as the plant's capacity was increased. Queensland also signed a long-term contract with New Caledonian firms. The two agreements were expected to fulfill the refinery's feedstock needs for several years.

Resolute Resources of Australia was planning to develop a nickel deposit with reserves estimated at 119 million short tons near Kalgoorlie in Western Australia. Plans called for the production of 14,000 tons of nickel per year over about 15 years.

An Italian state-owned company, AGIP SpA., announced that its subsidiary, Agip Australia Pty. Ltd., had formed a joint venture with an Australian company, Whim Creek Consolidated, to develop a nickel-copper mine in Australia. The property, known as Radio Hill, contained proven reserves of more than 1 million tons of ore grading 2.22% nickel and 1.68% copper. A feasibility study was being conducted by Agip at the site, located near Karratha, in the Pilbara region of Western Australia. The facility was 66.6% owned by Agip and the balance by Whim Creek. Mining was expected to begin in 1990 at a rate of 220,000 tons per year (TPY) of ore for 7 years. This was expected to produce more than 50,000 TPY of concentrate at 6% nickel and 3.6% copper, with minor quantities of cobalt and platinum-group metals.

Following Western Mining Corporation Ltd.'s purchase of the Leinster mining center (formerly called Agnew)

in late 1988, the company, recommissioned the mill in early 1989 and began developing the mines. Production began in mid-1989.

Canada

In August, Falconbridge Ltd. was jointly purchased by Noranda Inc., a large, Toronto-based resource firm and Trelleborg AB, a large Swedish metals producer.

Falconbridge announced plans to open a mine at its Sudbury operations. The new mine, to be called the Craig, was to provide more than 22,500 tons of nickel per year from late 1993 until beyond 2000. This quantity, which represented about 60% of Falconbridge's Sudbury production, was to replace production from other mines with diminishing reserves.

Falconbridge increased its ownership of New Quebec Raglan Mines Ltd. from 73.8% to 100%. The Raglan property was a nickel-copper deposit in the Ungava region of northern Quebec.

Inco Ltd. announced plans for the development of a major new mine near its nickel production complex at Sudbury, Ontario. The new mine, named the McReedy East, was to involve the largest known undeveloped high-grade nickel-copper sulfide deposit in the Sudbury basin. The engineering and preliminary development began in December, and production was to begin in 1993. Full production of 7,000 tons of ore per day was expected to be reached by 1996, resulting in the production of 20,000 tons of nickel per year. Because of the mine's size, grade, and use of the latest mining technology, the company expected the McReedy East to operate at a productivity level double the average of the other Inco mines.

Inco was forced to decrease production at its Thompson complex in Manitoba after encountering unacceptably high levels of arsenic at the Thompson Open Pit North Mine.

Inco reopened the Shebandowan Mine, which was west of Thunder Bay, Ontario. The mine was operated by McIsaac Exploration, which sent concentrates by truck to Inco's Sudbury smelter.

The 10-year contract, under which Sherritt Gordon Ltd. toll-refined nickel for Inco, expired at the end of the year. The contract had provided the Sherritt refinery with just over one-half of its

raw materials. In a search for additional raw material, Sherritt secured a new source of feedstock for its refinery in Fort Saskatchewan, Alberta. The Redstone Mine, located near Timmins, Ontario, a joint venture between Timmins Nickel Inc. and BHP-Utah Mines Ltd., was expected to produce about 5,000 tons per year of nickel in concentrate. Sherritt stated that, based on the projected quantities from its then current sources, feed supplies were sufficient to permit its refinery to operate at full capacity in 1989 and at 70% of capacity for the following 5 years.

Another source of Sherritt feed, the Namew Lake Mine in northern Manitoba, experienced production difficulties caused by water problems in the deepest part of the mine.

Finland

Outokumpu Oy signed an agreement to receive nickel concentrate from Nikkel and Olivin AS, a Norwegian company operating in Sweden. The Arneshjellet Mine, near Ballangen, Sweden, was expected to begin trial production in March. Outokumpu was to receive 16,500 tons of concentrate in 1989 and about 33,000 tons in each of the next 2 years. The concentrate was to go to Outokumpu's Harjavalta nickel smelter in southwest Finland.

Outokumpu formed a joint venture with the U.S.S.R. to develop a nickel mine in the Kola Peninsula, about 50 miles from Pechenga, in the eastern U.S.S.R. Subject to the successful conclusion of a feasibility study, Outokumpu was to exploit the underground part of the Tundrovoje deposit, which had been mined as an open pit for more than 30 years. Outokumpu was building a nickel flotation plant for Pechenga Nickel in the town of Zapolyarny.

Outokumpu was also actively involved in Australian projects (See Australia).

Indonesia

PT Aneka Tambang, a state-owned company, was planning to expand the capacity of its ferronickel plant and open a new nickel mine. The expansion would require the construction of a second furnace at the Pomalaa, Sulawesi, plant. The new mine was to be developed on Gag Island with the assistance of Queensland Nickel Joint Venture (QNJV). Nickel ore was to be

shipped to the Queensland nickel refinery in Yabalu, Queensland, Australia.

Inco Ltd. was proceeding with plans to offer up to 20% of the ownership of its 78%-owned subsidiary, PT Inco Indonesia, to the Indonesian public.

Japan

Pacific Metals Co. Ltd., was planning to increase its ferronickel capacity and production in 1990 from the 1989 capacity of 40,000 TPY to a capacity of 44,000 TPY.

Sumitomo Metal Mining Co. Ltd. was converting a refinery in Hosohima, which had been used to treat cobalt concentrates to a 360-short-ton-per-month electrolytic nickel refining unit. This was to increase nickel cath-

ode output capacity to a total of 2,400 tons per month.

Korea

Korea's first nickel refinery came on-line in June, with production reaching 375 tons. The Korea Nickel Corp. plant, jointly owned by Inco Ltd., (25%), Korea Zinc Co. Ltd., and Keo-Yang Co. Ltd., reached a capacity of 13,000 tons of nickel per year late in 1989.

Philippines

The Philippine Government agency, Asset Prioritization Trust (APT), which was responsible for selling the Nonoc Mining & Industrial Corp.'s nickel mine and refinery, made several unsuccessful attempts to sell the facility.

CURRENT RESEARCH

Outokumpu and ACM developed a process, which, if successful, could have a significant effect on the way sulfide deposits are developed. (See Australia section.) The Mt. Keith deposit in Western Australia is a low-grade sulfide deposit. Historically, nickel produced from a sulfide deposit has nearly always been in elemental form, and laterite deposits have been used to produce ferronickel. Pilot-scale metallurgical testing in Australia demonstrated the feasibility of producing a high-grade nickel concentrate with a low magnesium content. The low magnesium content was necessary to prevent the ore from being too refractory, because a high magnesium content would significantly raise the melting point of the concentrate. This process gave Outokumpu the ability to smelt the concentrate to ferronickel, effectively eliminating the traditional, and costly, midstage of processing concentrate into matte.

According to reports, Ford Motor Co. placed verbal orders for zinc-nickel coated sheet steel with Japanese steel mills. The zinc-nickel sheet is to be used in a 1990 model. The electroplated coating contains about 13% nickel; the balance is zinc. Zinc-nickel coated steel is already extensively used in Japan and Europe. Ford said that, after the initial 3 months of production, the company would be looking for domestic sources. Bethlehem Steel Corp., Pittsburgh, PA, is the only domestic steel producer known to have scheduled commercial production of zinc-nickel coated sheet steel for automobile applications. Other steel producers may be giving it consideration.

NKK Corp., formerly Nippon Kokan KK, Japan's second largest steel producer, used new technology that enabled the company to use nickel ore in place of ferronickel. The company was converting a mothballed converter at its Fukuyama facility to a 5,500-ton-per-month stainless steel production facility. The new process is said to cut costs by as much as 10% from conventional methods.

NKK also developed the world's first stainless steel-base shape-memory alloy for practical use.¹ A shape-memory alloy is one which when heated, returns to a previously formed or "remem-

¹ Refined nickel plus nickel content of ferronickel produced from ore and/or concentrates unless otherwise specified. Table includes data available through May 12, 1989.

² In addition to the countries listed, North Korea is believed to have produced metallic nickel and/or ferronickel, but information is inadequate for formulation of reliable estimates of output levels. Several countries produce nickel-containing matte, but output of nickel in such materials has been excluded from this table in order to avoid double counting. Countries producing matte include the following, with output indicated in short tons of contained nickel: Australia: 1984—56,330 (estimated); 1985—56,858; 1986—54,078; 1987—52,728; and 1988—50,000 (estimated); Botswana: 1984—20,507; 1985—21,567; 1986—20,913; and 1987—18,230; 1988—24,845; Indonesia: 1984—27,854 (revised); 1985—34,567 (revised); 1986—30,837; 1987—29,213; and 1988—31,000 (estimated); and New Caledonia: 1984—6,021; 1985—9,816; 1986—10,097; 1987—9,130; and 1988—11,541.

³ Refined nickel plus the nickel content of oxide.

⁴ Reported figure.

⁵ Nickel content of ferronickel only; no refined nickel was produced.

⁶ Revised to include nickel content of granular nickel oxide, nickel oxide powder, and nickel oxide sinter. Cuba also produces nickel sulfide, but it is not included in order to avoid double counting. Output of processed sulfide was as follows, in short tons: 1984—15,971; 1985—17,835; 1986—18,588 (revised); 1987—19,500 (estimated, revised); and 1988—19,850 (estimated).

⁷ Includes nickel content of nickel alloys.

⁸ Includes nickel content ferronickel, refined nickel, and nickel oxide.

⁹ Nickel content of ferronickel or matte only; no refined nickel was produced.

cobalt, iron, and aluminum were compacted under extremely high pressure.

Bureau of Mines researchers have determined that the addition of 4% aluminum to a 17% chromium, 9% nickel stainless steel in a high-temperature, wet sulfur atmosphere reduced surface corrosion rates by a factor of 3 to 10.⁵ A study of the morphology and composition of corrosion scales indicated that the aluminum addition allowed the stainless steel to form a compact, tightly adherent layer at the metal-scale interface that limited both inward diffusion of oxygen and sulfur to the base metal and outward diffusion of nickel. The aluminum-bearing alloy provided significantly better corrosion resistance, under the above conditions, than AISI type 310 stainless steel, which is used in high-temperature, corrosive environments and which contains 25% chromium and 20% nickel.

OUTLOOK

Stainless steel accounts for just over 60% of total world nickel demand and is of overwhelming importance in determining changes in the level of overall nickel consumption. Western World stainless steel demand grew at an average annual rate of 5.7% between 1960 and 1988. In light of this, a consensus forecast of 3% to 4% average annual growth in the 1990's seems reasonable. Moreover, the austenitic grades' (nickel-bearing) share of stainless steel production during the same period grew from 65% to 75%. There are, then, two long-term trends in the largest end-use sector. One trend is toward greater production of the product and the other is toward the use of more nickel in the product. Another large use of nickel in the United States is in superalloys, which are used in jet turbine engines. There are record numbers of orders for civil aircraft as air traffic steadily increases and aging fleets are replaced. World nickel consumption in 1990 is expected to decline from the record level of 1989, and, because of the cyclical nature of nickel demand, may not turn upward for a few years. Therefore, nickel demand through 1993 may be flat, but should recover afterward. Long-term consumption should grow at an average annual rate of about 2%, primarily as a result of stainless

bered" shape, produced through bending and heating the alloy to roughly 500° C. Because conventional shape-memory alloys, nickel-titanium and copper-base alloys had disadvantages, such as high cost and poor workability, their use as structural materials had not become widespread. The new stainless steel-base shape-memory alloy overcame problems associated with shape-memory alloys used in 1989. Its advantages included: high corrosion resistance, lower cost than nonferrous alloys, superior workability, and variable composition.

A superplastic duplex stainless steel, named SuperDux64, was developed by Nippon Yakin Kogyo Co. Ltd. in Japan.² The new alloy, when compared to the superplastic materials Ti-6Al-4V (titanium with 6% aluminum and 4% vanadium) and 7475Al (an aluminum alloy), can be formed into shapes at

least twice as fast as the titanium alloys and eight times faster than aluminum alloys. It also has superior elongation and ductility properties.

Sumitomo Metal Mining Co. Ltd., a Japanese nickel producer, developed new refining technology that allowed the company to produce nickel chloride from nickel matte through chlorine leaching.³ The next step, using conventional technology, was electrowinning to produce metallic nickel.

Metallgesellschaft AG, of the Federal Republic of Germany, developed an alloy that retained its integrity to between 1,300° and 1,350° C compared with then currently used alloys that could withstand temperatures of up to 1,200° to 1,250° C.⁴ The new alloy, targeted for use in next-generation gas turbine engines, was produced without using conventional melting processes. Instead, individual crystals of nickel, chromium,

steel demand. U.S. consumption should increase at about the same rate, owing to demand from the stainless steel and superalloy sectors. The fastest growth should be in the Far East. Recent events in Eastern Europe, after which these countries began moving toward market-based economies, could have a profound effect on nickel consumption. Pent-up consumer demand could cause the region to become a major stainless steel consumer. Consumption in the next 3 to 5 years is expected to rise faster in the Far East and in Eastern Europe than in the rest of the world.

BACKGROUND

Definition, Grades, and Specifications

Primary nickel is marketed in the form of nickel cathodes, powder, briquets, pellets, ingots, and shot, and in nickel oxide sinter and ferronickel. Commercial nickel in these forms usually is more than 99.5% pure, except for ferronickel and nickel oxide sinter. The ferronickel produced in the United States contains 48% to 52% nickel and is sold in 28-pound ingots; that produced in other countries contains 20% to 50% nickel. Nickel oxide sinter contains either 76% or 90% nickel.

Economic Factors

Prices.—Table 12 shows the time-price relationship for nickel over a 49-year span. The upward price trend in the 1970's reflected generally strong demand. In the early 1980's excess production capacity caused nickel prices to drop. In terms of constant dollars, nickel prices in the mid-1980's reached their lowest levels in more than 50 years. During this period, producers were forced to close at least six production facilities; some others were on the verge of failure and lost large amounts of money. Consumption, driven by stainless steel demand, rebounded dramatically in late 1987, reaching record levels for that year and each of the next 2 years. Prices soared along with demand.

NITROGEN

By Raymond L. Cantrell

Mr. Cantrell joined the Bureau's Chemical Materials group in June 1988 in the capacity of physical scientist, nitrogen commodity specialist. Ray's background in fertilizer market research and planning, technical services, and chemical research spans 25 years. He holds a B.S. in Chemistry from the University of Tennessee, Knoxville (1964). Ms. Tonya Hardin, Mr. Joseph Daniels, and Mr. Michael McTootle, mineral data assistants, prepared domestic data tables. Ms. Virginia Woodson, international data assistant, prepared international data tables.

Planet Earth is surrounded by an atmosphere rich in nitrogen. Nitrogen gas, in fact, accounts for about 78% of the Earth's atmosphere by volume. Nitrogen is an inert gas and reacts chemically only under conditions of high temperature, pressure or through biological processes to produce fixed nitrogen compounds. Ironically, fixed nitrogen (N) compounds are an absolute requirement for life on our planet. A natural phenomenon known as the nitrogen cycle provides a balance between fixed N forms on Earth and atmospheric nitrogen.

Global synthetic ammonia production approached 134 million short tons in 1989 and was valued at about \$15 billion. Fixed nitrogen in the form of synthetic anhydrous ammonia provided the base for the production of food and fiber required to support Earth's estimated 5.2 billion inhabitants. Ammonia also provided for a significant industrial chemicals industry. Synthetic fibers and resins, explosives, and an enormous array of inorganic and organic compounds were dependent upon ammonia feedstock.

U.S. ammonia plants operated at 96% of rated capacity in 1989, in producing 16.8 million product tons. Domestic demand for anhydrous ammonia and downstream nitrogen conversion products was buoyant during the spring of 1989, and producers operated above capacity in meeting demand. Import demand for anhydrous ammonia reached record proportions and the ammonia trade deficit soared to a record 3.4 million tons for the year. An oversupply situation developed in the domestic ammonia market following a disappointing spring fertilizer season, prompting a cutback in production and imports during the second half of 1989.

Ammonia prices fell precipitously during the second quarter and ammo-

nia sold at near producer cash costs f.o.b. plant through the third quarter of the year. Ammonia export and import data were withheld from public disclosure by the U.S. Department of Commerce in 1989, and many industry analysts believed that the loss of strategic trade data required for the monitor of domestic ammonia supply-demand fundamentals served to exacerbate the oversupply situation.

Persian Gulf countries landed 240,000 tons of ammonia in the United States during 1989, representing an increase of 330% above that of the prior year. Kuwait and Bahrain were new entries into the U.S. marketplace and accounted for about 70% of the Persian Gulf total. Saudi Arabia provided the remaining tonnage.

India rejected a Moroccan phosphoric

acid price increase in 1989 and opted to purchase record quantities of U.S. diammonium phosphate (DAP) instead. This unforeseen geopolitical event was fortuitous for both the U.S. nitrogen and phosphate industries and prevented a significant rise in the total U.S. nitrogen trade deficit, while tempering oversupply development in the domestic nitrogen and phosphate markets.

Significant restructuring continued to be experienced in the U.S. ammonia industry during 1989 as evidenced by a flurry of activity in the areas of acquisition and leveraged buyouts that led to further consolidation. Several projects designed to improve energy efficiency and capacity were either completed or in progress.

The U.S. ammonia industry experienced one of its more pronounced

⁶ International Fertilizer Industry Association statistics—World Anhydrous Ammonia Trade.

downturns and volatile business cycles during the 1980's. In the early 1980's, domestic commodity businesses were beset by a number of mutual problems, including inordinate energy costs, double digit inflation, global recession, growing international competition, surplus capacity, and rising inventories. The U.S. ammonia industry, in particular, was negatively impacted by prohibitive natural gas feedstock prices, an embargo on U.S.S.R. grain trade, surplus grain inventories, and the emergence of new ammonia capacity in the energy-rich, Government-controlled countries. Obsolete capacity was closed, plants were streamlined, and the industry was restructured. The downcycle ended in 1986, and supply-demand fundamentals gradually improved throughout the remainder of the decade.

DOMESTIC DATA COVERAGE

Domestic production data for anhydrous ammonia were developed by the Bureau of the Census, U.S. Department of Commerce. Preliminary monthly data are published under product code 28731 31 in Current Industrial Reports, Inorganic Fertilizer Materials and Related Products, M28B. Final monthly data are subsequently published in the companion annual report MA28B. The Bureau of the Census surveyed approximately 270 known producers of inorganic fertilizer materials during 1989. Production data are shown in table 1.

LEGISLATION AND GOVERNMENT PROGRAMS

The Natural Gas Wellhead Decontrol Act of 1989, Public Law 101-60, was signed into law on July 26, 1989.¹ This act took the final step in the wellhead decontrol of natural gas by removing those price and nonprice controls that remained in place following the partial wellhead decontrol implemented under the Natural Gas Policy Act of 1978, 15 U.S.C. 3301-3432 (1988). Congress enacted the 1978 legislation in response to severe shortages of gas in the interstate market that occurred in the early to

mid-1970's. The act restructured the regulation of natural gas by merging the interstate and intrastate markets, provided for phased deregulation of most "new" (postenactment) gas, and provided for the continued regulation of "old" (preenactment) gas. The Decontrol Act will serve to repeal the remaining controls by January 1, 1993.

The Environmental Protection Agency (EPA) disclosed the first annual Toxic Release Inventory of chemicals discharged to U.S. air, water, and land required under Title III of the Superfund Amendments and Reauthorization Act (SARA), known as the "Emergency Planning and Community Right-to-Know Act." More than 233 million pounds of ammonia was reportedly emitted into the air by industries in 1987. Ammonia emissions were second only to toluene according to the report. Nitric acid, ammonium nitrate, and ammonium sulfate were also included under title III.

The International Trade Commission rescinded an Antidumping Duty Order imposed against Chilean sodium nitrate in 1983.² The antidumping duties invoked against sodium nitrate landed by Sociedad Química y Minera de Chile, S.A. (SQM) were to be rescinded, retroactive to March 1, 1987.

DOMESTIC PRODUCTION

U.S. ammonia producers operated at 96% of design capacity in 1989. Ammonia production exceeded design dur-

ing the spring because of an expected 6%-10% increase in domestic fertilizer consumption. Production declined markedly in the fall in response to a significant buildup in field inventories. Field inventories were exacerbated by record ammonia imports and marginal growth in fertilizer consumption. Approximately 90% of domestic ammonia production was for fertilizer use. Louisiana, Oklahoma, and Texas provided 60% of U.S. ammonia production; the Southeast and Midwest, 15% each; and the Western States, 10%.

Both ammonium nitrate and ammonium phosphate production was up 6%, in 1989. Urea production declined marginally. Ammonium nitrate demand improved because of its use in the popular urea-ammonium nitrate (UAN) fertilizer solutions and ammonium nitrate fuel oil explosives (ANFO). New production and export records were established for ammonium phosphates in 1989. About 3.5 million tons of ammonia was required to meet the demand for ammonium phosphate production. Acrylonitrile and caprolactam performed well in the industrial sector.

Fertilizer Industries was formed during the year and was reported to have become the largest nitrogen solutions producer in the United States, and second only to Farmland Industries in ammonia production. Between May and November, the conglomerate negotiated the purchase of five nitrogen fertilizer producers in six States. The Arcadian Corporation name was adopted, and headquarters were established in Memphis, TN.

Sources: Bureau of the Census and International Trade Commission.

The firm purchased the plants of Arcadian Corp. at Geismar, LA, and LaPlatte, NE; Columbia Nitrogen Corp. at Augusta and Savannah, GA; Hawkeye Chemical, Clinton, IA; Nitrex at Memphis, TN, and Wilmington, NC; and Olin Corp., Lake Charles, LA. Arcadian's annual production capabilities were reported to be 2.1 million tons of ammonia, 2.9 million tons as nitrogen solution, and 0.8 million tons as urea and ammonium nitrate. The Geismar, LA, facility was also equipped to produce wet-process phosphoric acid and DAP.

Freeport-McMoRan-Agrico announced plans for the sale of its large nitrogen plants at Blytheville, AR, and Verdigris, OK. A new firm, Agricultural Minerals Corp., was organized by Agrico executives to purchase and run the

plants. Big River Inc. was revamping the ammonia plant it had purchased at Helena, AR, and planned to start up late in the year.

El Dorado Chemical Co. purchased American Cyanamid's idle nitric acid plant at Hannibal, MO, and moved the plant and equipment to El Dorado, AR. Ammonium nitrate annual capacity was to increase to 360,000 tons agricultural-grade and 250,000 tons industrial-grade in separate prilling towers. LaRoche Industries Inc. purchased Chevron's idle 550-ton-per-day nitric acid plant at Fort Madison, IA, and moved the unit to its Cherokee, AL facility for nitrogen solutions production. Atlas Powder Co. sold its 230,000-ton-per-year ammonium nitrate plant at Joplin, MO, and associated explosives business to Imperial Chemical Industries

of the United Kingdom. Coastal Chemical Co. expanded ammonia, urea, and ammonium nitrate capacity at Cheyenne, WY. A new 320-ton-per-day nitric acid unit, together with a 400-ton-per-day ammonium nitrate plant, was under construction. Coastal was considering a new nitric acid and ammonium nitrate plant near Elko, NV. Unocal Corp. closed its ammonia plant at Brea, CA, and was constructing new ammonium nitrate capacity at West Sacramento, CA.

The Tennessee Valley Authority (TVA) permanently closed ammonia, urea, and ammonium nitrate plants at Muscle Shoals, AL. TVA reportedly planned to sell the plants.

Cargill Ltd. of the United States and the Province of Saskatchewan announced plans for the construction of a 1,500-metric-ton-per-day ammonia plant and a 2,000-metric-ton-per-day urea plant. The Saferco Products joint-venture plant was to be built in Belle Plaine, Saskatchewan, at an estimated cost of \$400 million. Construction was scheduled to commence during 1990. Government and industry sources from both Canada and the United States debated the potential impact of major new nitrogen fertilizer capacity development in North America.

CONSUMPTION AND USES

Apparent domestic consumption of ammonia in 1989 was 16.7 million tons N. Of this total, 14.2 million tons N, about 85%, could be accounted for in downstream ammonia conversion products and in direct application ammonia fertilizer. Unaccounted disappearance amounted to 2.5 million tons N and was attributable to miscellaneous applications, shifts in field inventories, process losses, and statistical discrepancies.

Approximately 80% of accountable domestic ammonia conversion products was for fertilizer consumption and export. The remaining 20% was consumed in the industrial sector for synthetic fiber and resin manufacture, explosives use, animal feed supplements, and for the production of a wide variety of organic and inorganic compounds.

Urea is the most popular ammonia conversion compound in domestic use because of its versatility and high analysis (46% N). The material is used

extensively as a fertilizer in both solid and liquid form. UAN liquid blends enjoy a commanding share of the nitrogen fertilizer solutions market. In the industrial sector, urea forms the base for urea-formaldehyde resin adhesives and other polymeric materials and finds extensive use as a nonprotein nitrogen source in ruminant animal feeds.

Ammonium nitrate and ammonium phosphates are second to urea in N use. Ammonium nitrate is used predominantly in the fertilizer and explosives sectors. Ammonium phosphates are primary to domestic fertilizer use and export. Nitric acid is used principally for ammonium nitrate production, but about 0.5 million tons, as N, are used for other purposes, including organic chemical synthesis and metal treatment.

Acrylonitrile and caprolactam are used to produce acrylic and nylon fibers, resins, and plastics. Sodium azide (NaN_3) has surfaced as the propellant of choice for air bags, utilized by the U.S. transportation industry for vehicular safety. The material is currently imported, but Virtex Oil & Gas Corp. planned a 2-million-pound-per-year facility at Bristol, VA.

STOCKS

Producer ending inventories did not change between 1988-89 according to available statistics. Field inventories, however, were believed to have increased substantially because of a combination of high domestic capacity utilization, record ammonia imports, and flat domestic fertilizer demand.

TRANSPORTATION

The U.S. Department of Transportation (DOT) reversed an earlier decision to reclassify anhydrous ammonia from a nonflammable gas to a poisonous gas after substantial protest by the public and private sectors. The Research and Special Programs Administration of DOT elected to maintain the current nonflammable classification with the addition of an "INHALATION HAZARD" as a mechanism for hazard communication. DOT, however, extended the response period from October 24,

1989, to January 30, 1990, following a joint request by the Railway Labor Executives' Association and the Environmental Policy Institute/Friends of the Earth. The status of DOT's plans to formulate a final decision on the issue was indefinite.

Opponents of the original reclassification supplied information that showed anhydrous ammonia retail prices rising by at least \$10 per ton as a result. In addition to a direct price increase at the retail level, the U.S. farmer would have absorbed an added cost in transporting anhydrous ammonia to the farmgate.

Ammonia is transported by rail, truck, refrigerated barge, and pipeline. Koch Industries was operating the Gulf Central Pipeline it purchased in 1988. The 1,900-mile pipeline extends from

the gulf coast into the Midwest, as far north as Iowa. About 3 million tons of ammonia can be transported and stored along its length annually. Mid-America Pipeline Co. (Mapco) was operating a 1,000-mile pipeline that extended from Oklahoma to Minnesota. The Mapco system transports about 1 million tons of ammonia annually.

Seminole Fertilizer Corp. and the Royser Co. operate a joint-venture ammonia pipeline that serves ammonium phosphate producers in Florida. IMC Fertilizer Group Inc. operates a second ammonia pipeline in Florida for the same purpose.

PRICES

Prices for nitrogen products in all forms were firm during the first quarter of 1989. Ammonia prices declined significantly during the second quarter and approached cash costs by mid-May. Urea prices followed a similar trend. Ammonia and urea prices began to improve moderately during the fourth quarter.

Ammonium nitrate was in tight supply for much of the year, and prices were firm through August, after which there was a gradual downturn. DAP prices remained firm through early April, but trended downwards for the remainder of the year.

FOREIGN TRADE

The U.S. Department of Commerce, Bureau of the Census, adopted the new international Harmonized Commodity Description and Coding System (Harmonized System), effective January 1, 1989. The Harmonized System was de-

signed to standardize product codes for items traded in international commerce. Fertilizer and industrial grades of anhydrous ammonia and ammonium nitrate could no longer be distinguished because they were each reported under one code (fertilizer). Several other nitrogen classifications formerly grouped under one code were subdivided.

Total suppression of anhydrous ammonia export and import tonnage data was effected by the Bureau of the Census on January 1, 1989, following the review of a complaint filed by a domestic fertilizer producer. The producer believed that U.S.S.R. ammonia import price information that could be calculated from trade statistics was proprietary and should be withheld from the public domain. Value data by country continued to be reported. The U.S. Fertilizer Institute, the Canadian Fertilizer Institute, industry sources, and the Bureau of Mines worked cooperatively with the Bureau of the Census to develop a base for judging ammonia trade. Tables 9 and 10 were developed as a result of that effort. Late in the year, the Bureau of the Census announced that anhydrous ammonia export and import tonnage data would again be made available to the public in 1990. U.S.S.R. ammonia import tonnage data, however, continued to be suppressed.

The United States experienced a record ammonia trade deficit of 3.4 million tons during 1989. Ammonia

^P Preliminary.

¹ Value data suppressed by Bureau of the Census.

² Twenty-six countries; principally: El Salvador, Venezuela, Costa Rica, Trinidad, Canada, Spain, Taiwan, and Mauritius.

Source: Bureau of the Census (1988); Bureau of the Census and The Fertilizer Institute (1989).

exports declined by 40% and dipped to 0.46 million tons, whereas ammonia imports reached a record 3.84 million tons. A major disruption in world ammonia trade patterns was precipitated in 1989 when India rejected an increase in Moroccan phosphoric acid prices and declined to take the product used to produce domestic supplies of ammonium phosphates. Ammonia shipments from the Persian Gulf that would have normally been landed in India were diverted to the United States and other countries. About 240,000 tons of ammonia was shipped from the Persian Gulf to the United States, a 330% increase over that of 1988. Kuwait and Bahrain, countries that were believed to have never landed ammonia in the United States, accounted for more than 160,000 tons of the total. Ammonia imports from Trinidad also increased substantially. Many industry analysts believed that domestic ammonia oversupply and deteriorating prices were exacerbated by the suppression of U.S. ammonia trade data in 1989.

Overall, the U.S. total nitrogen trade deficit in 1989 was 1.6 million tons N, a moderate 3% improvement over that of 1988. The total nitrogen trade deficit peaked at 2.2 million tons in 1986. Record U.S. export shipments of DAP during 1989 were fortuitous and pre-

vented a significant increase in the total N deficit position. India negotiated record tonnages of U.S. DAP in response to its phosphoric acid price standoff with Morocco. China also imported record tonnages of U.S. DAP.

Urea antidumping actions imposed in 1987 against the German Democratic Republic (GDR), Romania, and the U.S.S.R. protected U.S. producers from unfair trade practices. The GDR was the only country in this group reported to land urea in 1989. According to Bureau of the Census data, the GDR shipped 11,434 tons of urea to the Baltimore, MD, Customs District.

WORLD REVIEW

Global ammonia production exceeded 133 million tons in 1989, establishing a new record. Production facilities in 71 countries provided the vast quantities of ammonia required to supply Earth's 5 billion inhabitants with food and fiber and industrial products. Asia and Eastern Europe commanded 62% of the global ammonia market; North America and Western Europe,

25%; and Latin America and the Middle East, about 10%. Approximately 88% of world ammonia disappearance was for nitrogen fertilizers, and about 12% was for industrial products. About 40% of world ammonia production was converted to urea, and another 10% was traded. International trade of synthetic nitrogen materials in all forms accounted for about 30% of total world ammonia demand.

The ammonia industry operated at 83% of design capacity in 1989, one percentage point below the prior year, and indicative of a relatively soft market. Ammonia production increased 1.5 million tons (1%) between 1988 and 1989, modest in comparison with the 9.1 million ton, 4% average annual growth experienced between 1986 and 1988. Major growth in supply capability has occurred in the centrally planned economies and in other energy-rich, Government-controlled countries during the past decade, whereas negative growth was experienced in the developed economies of North America, Western Europe, and Japan.

Population explosion and feedstock availability have been major factors for capacity development and demand in the developing nations. China and In-

dia compose 40% of world population and are notable examples. Indonesia provided significant quantities of nitrogen fertilizers for domestic use and export. The U.S.S.R. and other Eastern European countries produced ammonia for domestic use and generated strategic supplies of hard currency in the export market.

Significant growth in ammonia supply capability has developed in the Persian Gulf countries where abundant reserves of natural gas feedstock are available. Natural gas was once considered an insignificant byproduct of petroleum production in the Persian Gulf and was commonly flared. Today, natural gas is used to produce value-added ammonia and petrochemical products and liquefied natural gas (LNG) that generate foreign exchange. Iran and Iraq were poised to capture an increasing share of the ammonia market following the signing of a peace accord in 1988.

Ammonia plants in Trinidad and Tobago were strategically positioned to land ammonia in North America and Western Europe. Canada shipped major quantities of ammonia and finished fertilizers to the United States, while Mexico shipped surplus ammonia to the United States.

Capacity

The data in table 12 are rated capacity for ammonia plants as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

World anhydrous ammonia capacity stood at 160 million tons by yearend. Approximately 2 million tons of new capacity came on-stream in 1989, and about 1 million tons of obsolete capacity was permanently closed. Another 5 million tons of ammonia capacity was scheduled to come on-stream during 1990 and 1991. The major feedstock sources for ammonia production were natural gas, naphtha, fuel oil, and re-

finery off gases and condensates. Other sources included coal gasification, coke oven gases, and electrolysis.

In Canada, ammonia plants totaling 530,000 annual tons were closed by Glacier Ammonia Ltd. at Pincher Creek, Alberta, and by C-I-L Inc. at Courtright, Ontario. Cyanamid Canada Inc. planned to close its 220,000-ton-per-year plant at Welland, Ontario, in 1990. Cargill Limited of the United States and the Province of Saskatchewan let bids for a \$400 million ammonia and urea plant at Belle Plaine, Saskatchewan.

China brought 360,000 annual tons on-stream at Puyang, Hunan, and added 130,000 tons in small plants at various locations. China planned to start up 320,000 tons of small plant capacity in 1990–91 and 360,000 tons at Heijiang, Sichuan, in 1991. In Indonesia, Kaltim started up 360,000 tons at Bontang and PURSI let contracts for 500,000-ton ammonia and 650,000-ton

urea plants at Palembang. In India, Nagarjuna Fert. was to open 330,000 tons at Kakinada in early 1991. In Bangladesh, Jamuna Fert. Co. was to start up 390,000 tons at Jamalpur in late 1991. In the Republic of Korea, Yong Nam closed 120,000 tons at Ulsan in 1989.

Iran was to commence operation of two revamped 360,000-ton-per-year plants at Bandar Khomeini in 1989 and 1990. Iraq was to bring a 360,000-ton plant into operation at Baiji. In Turkey, a 360,000-ton plant was to be brought on-stream by Tugas at Gemlik in late 1990. Libya was to restart its damaged 440,000-ton plant at Marsa-El-Brega in early 1991.

The U.S.S.R. plan to bring 520,000 annual tons on-stream at Rovno, Ukraine, in 1990. Several debottlenecking projects were under way that would result in the addition of another 390,000 tons of capacity during 1991.

In Egypt, SEMADCO was to bring

150,000 tons per year into production at Suez in 1990. A 360,000-ton plant was due on-stream at Abu Qir in early 1991.

Kemira opened a new 280,000-ton-per-year plant at Hull, United Kingdom in mid-1989 and ICI closed 560,000 tons of annual capacity at Billingham and Severnside.

FERTRIN planned to debottleneck its plant at Point Lisas, Trinidad, adding 140,000 tons per year of capacity by 1992. In Chile, a joint-venture project between Kap Resources Ltd. and Atacama Resources Ltd, of Vancouver, Canada, was formed to exploit nitrate deposits in the Atacama Desert. North Lily Mining Co. of San Bruno, CA, was to operate the project. Davy McKee determined that the Yolanda deposit contained in excess of 20 million tons of "caliche" grading 11.8% sodium nitrate. Additional reserves were expected to be discovered on the property. Sodium nitrate and sodium nitrate-potash chemicals were to be produced.

CURRENT RESEARCH

The M. W. Kellogg Co. of Houston, TX, placed the first large-scale, centrifugal compressor ammonia plant in service in July 1965. The early plants cut ammonia production costs in half and began to replace the smaller and less efficient reciprocal compressor plants. Since that time, the Kellogg large-capacity, single-train ammonia plant design has been used in plants responsible for about one-half of the world's new fertilizer ammonia output.³

Kellogg has recently introduced a new Reduced Energy Ammonia Process that is expected to have a similar revolutionary impact on the nitrogen fertilizer industry worldwide. The total energy requirement is less than 25 million British thermal units (Btu) per ton of ammonia and represents a 25% improvement over feed-plus-fuel values found in conventional plants. Because the feed value is fixed at 18 million Btu per short ton, a 50% savings in the fuel requirement is realized. Kellogg to date has built Reduced Energy Ammonia Process plants in Canada, Belgium, and the Netherlands.

Kinetics Technology International (KTI), Monrovia, CA, has licensed the revolutionary new Leading Concept

Ammonia (LCA) process developed by Imperial Chemical Industries (ICI) of the United Kingdom. The LCA process has been hailed as the most significant breakthrough in small-scale ammonia plant technology in the past quarter century. The total energy requirement for a 500-ton-per-day plant was demonstrated to be 25.2 million Btu per ton. The LCA process separates the ammonia manufacturing operations from the utilities section of the plant, resulting in a low-cost, flexible design.⁴

Deshen International Inc. of Newton, MA, was developing novel technology based on the Birkeland and Eyde electric arc nitrogen fixation process fostered in Norway at the turn of the century. Mr. Mosche Alamaro, Deshen President and Principal Scientist, gave a number of seminars on the subject during 1989. An electric arc in air causes ionization of the nitrogen and oxygen. These charged particles are accelerated by the electric and magnetic fields, resulting in heating of the air. When the temperature of the air rises to 3500 degrees Kelvin, it becomes, according to chemical equilibrium, a mixture including about 5.25% nitric oxide (NO). Rapid cooling results in a solution of nitric acid.

Mr. Alamaro proposed building portable electric arc plants for use in areas where low-cost electricity could be obtained during off peak periods. Deshen reported the potential for the production of nitrogenous fertilizers in several forms using an ammonia-free electric arc process. Mr. Alamaro pointed out that in some respects the process was still in its infancy, allowing for technological breakthroughs in the 1990's that could lead to a competitive advantage for the U.S. industry.⁵

OUTLOOK

World ammonia supplies are expected to be more than adequate to meet global nitrogen demand during the period 1990-95. Ammonia demand in the past has tracked population growth, and this trend is expected to continue. The forecast was developed by taking into account supply and demand projections of the Food and Agriculture Organization of the United Nations (FAO), the International Fer-

NITROGEN MINERALS YEARBOOK—1989

⁵ Synthetic anhydrous ammonia; excludes coke oven byproduct ammonia.

tilizer Industry Association Limited (IFA), and Wharton Econometric Forecasting Associates (WEFA). Steady-state conditions were assumed for weather and macroeconomic trends, demographics, and geopolitics.

During the period 1985-90, the growth in demand slightly exceeded the growth in supply capability. Demand averaged 2.1% per year, while supply capability averaged 1.5% per year. Population growth averaged 2.0% per year. The forecast period shows a reversal in the historical trend with growth in supply capability slightly outpacing the anticipated growth in demand. Supply capability is forecast to grow at an average annual rate of 2.5% between 1990-95 and demand at 1.9%. This trend is indicative of a surplus supply situation during the forecast period. Population growth is forecast to average 1.9% per year, in line

with the expected growth in demand.

New ammonia capacity will come on-stream predominately in Asia, Eastern Europe (U.S.S.R.), and the Middle East, in order of importance. The brunt of growth in world demand will be concentrated in Asia and Eastern Europe (U.S.S.R.), followed by selected countries in the Middle East, Africa, and Latin America. Western Europe may experience a moderate decline in demand.

Domestic nitrogen fertilizer consumption in the United States was expected to reach 11.0 million tons N in 1990, a 4% increase. Industry analysts were forecasting 11.2 million tons N consumption for 1991, a 2% increase. The U.S. farm economy has experienced dramatic recovery since 1985. Net cash farm income now stands at about \$55 billion, and there is a good

balance between planted and idled acreage. Planted acreage was expected to approximate 332 million acres in 1990 and 1991, and was projected to range between 330 to 340 million acres in the future. Domestic demand in the industrial sector should continue to grow at an average annual rate of 2%-3% between 1990-95.

A continued resurgence in the U.S. nitrogen sector will be critically dependent upon a number of strategic domestic and international issues and events that unfold during the 1990's. Farm legislation to be enacted in 1990 will establish new domestic agricultural fundamentals for most of the decade. Natural gas deregulation mechanisms will determine the economics and availability of feedstock for domestic ammonia production. Clean air and ground water legislation will influence

domestic production economics and agricultural practices. The impact of consolidation in the European Community in 1992 and the profound restructuring in the Eastern European countries present both problems and opportunities. Capacity development in the energy-rich, Government-controlled sectors will affect supply-demand fundamentals.

BACKGROUND

Nitrogen is mined from the atmosphere through cryogenic air separation and membrane technologies. The global industrial nitrogen gas sector is significant, and in the United States alone, an annual 26-million-ton, \$0.7 billion industry has developed. Industrial nitrogen gas and liquid nitrogen find a variety of uses in the metals, chemicals, electrical, aerospace, food, and cryogenic sectors.

By the early 1900's, global demand for food and fiber had begun to outstrip nature's available supply of fixed nitrogen. World population had doubled in less than a century and approached 2 billion. Fortunately, a major technological breakthrough involving the direct synthesis of ammonia from air and hydrocarbons materialized in Germany.

The Haber-Bosch process revolutionized the concept of synthetic fixed nitrogen manufacture and fostered the technology responsible for today's economic production of ammonia on a large-scale basis.

The basic process for producing ammonia involves the catalytic reaction of a hydrocarbon, usually natural gas, with steam and air to produce hydrogen and nitrogen in the proper ratio to effect ammonia (NH₃) synthesis.

Natural gas is desulfurized and reacted catalytically with steam and then air at about 500 psig to produce raw synthesis gas in a primary and secondary reforming operation. Air is introduced into the secondary reformer in an amount required for ammonia synthesis.

Raw synthesis gas flows to a two-stage carbon monoxide (CO) shift converter for further production of hydrogen. The combined use of high and low temperature shift catalysts permits residual CO to be converted to carbon dioxide (CO₂). The gas is then treated with a regenerative solution for CO₂ removal using physical absorption techniques. Methanation is then effected to convert residual carbon oxides to methane.

Methane is removed, along with argon, from the air in a purge stream from the synthesis loop. Final purification includes the use of molecular sieve drying. The purified synthesis gas is

then compressed and mixed with synthesis loop recycle gas. The combined flow after additional compression is delivered to the synthesis loop where it is converted to ammonia in a horizontal catalytic reactor. Nominal operation pressures are 2000 psig and 3000 psig. Mechanical refrigeration, using ammonia as refrigerant, is used to condense the product ammonia.

Economic Factors

The data of table 15 provide historical trends in ammonia prices f.o.b. plant, natural gas feedstock prices at the well-head, and their mathematical relationship. Ammonia production costs are variably dependent upon natural gas feedstock prices which account for about 70% of the total. Ammonia market prices and indicative profitability are dependent upon natural gas prices, energy efficiency, and market forces.

Ammonia prices experienced a generally upward trend between 1970 and the early-1980's. The cyclical trends in prices are indicative of market conditions and the degree of profitability, and natural gas prices. Ammonia prices and profit margins reached record proportions in 1974-75 when ammonia was in extremely short supply. A firm balance between supply and demand during 1980-81 led to another surge in prices and profitability. Prices trended downwards for

67the remainder of the decade and profit margins were generally weak in spite of declining natural gas prices.

Energy efficiency in the U.S. ammonia industry has been significantly improved during the past 10 years through the closure of obsolete plants and through revamps and retrofits of existing plants. The decline in ammonia-natural gas price ratios between 1970 and the early-1980's demonstrated the sensitivity of ammonia costs to rising natural gas prices. The ratio leveled in 1982 and has been relatively constant since. A return to favorable profit margins in the U.S. ammonia industry will be dependent upon an improvement in world nitrogen supply-demand fundamentals.

PEAT

By Raymond L. Cantrell

Mr. Cantrell is a physical scientist and has served as the peat commodity specialist since joining the Bureau in June 1988. His professional experience includes 23 years in the private sector. Ms. Maureen Nash, mineral data assistant, monitored the survey and prepared domestic survey data. Ms. Pamela Shorter, mineral data specialist, monitored the survey and collected preliminary survey forms. International data tables were prepared by Ms. Audrey Wilkes, international data assistant. Ms. Jane Willard prepared the peat manuscript for publication.

U.S. peat demand peaked at 1.5 million tons in 1987, following a 4-year period of record growth. Demand improved by an average of 12% per year during the period, eclipsing previous records. Growth in domestic production was also strong, increasing at an average annual rate of 9%.

Domestic peat supply-demand fundamentals weakened in 1988, and the industry experienced a downturn that was still in evidence at the end of 1989. U.S. economic growth slowed, and there was a decline in housing starts and in the development of commercial properties that negatively impacted the domestic peat industry. An increase in competition from commercial composting operations and from recycled yard wastes was also experienced. Twenty-four domestic peat producers out of a total of 103 were idle in 1989.

Canadian sphagnum imports as a percent of total U.S. peat consumption

increased 5% between 1985 and 1989, and now command a record 41% share of the market. Minnesota continued to bring in new sphagnum operations at profitable margins: sales were up \$0.4 million, 38%, in 1989.

Domestic demand for horticultural peat should gradually regain momentum during the 1990's. New trends are developing in the areas of peat use for electric power generation and for specialty chemicals and consumer products. Peat fuel could capture a commanding share of the U.S. peat market, assuming that announced plans for the construction of powerplants in central Florida materialize.

DOMESTIC DATA COVERAGE

The Bureau of Mines conducts an annual survey of domestic peat produc-

ers. Information compiled from the Bureau's voluntary canvass was used to develop data tables for publication. Of the 111 domestic peat producers surveyed in 1989, 79 were reported to be active and 24 idle. Eight producers were reported to have closed permanently. Estimates were made taking into consideration historic information and macroeconomic trends, for active producers that did not report data in 1989.

PRODUCTION

Peat was harvested in 22 of the 48 contiguous States during 1989. The number of active producers dropped 10% to a total of 79, and production declined 11% to 755,000 tons. Florida and Michigan accounted for 65% of total production; Minnesota and Wisconsin, 7%; the Eastern States, 12%; the Midwest 11%; and the Western

¹ Apparent consumption equals U.S. primary production plus imports minus exports plus adjustments for industry stock changes.

States, 5%. More than 90% of the total output was generated by 50% of the producers from operations of 5,000 tons per year or greater. Reed-sedge peat accounted for 64% of production; humus, 18%; sphagnum moss, 13%; and other forms, 5%.

According to the State Division of Geological and Geophysical Surveys in Fairbanks, AK, Alaskan producers harvested 51,000 cubic yards of marketable peat, valued at \$0.4 million. Production in 1989 was down about 7% from the previous year.

During 1989, 23% of domestic peat producers were idle. The principal reasons cited for idle status included environmental constraints, competitive economics of domestic and foreign sources, payment deficiencies by bulk consumers, and the new emphasis placed on composting and the recycling of yard wastes.

Minnesota Sphagnum Inc. brought its new sphagnum moss bog and processing plant in St. Louis County, MN, into full production during 1989. Milled peat was collected by vacuum harvesters and transported to the plant for processing. Harvested peat was fed to a radar screen for sifting and removal of large debris. Crude sphagnum peat was fed to a double deck vibrating screen and hammer-milled to produce marketable quality peat. Dust was removed overhead through a closed circuit vacuum system. Product-grade sphagnum peat was compressed and baled for shipment.

Peatrex Ltd. was operating its new \$2 million state-of-the-art sphagnum processing plant in Carlton County, MN. This plant was designed to run for an extended period from sphagnum stockpiled during the harvest season. Before the plant came into operation, harvested peat was shipped to another producer for processing. Milled sphagnum moss was collected from the bog by a large Vapo vacuum harvester. Michigan Peat Co., the largest sphagnum producer in Minnesota, was operating a large bog and processing in Carlton County, MN.

Atkin Agri-Peat in Aitkin County, MN, is the largest bulk producer of peat in Minnesota. Reed-sedge peat was extracted from the bog by bulldozer and shaped into windrows. Conditioned peat was screened and stockpiled for bulk shipment. Davidson Peat was harvesting a combination of humus and reed-sedge peat under contract

¹ Revised.

¹ Data do not add to total shown because of independent rounding.

in Rice County, MN. Peat was extracted by power shovel, windrowed, and shipped by truck to Davidson's processing plant at Kenyon, MN. Davidson's product line included top dressing mixtures, heavy sand mixtures, and fine milled peat.

Hyponex Corp. was operating a large reed-sedge bog near the town of Montverde in Lake County, FL. Conventional agricultural disking equipment was used to loosen and aerate the peat. Wide-track bulldozers moved conditioned peat and prepared stockpiles for shipment to the processing plant. Peat was screened, hammermilled, and packaged for shipment. Peat was also prepared for bulk sales. Hyponex is owned by the O. M. Scott & Sons Co., the manufacturer of a popular line of lawn and garden fertilizers.

First Colony Farms' large fuel-grade peat property near Creswell, NC, was purchased in bankruptcy proceedings by The Conservation Fund for a reported \$8.8 million in September.¹ The Japanese firm, Nissho-Iwai American, joined with Westinghouse to bid \$8.6 million for the property, but fell \$0.2 million short. The tract consists of about 104,000 acres in Tyrrell, Hyde, Washington, and Dare Counties, NC. First Colony had envisioned the development of a 200-megawatt electric powerplant on the site.

The total area available for peat harvesting was about 18,000 acres, less than 20% of the acreage bought by The Conservation Fund. Approximately 38

million dry tons of peat reserves had been identified on the property.² Various parties negotiated for mining rights to a portion of the peat reserves on the property.

The Conservation Fund, a nonprofit organization, in coordination with the Richard King Mellon Foundation, proposed donating the property to the U.S. Fish and Wildlife Service, Department of the Interior, as an addition to the National Wildlife Refuge System.³ A decision as to whether the rights to the peat on the property should also be donated to the Service, had not been reached.

CONSUMPTION AND USES

Apparent domestic consumption of peat declined 5% for the second year in a row. A 10% decline in both domestic production and imports was partially offset by a 24% draw down in producer inventories. Domestic sales were off by 15% in 1989, but prices held steady. Bulk and packaged product commanded equal shares of the market.

Sphagnum moss sales by domestic producers were up 61% in 1989. Minnesota's sphagnum supply capability increased as new operations were brought into full production. Sphagnum was the material of choice for use by nurseries and also found extensive use in general soil improvement and as an ingredient for potting soils.

The demand for peat in general soil improvement, potting soils, and for use by nurseries generated 94% of the total domestically produced product sales in 1989. Reed-sedge peat commanded 67% of the market and was the most popular material used for general soil improvement in potting soils, on golf courses, as a seed inoculant medium, and for mushroom beds. Peat was also used for packing flowers, plants, and shrubs; as a fertilizer; for vegetable cultivation; and as an earthworm culture medium. Other uses for peat included chemical processing and medicine, environmental protection, and fuel.

STOCKS

Peat stocks in all forms declined 24% and stood at 5 months' production

¹ Values are f.o.b. producing plant.

² Data do not add to total shown because of independent rounding.

equivalent by yearend. Reed-sedge peat ending inventories were 64% of the U.S. total, humus 18%, sphagnum 13%, and other forms, 5%. U.S. ending inventories have averaged about 7 months' production equivalent during the past 5 years.

PRICES

The average value of domestic peat sales f.o.b. plant, was about \$23 per ton in 1989, an increase of 2.5% over the previous year. Packaged and baled prices were approximately 40% above bulk prices. Baled sphagnum moss sold for about \$13 per cubic yard, and packaged reed-sedge for about \$11 per cubic yard, f.o.b. plant.

FOREIGN TRADE

More than 99% of U.S. peat imports were from Canada. Quebec and New Brunswick in Eastern Canada accounted for about 75% of total Canadian shipments, while Manitoba, Alberta, and Saskatchewan, to the west, provided more than 20%. Canadian peat was also shipped from Newfoundland, Prince Edward Island, Nova Scotia, Ontario, and British Columbia. Approximately 75% of Canadian out-

put was exported, and the U.S. received about 90% of the total.

Canadian sphagnum trade fills a large void in the U.S. domestic peat market created by a deficiency in U.S. sphagnum moss supplies. Peat imports have captured an increasing share of the total U.S. domestic supply, rising from 36% in 1985 to 41% at present.

WORLD REVIEW

Global peat production remained level at an estimated 214 million tons in 1989. The U.S.S.R. was estimated to have accounted for about 93% of total world production, Europe 6%, and North America 1%. Data were not available for China.

In the U.S.S.R., harvesting was confined to the Baltic republics, the Moscow-Gor'kiy area, and Belorussia, although peat was known to be deposited throughout much of the country. Peat was produced for agricultural use, as a fuel source, and for use by the chemical industry. Peat was burned in thermal powerplants in European U.S.S.R. and was also used to fire industrial boilers and to fuel large heating plants. Peat briquets were manufactured for use in home heating. The use of peat as an energy source in the U.S.S.R. was declining because of insufficient reserves in the primary consuming areas and increasing demand in the agricultural sector. The chemical industry produced methanol and synthetic natural gas from peat.⁴

Ireland and Finland accounted for

about 70% of global peat production outside the U.S.S.R. in 1989. Each country was dominant in fuel peat production for use in power generation plants and other industrial applications and for home heating.

Bord na Móna was formed in 1946 to develop Ireland's peat resources. It produces peat fuel for use in the Electricity Supply Board's (ESB) peat-burning powerplants and machine turf and briquets for general industrial and domestic use. It also produces horticultural moss peat and a variety of fertilized peat products for the world market. ESB is Bord na Móna's major customer, accounting for 54% of annual revenues. In 1987-88, peat accounted for 36% of the Irish solid fuel market in terms of primary energy usage, down from 41% in 1986-87. The major

factor for this decline was the downward movement in international fuel prices. Horticultural peat products are currently the most dynamic growth component of the business. Twenty-seven countries now import Ireland's horticultural peat products.⁵

The development of Finland's peat industry has been dramatic. Peat production has increased twenty-fold since the mid-1970's. Peat accounts for about 4% of Finland's present energy supply, but the significance and relative proportion of peat is expected to increase despite declining world energy prices. Finland was planning to increase peat output substantially during the next 4 years. Finland's main product, milled peat, accounts for 80% of production, and sod peat, 20%. The use of peat in horticulture and as a raw material for different industrial and environmental purposes is increasing as well.⁶

Kemira Oy started up an 88,000-ton-per-year ammonia plant in Oulu, Finland, that was based on peat fuel synthesis gas.

Capacity

The data in table 10 are rated capacity for peat operations as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

CURRENT RESEARCH

The Natural Resources Research Institute (NRRI), University of MN, Duluth, assists in the expansion of natural resource industries in rural Minnesota by developing markets for peat, forest products, and minerals. Peat research activities were focused in four major areas: technical assistance to the local peat industry; peatland utilization and reclamation; waste treatment, including sewage effluent, oil absorption, and

composting; and chemical derivatives. Experiments were conducted in environmental chambers to test the growth of various plant species in mixtures of peat and composted natural organic materials. NRRI researchers also reported that sphagnum moss became hydrophobic when dried, producing an excellent medium for oil absorption. An experiment was to be conducted with a mechanical peat dewatering device in cooperation with the Minnesota Department of Natural Resources.

NRRI operated the Fens Research Facility north of Duluth, MN, on a virgin bog. Researchers conducted field experiments with various crops and trees. Blueberries, raspberries, and strawberries grew well in the reed-sedge bog. Hybrid willows and poplar trees also flourished in the bog environment. Wildlife had returned to the bog be-

cause of the increased food supply and cover.

The Center for Environmental Studies at Bemidji State University, Bemidji, MN, hosted its third International Symposium on Peat/Peatland Characteristics and Uses, May 16-19, 1989. Approximately 100 scientists from 14 nations attended. The subject matter dealt with peatland ecology and utilization; peat structure, composition and analysis; industrial products from peat; and plant-peat relationships. Some of the more interesting papers dealt with the extraction and properties of peat waxes, progress in the uses of peat resources in China, use of pre-treated peat for oil removal, and the use of biofilters in odor and volatile organic solvent control. Johnson & Johnson was reported to have numerous patents for peat-based disposable

diapers and was reportedly gearing up to manufacture biodegradable diapers using peat as the absorbent.

The Bureau of Mines developed porous polymeric beads, designated BIO-FIX beads, containing sphagnum moss. The beads have been demonstrated to effectively remove metal contaminants from mining and mineral processing wastewaters. The beads were utilized in a three-column fixed-bed circuit to remove cadmium, manganese, and zinc from wastewater emanating from an inactive zinc mining operation. The removal of toxic and heavy metal contaminants from aqueous waste streams is one of the most important environmental issues facing the United States today.⁷

The United States National Committee of the International Peat Society announced that an international peat

symposium would be held in Duluth, MN, August 19-23, 1991. The symposium site will be the new Convention Center, located on the shore of Lake Superior. Prospective speakers and attendees were encouraged to contact Mr. Donald N. Grubich, Organizing Chairman, c/o IRRRB, P.O. Box 441, Eveleth, MN 55734, U.S.A.

OUTLOOK

The global outlook for peat supply-demand is shown in table 12. Demand was developed by assuming that per capita peat consumption would continue to decline at an average annual 0.9 pounds per capita, experienced be-

tween 1984 and 1988. World peat demand should grow at about 1% per year between 1985 and 1990, about half that of world population. Under the forecast scenario, peat demand will grow at an average annual 0.7%, and world population at 1.9%, between 1990 and 1995.

About 50% of the projected growth in demand can be accounted for by announced plans in Finland and the United States. In addition, demand for agricultural peat in the U.S.S.R. should also increase. Peat reserves in Bangladesh, China, Indonesia, and Malaysia are also expected to be developed and expanded during the forecast period. Canada should expand dependent primarily on U.S. sphagnum requirements. The Bureau's demand forecast appears to be both reasonable and moderate, based on information currently available. Geopolitical events that unfold in the U.S.S.R. and in the developing countries during the forecast period, however, could impact forecast demand in either a positive or negative direction.

Global peat reserves under cultivation are sufficient for about another 20 years at current production rates. The identified reserve base of 528 billion tons, however, could theoretically support current production rates for more than 2000 years. New bogs will be developed to replace depleting bogs and to expand world peat production. Total world resources of peat are estimated to be 2.1 trillion tons. The deposits in the U.S.S.R. are estimated at 850 billion tons and in Canada at about 560 billion tons. Domestic deposits of peat occur in all 50 States, with estimated resources of 340 billion tons, about 16% of the world total.

U.S. production and primary demand turned up in 1984, and peaked at record highs during 1986 and 1987. The market turned down, in 1988 and 1989, in line with a slowdown in U.S. economic growth. Housing starts and the development of commercial properties slowed, and peat demand declined. The market is expected to stabilize during the forecast period, and demand for horticultural and agricultural peat products should return to, or exceed, 1986-87 levels by 1995. Demand will be impacted by industrial composting and residential recycling of yard wastes. Fuel-grade peat demand should in-

peat industry during the 1990's.

BACKGROUND

Peat deposits were developed by the gradual decomposition of biomass materials under anaerobic conditions in shallow basins. Most of the peat deposits in existence today have formed since the last ice age, approximately 10,000 years ago. Peat bogs are more extensive in the temperate, boreal and subarctic zones of the Northern Hemisphere and more limited in the cool and humid zones of the Southern Hemisphere. Peat is a precursor of lignite and coal. Humates are found in the Upper Cretaceous coal-bearing sediments of the San Juan Basin in New Mexico. Humates are humic acid-rich carbonaceous shales or claystones. They are used for a variety of purposes, including soil conditioning. Peats are commonly classified as sphagnum moss, hypnum moss, reed-sedge, and humus. Sphagnum moss is a high-fiber, low-density, acidic peat, while humus, at the opposite end of the scale, is a high density, moderately acidic material.

Specifications

Peat has various definitions and the term is often misused. Peat scientists

use a selected set of physical and chemical criteria to characterize peat materials. Standards established by the American Society for Testing and Materials (ASTM) are usually followed in characterizing peat in North America. ASTM Classification of Peats, Mosses, Humus, and Related Products requires the use of three parameters: ash content; fiber content, and botanical composition. The ash content must be less than 25% by dry weight. The botanical composition of the peat, especially of the peat fibers, is critical to determining whether the peat is "sphagnum moss peat" (greater than 66% fiber, all of which must be derived from the genus *Sphagnum*), "hypnum moss peat" (minimum of 33% fiber, of which 50% must be derived from the genus *Hypnum*), or "Reed-Sedge Peat" (minimum of 33% fiber containing more than 50% reed-sedge and other nonmoss fibers). Many researchers endorse the use of von Post's humification factors as a direct method for defining peat types and properties in the field.

Sphagnum peat moss is a low density, fibrous material with excellent water retention properties. Sphagnum bogs are found in the northern latitudes of the United States. Sphagnum is an acidic, chemically active peat. Reed-sedge peat is less fibrous than sphagnum, has a much higher density and is mildly acidic. Reed-sedge bogs are abundant in both

Technology

Down East Peat commenced operation of North America's first peat-fired electric powerplant at Deblois, ME, at midyear. The plant output design is 22.8 megawatts and can be fueled by peat or a combination of peat and woodchips. Pelleted sod peat from the adjacent Denbo Heath bog provided fuel for the boilers. The \$55 million project took 6 years to complete. The plant will employ about 50 full-time and 40 seasonal work-

ers and will generate about \$500,000 in revenues annually.

An agreement was reportedly reached between Florida Power Corp. and General Peat Resources LP, for the utility to purchase power from three peat-fueled plants to be built in central Florida. The action paved the way for General Peat of St. Petersburg, FL, to build three, 52-megawatt generating units near Lake Placid at an estimated cost of \$300 million. General Peat will harvest peat in the immediate area where bogs contain a 50-year supply of the fuel. At full capacity, the powerplants would require more than 1 million dry tons of peat annually, more than double current U.S. peat output.⁸

PERLITE

By Wallace P. Bolen

Mr. Bolen, a physical scientist, is a graduate of the University of Virginia and has been the acting commodity specialist for perlite since September 1989. Domestic survey data were prepared by Blanche S. Hughes, mineral data assistant, and the international production table was prepared by Audrey Wilkes, international data coordinator.

U.S. production of processed perlite increased 4% in quantity and decreased 8% in value. Expanded perlite sales increased 8% in quantity and were virtually unchanged in value. Construction uses of processed perlite accounted for 64% of total domestic sales in 1989.

DOMESTIC DATA COVERAGE

Domestic production data for perlite are developed by the Bureau of Mines from two voluntary surveys, one for domestic mine operations and the other for expanding plants. Of the 12 mining operations to which a request was sent,

10 responded, all active, and accounted for 100% of the total processed ore sold or used in table 1. Of the 68 expanding plants canvassed, 61 were active; of these, 42 plants, or 69% responded, representing 64% of the total expanded perlite sold or used shown in table 1.

PRODUCTION

Perlite mined for processing came from 9 companies with 10 operations in 6 Western States and totaled 722,000 short tons. New Mexico operations accounted for a large majority of the total tonnage mined. The remaining tonnage came from Arizona, California, Colorado, Idaho, and Nevada. Apparent domestic

consumption is defined as production plus imports minus exports. Apparent domestic consumption of processed perlite in 1989 increased 6% to 641,000 tons compared to that of 1988.

Ore producers were Harborlite Corp. and Nord Perlite Co. in Arizona; American Perlite Co. in California; Persolite Products Inc. in Colorado; National Perlite Co. in Idaho; Delamar Perlite Co. in Nevada; and Greco Inc., Manville Products Corp., and USG Corp. in New Mexico.

The quantity of expanded perlite sold and used from 61 plants in 33 States increased 7% in quantity compared with 1988. Value of expanded perlite decreased slightly in 1989. Leading States, in descending order of sales, were Mississippi, Pennsylvania, Illinois,

¹Crude ore mined and stockpiled for processing.

California, Georgia, Arizona, Kentucky, Virginia, and Minnesota.

CONSUMPTION AND USES

Construction-related uses, the major market for expanded material, increased 5% to 336,600 tons. Expanded perlite used as filter aid, fillers, and in

agricultural markets totaled 148,600 tons, an increase of 7% compared to 1988.

FOREIGN TRADE

Perlite exports, primarily to Canada, were estimated to be 5,000 tons. Imports of perlite ore from Greece were estimated to be 65,000 tons compared with 62,000 tons in 1988.

PHOSPHATE ROCK

By William F. Stowasser

Mr. Stowasser, a physical scientist with 19 years Bureau of Mines experience, has been the commodity specialist for phosphate rock since 1974. Domestic survey data were prepared by William Fields, mineral data assistant, and the international data table were prepared by Peter Roetzel, international data assistant.

Phosphate rock production in the United States increased almost 10% in 1989 over that of 1988. The production of 49,817,000 tons¹ was consumed in several markets. The estimated U.S. demand pattern was 19,180,000 tons used in domestically consumed fertilizer, 20,803,000 tons was converted to fertilizer and exported, 1,647,000 tons was used domestically in other than fertilizer applications, and 512,000 tons was exported as other than fertilizer chemicals.

The United States exported 7,842,000 tons of phosphate rock and imported 704,000 tons preserving the general trends of declining phosphate rock exports and increasing imports.

World production of phosphate rock was similar to that of 1988. Production remained at a plateau of about 162 million tons.

DOMESTIC DATA COVERAGE

Domestic production data for phosphate rock are developed by the Bureau of Mines from two separate voluntary surveys of U.S. operations. Typical of these surveys is the semiannual Phosphate Rock Survey. Of the 19 operations to which a survey request was sent, all responded, representing 100% of the U.S. production data shown in table 1.

LEGISLATION AND GOVERNMENT PROGRAMS

Section 3001(b)(3)(A)(ii) of the Resources Conservation and Recovery Act (RCRA), known as the Bevill Exclusion, excludes "solid waste from the extraction, beneficiation, and process-

ing of ores and minerals" from regulation as hazardous waste under subtitle C of RCRA, pending completion of certain studies by the Environmental Protection Agency (EPA). In 1980, the EPA interpreted this exclusion on a temporary basis to encompass "solid waste from the exploration, mining, milling, smelting, and refining of ores and minerals." On September 1, 1989, EPA published the final criteria and

took final action on all but 20 mineral processing waste streams. The wastes proposed for removal from the Bevill Exclusion were furnace offgas solids from elemental phosphorus production, phosphogypsum from phosphoric acid production, and furnace slag from elemental phosphorus production.

As of September 1, 1989, the status of previously proposed Bevill mineral processing wastes in the phosphoric

¹ Data for the same items appearing in this and other tables may not reconcile because of manual or computer rounding.

² The total value is based on a weighted value.

³ Computer-calculated average value based on the weighted sold or used values.

⁴ Includes domestic sales and exports.

⁵ Weighted average of sold or used values.

⁶ Exports reported to the Bureau of Mines by companies.

⁷ Bureau of the Census data, excluding reported Canadian and Israeli imports.

⁸ Average unit value obtained from unrounded data.

⁹ Expressed as sold or used plus imports minus exports.

acid and elemental phosphorus sectors was as follows:

1. Furnace off-gas solids was conditionally retained because it passed high-volume criteria.

2. Furnace scrubber blowdown was removed because of low volume.

3. Process wastewater was removed because of low volume.

4. Slag was retained because it passed all criteria.

5. Phosphogypsum was retained because of high volume.

6. Process wastewater was conditionally retained because of high volume.

As of September 25, 1989, the proposed status of each of the phosphate commodity wastes and the basis for each were as follows:

1. Elemental furnace off-gas solids from 5 operations was not retained within the Bevill Exclusion.

2. Phosphoric acid process wastewater from 28 operations was retained within the Bevill Exclusion.

The Office of Radiation Programs, EPA, ruled that conditionally and pending further studies, a reduction of radon emissions from phosphogypsum stacks would not be required. The emissions were within the acceptable risk of 1 cancer death per year for every 10,000 people from radon-222 gas from an active phosphogypsum stack. The maximum mortality risk from radioactive particulates was estimated at about 2 in 1,000,000.

STRATEGIC CONSIDERATIONS

Phosphate rock is not strategically stockpiled. The United States is a net exporter of both phosphate rock and phosphate chemicals. There is concern, however, over the adequacy of domestic supply in future years when the deposits of phosphate rock in Florida that have sustained domestic and export markets for many decades are mined out. Phosphate rock deposits in Florida, after 100 years of production, have a limited supply of high-quality reserves remaining. (The subject of phosphate rock reserves is discussed in this publication under reserves.) A review of mine production plans of Florida mines shows that as years progress, the supply of phosphate rock from remain-

ing mines will decline. The rate of decline will depend on future mining rates, if environmentally sensitive wetlands and hardwood stands will be permitted and mined, if technology to improve the quality of phosphate rock can be developed, and if the economics of mining and processing phosphate rock become sufficiently attractive to develop new mines in Florida and expand the capacity of the mine in North Carolina.

Raw material demand for phosphate rock is closely associated with production levels in the world's fertilizer industries. The demand for agricultural products is tied to population. A world population over 5 billion in 1989 is forecasted to reach 6.2 billion in the year 2000.

The increase in population and an anticipated increase in per capita income will increase the demand for food, feed, and fiber, increasing the pressure on world agriculture to produce the necessary quantities of these products. Programs and policies are needed to promote growth in fertilizer application and food production so that people, particularly in developing countries, can have higher nutritional levels in the year 2000.

ISSUES

The demand for U.S. phosphate rock in 1989 was more than expected when India discontinued receiving Moroccan phosphoric acid and purchased an additional 1.5 to 2 million metric tons of diammonium phosphate (DAP). The tonnage was supplied for the most part by U.S. producers, and with this windfall, prices were sustained during the main shipping period of the year. As shipments to India declined, prices for DAP fell, indicating overcapacity of the U.S. DAP industry. The decline in prices forced high-cost plants to close or reduce production. Overcapacity in the U.S. DAP industry was the reason, and it was forecasted that India's imports of DAP will be less in 1990. Low DAP prices will probably encourage sales into some areas; however, the quantities sold were not expected to increase in 1990 over that of 1989. Closing DAP plants in the United States may not resolve the issue as

Morocco plans to double its DAP capacity at Jorf Lasfar in the next few years.

After 100 years of production from Florida's Bone Valley Formation, it is difficult to accept the prognosis of a decline in the supply of phosphate rock from the region. This decline was particularly difficult to accept in 1989 when efforts were made to replenish domestic grain stocks, depleted by the drought in 1988, and supply an exceptionally strong export market for phosphate fertilizers. At issue is the development of replacement mines to offset production losses as phosphate rock deposits are mined out in Florida. There are a limited number of remaining deposits from which acceptable products could be produced in Florida. Investors have been reluctant to develop new mines in Florida without assurance of a profitable return. Current selling prices and estimated production costs from a potential new mine do not encourage investments.

The future supply of phosphate rock could be increased by investment in North Carolina, where large reserves are available, to accommodate a mine expansion. Expansion of existing mines in Florida does not appear at this time to be economically feasible, and quality reserves are limited.

PRODUCTION

Compared with 1988, domestic production of marketable phosphate rock increased 10% in 1989 to 49.8 million tons. Production was 2 million tons higher than planned by producers as they responded to improved demand in the domestic and export sectors for phosphate fertilizers and elemental phosphorus derivatives. Most of the increased supply originated in Florida. Of the total U.S. production, Florida and North Carolina supplied 88%, and the balance was produced in Idaho, Montana, Tennessee, and Utah.

Florida and North Carolina

Phosphate rock was produced in Florida by Agrico Mining Co., a division of Agrico Chemical Co., owned by Freeport-McMoRan Resource Partners L.P.; CF Industries Inc.; Estech Inc., owned by C&G Holdings Inc.; Gardinier Inc.,

80% ownership by Cargill, Inc.; IMC Fertilizer Inc. (IMC); Mobil Mining and Minerals Co.; U.S. Agri-Chemicals Corp.; Seminole Fertilizer Corp., owned by Tosco Corp.; and Occidental Chemical Agricultural Products Inc. in northern Florida. Nu-Gulf Industries Inc., a subsidiary of Nu-West Industries Inc., shipped phosphate rock from inventory but did not produce it in 1989.

Low-fluorine soft phosphate rock was recovered from hard phosphate rock tailing ponds in north-central Florida by Manko Co., Howard Phosphate Co., and Loncala Phosphate Co.

Texasgulf Inc., a subsidiary of Elf Aquitaine Inc., was the only producer of phosphate rock in North Carolina. Studies to deepen the harbor and channel at Morehead City, NC, for navigation by deeper draft vessels were in progress. Texasgulf produced phosphate rock from the Lee Creek Mine adjacent to the Pamlico River.

Western States

Phosphate rock was mined in Idaho, Montana, and Utah. Nu-West produced phosphate rock from a number of deposits in Idaho. The phosphate rock was beneficiated and calcined at Conda, ID. J. R. Simplot Co. produced phosphate rock from the Gay Mine, Fort Hall Indian Reservation, and the Smoky Canyon Mine, Caribou National Forest. The Gay Mine's main bed phosphate rock was used by Simplot, and the lower-grade shale was used in FMC Corp.'s electric furnaces. Monsanto Co. supplied its Soda Spring, ID, electric furnaces from the Enoch Valley Mine. Rhône-Poulenc Basic Chemicals Co. operated the Wooley Valley Mine, ID, to supply phosphate rock to its Silver Bow, MT, electric furnaces. Cominco American Inc. operated an underground mine, beneficiation, and drying plant near Garrison, MT. The dried product was

exported to Canada. Chevron Resources Co. produced phosphate rock from the Vernal Mine, UT. It was transported by pipeline to Rock Springs, WY.

CONSUMPTION AND USES

The demand pattern for phosphate rock in the United States was stable during the past decade. Between 85% and 90% of phosphate rock consumed was used to produce phosphate fertilizer for domestic or export markets. Frequently, over 50% of the manufactured fertilizer was consumed domestically; however, there were several years during the past decade that fertilizer exports exceeded domestic consumption.

Phosphate rock exports have declined from a 14 million ton-per-year level in 1979 to about 8 million tons-per-year in recent years as the industry

converted more phosphate rock to higher value intermediates or finished fertilizer. The emergence of phosphate fertilizer industries in developing countries with domestic phosphate rock deposits caused major changes in trade patterns. Countries with indigenous phosphate rock deposits like Jordan, Morocco, Senegal, and Tunisia established fertilizer plants that competed in markets throughout the world. Phosphate rock imports, particularly shipments from Morocco and Togo, to plants on the Mississippi River increased in the last years of the decade to similar levels that existed at the beginning of the decade. The resumption of substantial imports was prompted by a need for higher quality phosphate rock than was available domestically to produce high purity fertilizers.

The balance of phosphate rock was consumed with silica and coke in electric furnaces to produce elemental phosphorus. Elemental phosphorus was used to produce high-purity phosphoric acid, salts, and phosphorus chemicals for industry and home consumption. These included detergents and cleaners, chemicals for food and beverages, and metal-treating chemicals.

The detergent builder, sodium tripolyphosphate, was the principal derivative of elemental phosphorus. The manufacture of thermal or furnace phosphoric acid accounted for 80% to 85% of U.S. elemental phosphorus production. About 10% of the elemental phosphorus production was used to produce phosphorus pentasulfide, phosphorus pentoxide, and phosphorus trichloride. About 50% of the elemental phosphorus produced was used to manufacture sodium tripolyphosphate.

The gradual decline in elemental phosphorus production and the quantity of phosphate rock consumed in electric furnaces during the past decade was caused by banning phosphates from home laundry products in some areas of the country. Several companies decided to construct plants to produce higher quality, lower cost, wet-process phosphorus acid purification plants that would produce a purified acid to replace thermal acid in food and detergent grade products. Thermal acid will continue to be used by semiconductor manufacturers and in other ultrahigh-purity markets. Where thermal acid competes with purified wet-process

acid, lower cost wet-process acid will probably be the choice selected in the future.

STOCKS

Phosphate rock was inventoried in wet rock piles adjacent to the beneficiation plants in Florida and North Carolina. The stocks were reclaimed for drying or calcining for export or for wet-grinding before wet-process phosphoric acid manufacture. Industry stocks peaked in 1981 when about 20 million tons was reported at yearend. Since 1981, the phosphate rock inventory tonnage declined each year, reaching 9.3 million tons in 1988. In the Western States, where the climate made it diffi-

cult to unload frozen ore from trucks or rail cars, ore was stockpiled near the electric furnaces and chemical plants to permit year-round production.

During 1989, stock levels were about 9.5 million tons in January, 10.9 million tons in June, and stabilized at about 11 million tons for the balance of the year.

TRANSPORTATION

Phosphate rock was moved by rail from production centers in central and north Florida to terminals on Hillsborough Bay, FL and in Jacksonville, FL. The CSX Transportation Railroad moved phosphate rock from central Florida to Eastern Associated Terminals Co., Rockport Phosphate Terminal, International Minerals & Chemical Phosphate Terminal Co., and Agrico's Big Bend Terminal. Phosphate rock was shipped in bulk carriers to ports around the world and barged from Hillsborough Bay to chemical fertilizer plants on the Mississippi River. Freight, loading, and weighing charges were components of the cost of transporting phosphate rock from mine to vessel in central Florida. In 1974, the cumulative cost was \$2.20 per ton. By 1990, the total cost increased to \$6.98 per ton plus a Rockport Phosphate Terminal improvement charge of \$0.36 per ton. Weighing charges were available at the shipper's request that reduced the cost from \$0.22 per ton to about \$0.02 per ton for a 20,000 ton cargo.

In north Florida, the Norfolk Southern Railroad transported phosphate rock from mine to vessel at Jacksonville, FL at a total cost of \$9.08 per ton.

Specially designed barges with a capacity of 2,431 tons moved phosphate rock from the Lee Creek Mine to the Morehead City Port Terminal. The barge's capacity can move more than 15,400 tons every 3 days over the 93-kilometer section of the intercoastal waterway. Self-unloading barges discharged to conveyors for either direct delivery to a traveling shiploader or to a storage building. In Tennessee and the Western States, phosphate rock was moved by rail or truck from mine to beneficiation plant. Recently, two companies have installed slurry pipelines to convey concentrates to chemical fertilizer plants.

NA Not available.

¹ Includes Idaho, Montana, and Utah.² Data for the same items appearing in this and other tables may not reconcile because of manual or computer rounding.³ The total value is based on a weighted value.⁴ Data for Tennessee and Western States were reported separately in the 1985 Minerals Yearbook chapter.

PRICES

The price or value of phosphate rock was obtained by semiannually surveying the industry to obtain domestic and export prices, f.o.b. mine, from each company in the United States. Price or value was obtained for each grade of phosphate rock produced by each company. Weighted averages were calculated for each grade and market. The average composite domestic and export f.o.b. actual mine price, dollars per ton, are shown in table 12.

The selling price of phosphate rock is negotiated between the buyer and seller. If exported from Tampa or Jacksonville, FL, the price included a freight, loading, and weighing cost of \$6.53 per ton and \$8.82 per ton, respec-

tively. The severance tax included in the export price was \$1.54 per ton.

FOREIGN TRADE

Exports

The United States was a net exporter of phosphate rock in 1989. The demand for phosphate rock was principally tied to the demand of downstream phosphate fertilizer industries. India has, in past years, purchased phosphoric acid from Morocco. In a dispute over pricing, India stopped purchasing phosphoric acid and manufacturing DAP. It chose instead to purchase about 2.5 million tons of DAP, which was, for the most part, supplied by United States producers. In addition, shipments of DAP to China were 2.3 million tons. With large volumes

the range of 700 to 900 thousand tons.

Phosphate rock exports were 7.8 million tons, continuing the trend of gradually declining tonnages. After exports peaked in 1979 at 14 million tons, phosphate rock exports declined, and except for a small improvement in 1983, the trend persisted in recent years. The gradual loss of this market

was attributed to converting more phosphate rock to higher value products, intense competition from other producing countries offering high-quality phosphate rock and positioned closer to markets than U.S. exporters, and the inability of U.S. companies to export phosphate rock of competitive grade and quality. Although the U.S.

industry's supply problem will persist, overcapacity in all phosphate commodity lines will probably remain with the industry in the near term.

Imports

Phosphate rock imports had reached levels of 500 to 900 tons from 1978-80 when a company imported phosphate rock while developing its own mine. From 1981 through 1985, imports declined to a level of 9 to 34 thousand tons of low-fluorine material. Imports significantly increased to the 500 to 700 thousand ton level from 1986 through 1989. High-quality and grade phosphate rock was imported to satisfy a demand for phosphate rock that was unavailable domestically. It is probable that phosphate rock imports will increase in the future to plants in the United States located on water and with limited supplies of domestic high-grade and quality phosphate rock.

WORLD REVIEW

Phosphate rock production was maintained at about 162 million tons. Production was maintained from existing mines and from reactivating several that were closed. Not only were no new mines producing in 1989, there were no announcements of new mine development during the year. In the United States, demand for downstream products actually increased, but producers oversupplied the market in anticipation of an 8% to 10% growth rate after the drought of 1988. The oversupply caused DAP prices to drop after the Indian market was supplied.

The United States share of world production of phosphate rock declined to about 30%. The world supply of phosphate rock again exceeded demand allowing only a modest increase in prices. The Four Corners Mine in central Florida was restarted at the beginning of the year. The Wingate Creek Mine remained closed, and several other mines were scheduled to close in 1990 and 1991 as the deposits were mined out.

The principal producing countries in decreasing order of production were the United States, the U.S.S.R., Morocco, China, Tunisia, Jordan, Brazil, Togo, and the Republic of South Africa. No new mines were commissioned during the year. Production increases were achieved from existing mines.

Industry Structure

There were no significant changes in the structure of the phosphate industry

other than ownership changes in the United States.

Capacity

The estimates of phosphate rock production capacity as shown in the accompanying table were not significantly changed from those of 1988. With an excess of capacity, there was no incentive to increase capacity.

Reserves

The availability of phosphate resources to support domestic fertilizer production for the U.S. agricultural sector and export demand has been questioned for a number of years. Both pessimistic and optimistic estimates have been made by scientists and busi-

nessmen. It appears, however, that the differences between estimates, if made with integrity, were frequently caused by what was being estimated rather than how much was there. Differences may relate to potential availability or currently available phosphate rock. Differences may be found in areas treated, in price assumptions or mining and beneficiation technology, in the quality of phosphate rock for different purposes, in the geologic assurance of existence or measurement, in the data used for estimates, and finally, in the methodology of assessing the resource.

Difficulties in producing compatible phosphate rock resource estimates also occur because of imprecise and confusing technical language. To eliminate the confusion, a sedimentary phosphate

rock resource classification system was prepared to permit the differences to be analyzed. The principles of this classification system were presented in *U.S. Geological Survey Circular 831*, published in 1981 and prepared by the U.S. Geological Survey and the U.S. Bureau of Mines to facilitate the assessment of national phosphate rock resources. The criteria developed relate as much as possible to current industrial practice. Because industry practices vary from mine to mine, parameter limits will vary, and tradeoffs are possible. The criteria are guidelines that may be replaced for specific deposits.

As high-grade phosphate rock deposits are depleted, it is probable that technology will change to permit the mining and processing of lower quality phosphate rock. If favorable economics permit, this could change the classification criteria for the resource classes.

The classification system was based on the degree of geologic assurance and the feasibility of economic recovery. Phosphate rock resources were classified as identified or undiscovered. The varying degrees of geologic certainty were expressed as proved, probable, and possible. Resources can be classified according to their degree of economic feasibility. These include economic, marginally economic, and subeconomic resources.

Phosphate economic resources may be profitably extracted and produced under defined investment assumptions that are established or assumed with reasonable certainty. Phosphate reserves are that part of the demonstrated resource that can be profitably extracted or produced at the time of determination.

The phosphate reserve base is defined as that part of an identified phosphate resource that meets specified minimum physical and chemical criteria relating to current mining and production practices, including those for grade, quality, thickness, and depth. The reserve base is the in-place demonstrated resource from which reserves are estimated. It may include those parts of the resource that have a reasonable potential for becoming economically available within planning horizons beyond those that assume proven technology and current economics. Tables 28 and 29 show the United States and world phosphate reserves and reserve base estimates.

OUTLOOK

Mine production plans offer a reasonable guideline on what to expect from phosphate rock mines in future years. It is probably the most reliable method of forecasting future supply. However the industry responded to demand in 1989 and produced about 2 million tons more than was planned. Based on producer's plans, phosphate rock production estimates were 48, 48, 49, 53, 53, and 54 million tons in 1990, 1991, 1992, 1993, 1994, and 1995, respectively. It is probable that this supply scenario will be followed. During this period, some mines will deplete and close, others will be reactivated or remain closed.

In 1988, the Bureau of Mines contracted with Wharton Econometric Forecasting Associates to develop a model for projecting long-term and short-term demand for primary fertilizer nutrients and raw materials. The demand estimates were based on projected trends in world population, harvests of major crops, harvested area, and fertilizer application rates. The report concluded that North American phosphate rock demand will depend on North American phosphate rock production and demand for phosphates. Between 1975 and 1980, phosphate rock demand increased by 6% annually, reaching 38.4 million tons in 1980. However, since 1980, phosphate rock demand declined to 33.9 million tons, an average decline of 1.7% per year. Because North American phosphate fertilizer demand is projected to increase by 20% and world phosphate fertilizer demand is projected to increase by 16% through 1995, North American phosphate rock demand will increase to 41 million tons in 1995. Based on this supply-demand analysis, phosphate rock supply will exceed demand in 1995.

BACKGROUND

The United States phosphate rock industry entered the 1980 decade by producing a record 54.4 million metric tons in 1980, and the outlook for the decade was highly optimistic for the mining industry. The U.S. agriculture

sector drove the demand for phosphate fertilizers to feed an expanding world population. Farm land prices increased as more acreage was planted. Phosphate mining company representatives forecasted substantial new phosphate mining capacity to be developed in the southern extension of the Bone Valley Formation in central Florida.

At the end of 1980, President Carter embargoed grain shipments and phosphates to the U.S.S.R. to retaliate for the U.S.S.R.'s invasion of Afghanistan. By 1982, demand for farm products weakened, and demand for phosphate fertilizers declined substantially in the domestic and export markets. During the economic downturn in 1982, several phosphate rock mines were closed or operated at reduced levels. Annual phosphate rock production declined to 37.4 million tons. The industry began recovering in 1983 with the implementation of the Government's "payment-in-kind" program to attempt to reduce grain inventories and stimulate demand. In the eastern United States, unfavorable economic conditions, environmental concerns, and political attitudes virtually ensured that no new phosphate rock mines would be developed during the rest of the decade.

Although the phosphate mining industry increased production through 1985, the depressed state of the U.S. agriculture sector limited demand. The export market helped the industry survive; however, mines and plants were temporarily closed, some merged, and some closed to reduce inventories and bring about a supply-demand balance. The recession in the phosphate rock mining industry appeared to abate by 1985 when production reached 50.8 million tons. However, in 1986 the phosphate rock mining industry produced only 40.3 million tons as demand remained suppressed. Inventories were controlled by plant closings and reduced operating schedules. Employment declined as the industry attempted to minimize losses. Production stabilized as 41.0 million tons was produced in 1987. The demand for phosphate fertilizers improved in early 1988, but the drought of 1988 reduced phosphate fertilizer consumption. Production rose to 45.4 million tons. The recessionary decade of the 1980's ended for the phosphate rock mining industry in 1989

when 49.8 million tons was produced. Although some forecasters expected demand for phosphate fertilizers to exceed the 51 million tons consumed, production and consumption gains over those of 1988 were modified by continuation of the drought in some areas and excessive moisture in other areas. The export demand for manufactured fertilizers exceeded those of prior years, a windfall that was not expected to reoccur in 1990.

The phosphate rock mining industry

exported 7.8 million tons, imported 705,000 tons, and consumed an apparent 42.1 million tons. A summary of the industry's production plans indicated that it would produce 48 million tons in 1989 or about 4% less than the 49.8 million tons actually produced.

U.S. production of elemental phosphorus produced from electric furnaces reached 565 thousand tons in 1969 and has gradually declined since that time. By 1988, production had leveled off at

about 320 thousand tons per year. The drop in production was attributed to restrictions on the use of phosphate detergents in an attempt to reduce environmental damage to receiving waters. About 85% of U.S. elemental phosphorus production was converted into thermal or furnace-grade phosphoric acid. About 50% of the phosphoric acid was used to produce sodium tripolyphosphate, the detergent builder.

Several processes have been developed to purify wet process phosphoric acid to an acceptable level for some applications normally served by phosphoric acid produced by the thermal process. The purified wet-process phosphoric acid can be used in the production of high-purity products for industrial cleaning markets. Thermal acid will probably continue to be used in electronic applications. A shift to production of more purified phosphoric

acid appears probable in North America to reduce costs and minimize the impact on the environment.

Definitions

In Florida and North Carolina, the phosphate ore zone or bed is called the matrix. The industry practice in Florida, North Carolina, and Tennessee is to express production and reserves in terms of concentrated product. Chemical analysis of the product may be reported as percent P_2O_5 or tricalcium phosphate, $Ca_3(PO_4)_2$, also referred to as bone phosphate of lime (BPL).

The phosphate content or grade of phosphate rock is normally reported as percent P_2O_5 , determined by chemical analysis. It may also be expressed as percent BPL, reminiscent of the time when bones composed the principal source of phosphate in fertilizer manufacture (percent BPL = $2.1853 \times$ percent P_2O_5). It is the basis on which phosphate rock is sold, almost always as a beneficiated concentrate.

The chemical analysis of pebble, the plus 16-mesh washer product, and the 1 millimeter by 0.1 millimeter flotation concentrates, ranges from 25% to 34% P_2O_5 in Florida mines. Of interest is the percent P_2O_5 , or percent BPL, and the CaO , Fe_2O_3 , Al_2O_3 , and MgO content. For phosphoric acid and DAP phosphate manufacture, a phosphate rock product with a ratio of $Fe_2O_3 + Al_2O_3 + MgO$ to P_2O_5 less than 0.1 is preferred. This product specification can be achieved more easily from deposits in the Bone Valley Formation of central Florida than from deposits in the southern extension of the Bone Valley Formation in south-central Florida.

North Carolina phosphate rock concentrated by single anionic flotation analyzes about 28% P_2O_5 and contains some free silica, which is not particularly detrimental to phosphoric acid production. North Carolina phosphate rock, because of its high level of organic matter and other composition variations, is lower in grade than Florida rock. The organic matter may be burned off by calcining at 790° C to 820° C. Single flotation calcined rock of about 65% to 66% BPL (30% P_2O_5) is produced for captive phosphoric acid manufacture. It produces high-quality acid, but the capacity of the phosphoric acid plant may be reduced by lower filtering rates. Two-stage flotation cal-

cined rock analyzes about 72% BPL (33% P₂O₅) and is sold in the phosphate rock market or converted to clear phosphoric acid.

Phosphate ore mined in Tennessee was washed and classified to produce a sand sized product ranging from 0.044 to 6.35 millimeters. Washer feed ranges from 18% to 25% P₂O₅, and the sand-size product contains 23% to 32% P₂O₅. All of the sand-size product was agglomerated and blended with proportioned quantities of sized coke and quartz pebble before smelting in elec-

tric furnaces. The silica and calcium constituents combine to produce a fluid slag, the carbon oxidizes to carbon monoxide gas, and volatilized elemental phosphorus is conducted out of the furnace, condensed in cooling towers with water sprays, and collected under water. The slag and a ferrophosphorus byproduct are tapped periodically from the furnace.

Most Western U.S. phosphate ore was beneficiated by crushing, washing, classifying, and drying. Several mines also used a flotation circuit. The prod-

uct from the beneficiation plant was normally calcined to reduce the hydrocarbon content before shipment to a chemical plant. To meet the demands of fertilizer plants and electric furnaces, western phosphate rock is classified as + 31% P₂O₅ acid or fertilizer grade; 24% to 31% P₂O₅ furnace grade; 18% to 24% P₂O₅ beneficiation grade; and 10% to 18% P₂O₅ low-grade shale. Acid-grade rock was used directly in fertilizer plants, furnace-grade rock was charged to electric furnaces, beneficiation-grade rock was upgraded to acid grade or furnace feed, and low-grade shales were stockpiled for possible future use.

Products for Trade and Industry

Phosphate rock was the raw material used to manufacture phosphate fertilizer, animal feed supplements, and industrial chemicals.

Manufactured fertilizers, or commercial fertilizers, contained one or more essential plant nutrients and were differentiated from green cover crops, farm manure, and ashes that also qualify under the definition of fertilizer, i.e., to make farming more productive. The primary plant nutrients are nitrogen, phosphorus, and potassium. Unfortunately, the phosphate mineral is very insoluble and, therefore, a poor source of phosphorus for plants. For this reason, phosphate rock is treated with an excess of sulfuric acid to produce merchant-grade, wet-process phosphoric acid that contains 52% to 54% P₂O₅ after water evaporation. It is used to make the monoammonium phosphate and DAP fertilizers and liquid mixed fertilizers.

Furnace-grade phosphoric acid is produced by smelting phosphate rock with fine free coke and silica in an electric furnace. Elemental phosphorus offgas is collected underwater. It is burned and converted to a relatively pure phosphoric acid that is used principally in the detergent and food industries.

Superphosphoric acid is produced by concentrating merchant-grade acid to 68% or 72% P₂O₅. It contains polyphosphates rather than orthophosphates, has the advantage of higher solubility, and can dissolve more impurities when making liquid fertilizers.

Triple superphosphate is produced by treating phosphate rock with phosphoric acid. The product has 44% to 46% P₂O₅ and is manufactured in granular or pow-

dered form.

Normal or ordinary superphosphate was for many years the leading commercial fertilizer because of its ease of manufacture; pulverized phosphate rock was mixed with sulfuric acid and cured. The popularity of this fertilizer declined because of its relatively low, 18% to 20% P₂O₅, analysis.

Ammonium phosphate is made by treating phosphoric acid with ammonia. The most popular ammonium phosphate product contains 18% nitrogen and 46% P₂O₅ (18-46-O) and is commonly called DAP. Other ammonium phosphate product compositions are 16-48-O, 11-48-O, and 12-52-O.

Nitrophosphates are produced by reacting nitric acid with phosphate rock to produce a 14% to 22% nitrogen, 10% to 22% P₂O₅, fertilizer.

Phosphorus products used to supplement animal feeds include diammonium and monoammonium phosphates, monohydrate and anhydrous monocalcium phosphate, dihydrate and anhydrous dicalcium phosphate, tricalcium phosphate, phosphoric acid, a number of sodium phosphates, sodium tripolyphosphate, and trisodium phosphate.

Industry Structure

The principal phosphate rock-producing countries in the world in order of decreasing production were the United States, the U.S.S.R., Morocco, China,

Tunisia, Jordan, Brazil, and Israel. Thirty-four countries reported producing phosphate rock in 1989. World production was an estimated 162 million tons.

In the United States, phosphate rock was mined in Florida, Idaho, Montana, North Carolina, Tennessee, and Utah. In central Florida, 8 companies operated 14 mines that produced phosphate rock from the Bone Valley Formation. Agrico operated the Payne Creek and Fort Green Mines. CF Industries produced phosphate rock from its Hardee Complex Mine in Hardee County on a reduced operating schedule. Estech Inc. produced phosphate rock from its Silver City Mine and planned to produce in 1990 until the reserve was depleted. C&G Holdings own the Silver City Mine. Gardinier, operated its Fort Meade Mine in Polk County. Seminole purchased the assets of W. R. Grace & Co. in Florida and sold the company to Tosco Corp. in 1989. The company operated the Hookers Prairie Mine. Hopewell Land Partners Ltd. sold its mine to IMC. IMC will recover about 10 million tons of phosphate rock from its Hopewell Mine. IMC reopened its Four Corners Mine in central Florida and planned to pump matrix from its Lonesome deposit in southeast Hillsborough County to Four Corners in 1990. IMC closed the Haynsworth Mine, purchased the Hopewell Mine, and produced phosphate rock from Clear Springs, Kingsford, Noralyn/

Phosphoria, and Four Corners Mines. The Lonesome Mine beneficiation plant was idle during the year. Mobil reactivated the Nichols Mine in 1989 and planned to reopen the Big Four Mine in 1990 to coincide with closing the Fort Meade Mine. The South Fort Meade deposit was projected to start producing in 1995 after the Big Four Mine was depleted. USX Agri-Chemical Div. was purchased by Sinochem U.S.A. Inc., was renamed U.S. Agri-Chemical Corp., and continued to mine the Rockland Mine. Nucor did not operate the Wingate Creek Mine, and it was reported for sale. Occidental operated the Suwannee River and Swift Creek Mines in north Florida to produce superphosphoric acid for export to the U.S.S.R.

In its 1988 annual report, Elf Aquitaine published that Texasgulf produced 4.9 million tons of phosphate rock in that year. Texasgulf installed bucket-wheel excavators to strip overburden in 1989.

The remaining phosphate companies in Tennessee, Occidental Chemical Corp., Columbia, TN, and Rhône-Poulenc (formerly Stauffer Chemical Co.), Mt. Pleasant, TN, mined phosphate rock from Giles, Williamson, and Maury Counties. After sizing and agglomeration, the phosphate rock was smelted in electric furnaces to produce elemental phosphorus.

In Idaho, Rhône-Poulenc produced

phosphate rock from its Wooley Valley Mine for shipment to its electric furnace plant at Silver Bow, MT. Rhône-Poulenc is planning a purified wet-process plant at Geismar, LA, to increase its capacity of high-purity phosphoric acid. The Conda Partnership mined the Mountain Fuel and Maybie Canyon deposits. The phosphate rock was used in Nu West's fertilizer plant at Conda, ID. Monsanto mined phosphate rock from its Enoch Valley Mine and smelted the rock in its Soda Springs, ID, electric

furnaces. J. R. Simplot operated the Gay and Smoky Canyon Mines. A slurry pipeline from the Conda Mine to Conda, ID, will be extended to Pocatello to replace the railroad system. Reserves of the Gay Mine on the Fort Hall Indian Reservation will permit the mine to produce through 1994. Thereafter, production will be increased at Smoky Canyon to supply J. R. Simplot's fertilizer plant demand, and FMC Corp. will develop a new mine in Dry Valley to supply phosphate rock to its Pocatello, ID, electric furnaces.

Chevron produced phosphate rock concentrates from its Vernal, UT, mine. The concentrates were pumped to Rock Springs, WY, for conversion to phosphoric acid and DAP.

Cominco installed a new beneficiation and drying plant to process phosphate ore from its underground mine near Garrison, MT in 1988 and exported to Canada in 1989.

Tariffs and Taxes

Phosphate rock and phosphate fertilizers were imported duty free. The phosphate industry was subject to the usual local, State, and Federal taxes. In addition, a severance tax of \$1.35 per metric ton (\$1.49 per short ton) was applied in Florida in 1989; 2% of the net value in Idaho, and \$25 plus 0.5% of the gross value over \$5,000 in Montana was assessed. A history of the severance tax in Florida indicates the tax rose from \$0.102 per ton in 1971 to a peak of \$2.52 per ton in 1985. The Florida severance tax is currently based on \$1.35 per ton at point of severance, then was adjusted with the Producers Price Index to \$1.54 per ton in 1989.

Technology

Production of phosphate rock was similar in each of the 14 operating mines in Florida. The phosphorus-containing component in the matrix is apatite, a calcium phosphate containing varying amounts of carbonates and fluorides. The phosphate bearing matrix varies from 1.5 to 6.1 meters in thickness under an overburden of sand, clay, and a leach zone. The total overburden thickness, including the leach zone, ranges from 5.6 to 8.6 meters.

Mine planning was accomplished by taking core samples and processing the cores through bench-scale washing and flotation procedures, similar to those

of a commercial plant to determine recoveries, quality, and product grade. Stripping overburden and mining matrix was accomplished with electric walking draglines with 32-cubic-meter or larger buckets on 68 meter booms. Mining cuts, after overburden was progressively stripped, were 900 meters in length and 90-meters wide. Pumps were used to prevent the pits from flooding. The dragline fed matrix to a sump where water monitors operating at a pressure of 17 kilograms per square centimeter slurried the matrix. It was pumped in 900-meter stages in steel pipe to the washing plant.

Washing plants were designed to size the material pumped to them. Trommel screens were frequently used to scrub the phosphate from the sand and clay matrix and reject material over 19 millimeters. The trommel undersize was screened at 14 mesh. The 19 millimeter by 14-mesh material was further washed on screens and log washers to liberate the phosphate mineral. Minus 14 mesh material reported to cyclones. The separated cyclone overflow, minus 150-mesh colloidal material, was pumped to settling ponds. The flotation process was used to separate the sand from the phosphate mineral. The flotation feed was conditioned with fatty acids to create a hydrophobic surface, and the phosphate mineral was floated to produce a rougher

concentrate. The rougher concentrate was treated with sulphuric acid to strip the fatty acids. An amine flotation circuit was used to float carryover sand, and the phosphate mineral was depressed. Flotation concentrates were conveyed into silos for dewatering and loaded into railroad cars for export or a fertilizer plant. The beneficiation plants' products, pebble and concentrate, were used in Florida chemical fertilizer plants or barged to fertilizer plants on the Mississippi River.

Sulfur, either recovered or Frasch, was received from heated ships at Tampa terminals or receiving terminals on the Mississippi River. In Florida, liquid sulfur was pumped into road tankers that delivered molten sulfur to the chemical plants. The liquid sulfur was burned to produce sulfuric acid. The phosphate rock was digested in sulfuric acid to produce phosphoric acid and waste phosphogypsum. The phosphoric acid was passed through evaporators to increase the phosphorus pentoxide concentration to the commercial grade, 54% P_2O_5 . Phosphoric acid was reacted with anhydrous ammonia to produce DAP or reacted with phosphate rock concentrates to produce triple superphosphate.

Mining procedure was similar in North Carolina; however, the overburden was about 30 meters, considerably thicker. Hydraulic dredges were used to remove the top 12 meters of overburden. The dredges were replaced in 1989 with bucketwheel excavators. Draglines were used to strip the remaining overburden and mine approximately 12 meters of matrix. The matrix was beneficiated to produce a 67%-BPL product. Some of this product was calcined to remove organic compounds, carbon dioxide, and water and raise the grade to 72% BPL.

All phosphate rock in the Western States of Idaho and Utah was surface mined. There is an underground mine in Montana. Operators in southeastern Idaho principally used scrapers and bulldozers to remove overburden and mine the ore. Main bed ore for consumption in wet-process phosphoric acid plants and adjacent bedded furnace shale for electric furnace feed were mined selectively. In Utah, the phosphate rock was quarried after the limestone caprock was drilled, blasted, and trucked to waste. Underground ore in

^e Estimated. ^P Preliminary. ^r Revised.¹ Table includes data available through May 30, 1990. Data for major phosphate rock producing countries derived in part from the International Fertilizer Industry Association; other figures are from official country sources where available.² In addition to the countries listed, Belgium and Uganda may have produced small quantities of phosphate rock and Namibia may have produced small quantities of guano, but output is not officially reported, and available information is inadequate for formulation of reliable estimates of output levels.³ Reported figure.⁴ Less than 1/2 unit.⁵ Includes only output used to manufacture fertilizers.⁶ Production from Western Sahara area included with Morocco.⁷ Does not include aluminum phosphate production, gross weight, in thousand tons: 1985—355; 1986—131; 1987—191; 1988—119; and 1989—100 (estimated).

phoric acid. The technology was similar to that of Florida and Tennessee, although plant flowsheets were tailored to fit the characteristics of each deposit. Western phosphate rock used to produce phosphoric acid was calcined to reduce hydrocarbon levels. Phosphate rock, as mined or beneficiated, was agglomerated before charging electric furnaces to produce elemental phosphorus.

In Tennessee, 150,000- to 200,000-ton ore bodies were stripped of overburden and mined with small draglines. The small dragline bucket was able to

remove phosphate bearing ore between limestone crevices and cones (cutters) in the bedrock and light enough to be easily transported by low-boy from one deposit to the next selected for mining. Bulldozers were used to clear access roads to the deposit and remove topsoil and clay overburden. Trucks loaded by dragline moved ore to either a field washer, a railroad loading tippie, or a washer at the electric furnace plant.

Tennessee phosphate rock was beneficiated by washing through a 25-centimeter grizzly screen. The screen undersize was passed through a series of

log washers, scrubbers, screens, and cyclones to produce a 0.044- to 6.35- millimeter sand product. Washer feed ranged from 18% to 25% P₂O₅, and the sand concentrate analysis ranged from 23% to 32% P₂O₅. The sand concentrate was nodulized in rotary kilns to convert the sand to 1.9- to 5.1-centimeter nodules, which, after screening to remove oversize and undersize material, were charged to electric furnaces with fine free coke and quartz pebbles to produce elemental phosphorus.

¹ All quantities are in metric tons unless otherwise specified.

PLATINUM-GROUP METALS

By J. Roger Loebenstein

Mr. Loebenstein, a physical scientist with 15 years industry and Bureau of Mines experience, has been the commodity specialist for platinum-group metals for 9 years. Domestic survey data were prepared by Evangeline Hemphill, mineral data assistant. International data tables were prepared by Harold Willis, international data assistant.

The Republic of South Africa remained the leading producer of platinum and the U.S.S.R. remained the leading producer of palladium. In the future, most new production capacity for platinum-group metals (PGM) was expected to come from the Republic of South Africa.

Environmental legislation and concern over clean air continued to be a major factor driving PGM demand in the United States and Western Europe. With political changes sweeping Eastern Europe, it remains to be seen whether these countries will use catalytic converter technology to reduce automobile emissions. While the need is clear, the required capital to pay for clean air remains a problem.

LEGISLATION AND GOVERNMENT PROGRAMS

A bill authorizing the minting of a palladium commemorative coin was not approved by the House. The staff of the U.S. Mint testified that the coins would be difficult to produce. In addition, domestic sources of palladium are limited, and it is possible that some of the metal for the coin would have to come from sources originating in the U.S.S.R. or the Republic of South Africa.

The Administration's proposed Clean Air Bill called for decreasing the hydrocarbons limit for automobiles from the current 0.41 gram per mile to 0.24 gram per mile.

STRATEGIC CONSIDERATIONS

While domestic production of platinum and palladium from the Stillwater

Mine increased, domestic mine production was refined in Belgium and in 1989 accounted for only 3% of U.S. imports of refined platinum and 9% of U.S. imports of refined palladium. Even though the Federal Government stockpiled platinum, palladium, and iridium, there were no Government programs engaged directly in the development or exploitation of mineral deposits. Exploration, development, and mining were considered to be functions of the private sector.

Import dependence on the Republic of South Africa and the U.S.S.R. remained an area of concern for the United States. The threat of disruption from South Africa appeared more related to mining labor unrest than any other factor. A disruption in supplies from the U.S.S.R. appeared unlikely given improvement in relations with that country and the need of the U.S.S.R. to generate foreign currency.

The Department of Defense, which oversees the National Strategic Stockpile, recommended to Congress that the Government purchase 933 kilograms of rhodium and 2,022 kilograms of ruthenium for the Stockpile.¹ In 1988, an advisory panel of the American Society of Metals also recommended the purchase. Stockpile goals remained unchanged at 40,746 kilograms of platinum, 93,311 kilograms of palladium, and 3,048 kilograms of iridium.

PRODUCTION

The only PGM mine in the United States, southwest of Billings, MT, was operated by the Stillwater Mining Co. (SMC), owned 50% by Chevron Corp. and 50% by Manville Corp. Estimates from published sources showed that production of platinum at the Stillwater

Mine in 1989 was about 1,430 kilograms and production of palladium was about 4,850 kilograms. Small amounts of PGM were recovered as byproducts of domestic copper refining.

In 1989, SMC shipped its concentrates to Belgium for smelting and refining, but applied for permission to construct a \$6 million smelter to process its PGM concentrates. The company hoped to complete construction by the end of 1990. Final refining of the precious-metal matte probably would still be done in Belgium.

CONSUMPTION AND USES

Platinum, palladium, and rhodium were used in emission catalysts for light trucks (trucks weighing 14,000 pounds or less, gross weight) and automobiles. A typical emission catalyst in 1989 contained approximately 1.77 grams of platinum, 0.47 gram of palladium, and 0.2 gram of rhodium, for a total of 2.44 grams PGM. These average quantities have not changed since 1985. There was variation in the quantities of PGM contained in each catalyst for any given year, depending on the year the vehicle was manufactured, the engine size, the normal operating temperature of the vehicle's engine, and the manufacturer of the catalyst. In 1989, there were 10.6 million vehicles produced in the United States that were subject to emissions control and outfitted with catalytic converters, of which about one-third were light trucks.

In electronic applications, ruthenium was the principal PGM used in thick film resistors, and palladium was the principal PGM used in thick film conductors, multilayer ceramic capacitors, and connectors. Platinum "targets" were used for sputtering thin films on circuit boards. Platinum-rhodium alloys were

used for manufacturing thermocouples for precise temperature measurement.

For glass manufacturing applications, most of the PGM, specifically platinum, rhodium, and palladium, were used in bushings for the extrusion of textile or continuous filament glass fiber.

The nonautomotive catalyst applications of PGM were numerous. The petroleum refining industry used PGM, principally platinum, in reforming, cracking, and isomerization reactions. Chemical catalysts containing platinum

and rhodium were used in inorganic syntheses of nitric acid and hydrogen cyanide. Palladium was used in the production of hydrogen peroxide. A wide variety of organic chemicals and pharmaceuticals were produced using PGM catalysts.

The Bureau of Mines does not collect data on domestic investor demand for platinum, but according to Johnson Matthey PLC, projected investor demand for 1989 in North America was expected to be about 1,866 kilograms, down from 2,644 kilograms in the pre-

vious year.² A summary of the typical uses for each PGM is shown in tables 4 and 5.

STOCKS

In addition to the reported stocks held by refiners, importers, and dealers, end users of PGM held sizable quantities of PGM that were not reported to the Bureau of Mines.

⁴ Less than 1/2 unit.

PRICES

In March, two scientists from the University of Utah announced that they had fused deuterium nuclei at a relatively low temperature using a palladium cathode immersed in heavy water. The process was regarded by some as a potential breakthrough in the decades-long search for a way of generating electricity from controlled nuclear fusion. While results of the experiment were being evaluated by other scientists, news of the announcement produced a flurry of speculation in palladium and caused dealer prices to increase from \$135 per ounce in January to a high of \$166 per ounce in April. As speculation tapered off, prices declined to about \$137 per ounce by October.

The dealer price of rhodium began

Thermocouples		

increasing sharply in November and continued increasing in December, with spot prices approaching \$2,000 per ounce. The increase was attributed to the reported technical difficulties at Johnson Matthey's newly commissioned Rustenburg refinery in Bophuthatswana. Also contributing to the price rise was the absence of rhodium sales by the U.S.S.R., the second largest supplier of rhodium after the Republic of South Africa.

WORLD REVIEW

In July, the European Community (EC) voted to require that all member nations comply with automobile exhaust emissions limits, comparable to those in the United States, by January 1, 1993, for cars with engine displacements less than 1.4 liters. Until now, most automobile catalytic converters in the EC were on cars with engine displacements greater than 1.4 liters. Consequently, the major producers of cat-

alytic converters planned to expand capacity to meet the demand of what is potentially the world's largest automobile market. About 13 million new cars are sold per year in the EC. Plant expansions of autocatalyst facilities were anticipated in the Federal Republic of Germany, the Republic of Korea, Belgium, and France to meet the increased demand in Europe.³

According to the interim 1989 review on platinum published by Johnson Matthey, world investment demand for platinum decreased from 19,600 kilograms to only about 5,000 kilograms in 1989. Higher interest rates and less fear of a disruption in supply from South Africa contributed lower investor interest in platinum.

The International Precious Metals Institute (IPMI) of Allentown, PA sponsored a seminar on platinum-group metals January 29-31 in Las Vegas, NV. Presentations centered around the use of PGM in autocatalysts, industrial pollution control, fuel cells, jewelry, electronics, and health applications. Proceedings of the meeting are available for

purchase through IPMI.

Capacity

Capacity for PGM is generally cited in terms of platinum capacity. The data in table 12 represent rated capacity, defined as the maximum quantity that can be produced on a normally sustainable long-term operating rate, based on the physical equipment of the plant and routine operating procedures for labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that in the judgment of the author can be brought into production within a short period of time with minimum capital expenditure.

South Africa, Republic of

Barplats Mines (formerly Lefkochrysos Ltd.) produced 933 kilograms of platinum at the Crocodile River Mine. Barplats is controlled by Rand Mines. All of Barplats' production was from the UG-2 reef, rather than from the more easily processed Merensky reef.⁴ In the past, platinum producers have overcome the metallurgical problems of treating UG-2 ores by blending them with Merensky ores. It appears, however, that technical problems for treating pure UG-2 ores have been overcome.

Rustenburg Platinum Mines Ltd. decided not to develop the Maandagshoek platinum mine in the eastern Transvaal because of its inability to obtain tax concessions from the South African Government. The costs of developing the mine would have been too high without the tax concessions.

U.S.S.R.

The U.S.S.R. began marketing and selling a one-ounce palladium coin honoring Russian Ballet. The Ballerina palladium bullion coin is the world's first palladium bullion coin. Owing in part to the difficulties in minting, only about 30,000 coins were sold in 1989.⁵

Platinum-silicide was being investigated as a material that substitutes for cadmium-mercury-telluride in infrared detectors. Platinum-silicide performs better and is cheaper to produce than the traditional cadmium-mercury-telluride. Platinum-silicide detectors are made by depositing a layer of platinum only a few molecules thick over silicon integrated circuits. Infrared detectors made with platinum-silicide are used in military applications such as heat-seeking missiles.⁶

The Bureau of Mines investigated leaching PGM from scrapped automo-

bile catalysts using a solution of sodium cyanide. Recovery rates for platinum, palladium, and rhodium were over 90% and the process was environmentally safe. Work on the process to reduce recovery costs was progressing through 1990, at the Bureau's Reno Research Center.

OUTLOOK

World Supply of Platinum

The Republic of South Africa and the U.S.S.R. were the most important countries supplying platinum. Because of the planned opening of new mines and the expansion of existing ones, production of platinum in South Africa was projected to increase by one-third from about 83,000 kilograms in 1989 to about 111,000 kilograms by 1994.⁷ For the U.S.S.R., sales of platinum to market economy countries was

expected to decline because the Soviets are expected to boost their own consumption and/or increase sales to Eastern Europe, where platinum can be used to produce unleaded gasoline and reduce automobile emissions. Over the next 5 years, Canadian production of platinum should remain flat, while U.S. production could grow another 25% from expansion of the Stillwater Mine in Montana.

Jewelry demand for platinum in Japan should grow about 25% to 44,000 kilograms by 1994. Investment demand for platinum is probably the most volatile end use, subject to wide swings in either direction, depending on economic conditions, exchange rates, and interest rates.

World Demand for Platinum

Demand for platinum in automobile catalysts, particularly 3-way catalysts that use platinum and rhodium, was expected to be strong over the next 5

years.

In the United States, the number of cars and trucks outfitted with catalytic converters has remained between 10 million vehicles and 11 million vehicles from 1987 through 1989. While production of cars and trucks was expected to remain flat, overall consumption of platinum was expected to rise because of the greater amounts of platinum expected to be used in each catalytic converter. As mentioned earlier, the proposed Clean Air Bill called for reducing hydrocarbon and nitrogen oxide emissions. Another proposal being debated was extending the certification period for catalytic converters from 50,000 miles to 100,000 miles. All these measures, if enacted, would require about one-third more platinum per converter than currently used.

The decision of the Economic Community (EC) in 1989 to adopt emissions limits for cars with engines smaller than 1.4 liters will result in a large

increase in demand for platinum. By 1994, demand for platinum used in autocatalysts in the EC is expected to double from about 9,300 kilograms in 1989 to 18,000 kilograms.

Autocatalysts are currently required in Australia, Canada, Japan, South Korea, the United States and most of Western Europe. Other countries, such as Brazil, Mexico, and Taiwan were expected to begin requiring autocatalysts in the early 1990's. World demand for platinum in autocatalysts could increase from about 40,000 kilograms in 1989 to 56,000 kilograms in 1994.

BACKGROUND

Products for Trade and Industry

The basic commercial forms of PGM were sponge or powder, which may be converted to other forms such as bars, pastes or chemicals. The catalyst industry employs an extensive number of

chemical compounds containing PGM. A typical PGM catalyst may consist of a platinum-rhodium gauze woven from wire. The electronics industry purchases PGM pastes and the dental industry uses wire and a variety of alloys.

Industry Structure

In North America, PGM are recovered by a small number of scrap refiners, as shown in table 14. Other companies collect scrap materials such as catalysts and PGM bearing solutions and process them to increase the grade. These upgraded secondary materials are then sold to or treated on toll by refiners. For example, in addition to its refining operations, Mulit-Metco, Aniston, AL, produces a 90% PGM concentrate from scrapped autocatalysts, which in turn is refined by another company. World Resources Co., McLean, VA, collects electroplating solutions, upgrades them, and sells the concentrate to another refiner. Most companies specialize in refining or up-

grading a particular type of scrap, such as petroleum catalysts, autocatalysts, or electronic scrap.

Refiners often charge a consumer a fee to have scrap toll refined, but ownership of the scrapped catalyst remains with the consumer. A refiner replaces a wornout catalyst with a fresh catalyst and charges the consumer for the refining and fabrication costs. In some cases, refiners simply refine scrap and sell it to other companies to fabricate catalysts.

Geology—Resources

PGM deposits are associated with magmatic intrusions of mafic and ultramafic rocks. They also occur to a lesser extent in placer deposits. Layered deposits associated with stratiform complexes are the only ones mined principally for the PGM, with nickel, copper and cobalt sometimes produced as byproducts. These are found in the Bushveld Complex, Republic of South Africa, and the Stillwater Complex,

United States. In other PGM deposits, such as those found in the Sudbury Complex, Canada, and Noril'sk, U.S.S.R., the PGM are produced as byproducts of nickel and copper mining.⁸

In South Africa, it is interesting to note that base metals such as nickel and copper are important in generating revenues from the Merensky and Platreef ores. This is not the case at the Stillwater Mine in the United States, where platinum and palladium contribute nearly 100% of revenues.⁹

World reserves of PGM are about 56 million kilograms, with 89% contained in the Bushveld Complex, Republic of South Africa, and most of the remaining 11% located in the U.S.S.R., Canada, and the United States.

Technology

Assaying.—Fire assay techniques have long been used to determine the presence of precious metals. The use of

lead as a collector for fire assays is suitable for gold and silver, but not for the PGM. For the PGM, nickel sulfide or copper sulfide is the preferred collector. In addition to fire assays, PGM can be determined by chemical methods and instrumental methods such as X-ray fluorescence and spectrochemical methods.¹⁰

A list of independent PGM assayers is shown in table 15. The list is meant to be a sampling rather than a complete list of assayers.

Primary Processing.—The processing of PGM entails four general steps: mining, concentrating, smelting, and refining. After mining, platinum ore is crushed, ground, and concentrated by froth flotation. The concentrates are dried, roasted, and smelted to form a sulfide matte containing the PGM. The matte is treated in a refinery using solvent-extraction techniques to separate and purify the six PGM.

TABLE 12

PLATINUM ANNUAL MINE CAPACITY OF MAJOR PRODUCING COMPANIES, AS OF DECEMBER 31, 1989

(Kilograms)

	Capacity

Impala Platinum Holdings (Pty.) Ltd. ³	34,000
Western Platinum Ltd.	7,800
Barplats Mines	1,000
Total	86,800
World total (rounded)	93,300

¹ Jointly owned by Chevron Corp. and Manville Corp.² Owns Lebowa Platinum Ltd.³ Owns the Karee Mine and Messina Mine.

Recycling.—Because of their high value, PGM are routinely recovered from petroleum catalysts, chemical catalysts, automobile catalysts, glass fiber bushings, electronic scrap, laboratory equipment, dental materials, and jewelry. Johnson Matthey estimated that 4,510 kilograms of platinum and 2,333 kilograms of palladium were recovered from scrapped catalytic converters in North America in 1989. Small quantities of rhodium were also recovered.

Major collectors and refiners of autocatalysts are shown in table 16. In the United States, only Multi-Metco, the successor of Texas Gulf Corp., refined any substantial quantities of PGM. Multi-Metco's output required further processing by other companies to produce commercial grade metal. The other major refiners of scrapped automobile catalysts are in Canada, Belgium, and Japan.

Economic Factors

Prices.—A time series of historical prices for each of the six PGM and a brief discussion of factors influencing prices is given in a Bureau of Mines publication entitled "Nonferrous Metal Prices in the United States Through 1988."¹¹

Total ⁹	^r 246,988	^r 260,192	273,582	281,854	283,643

^c Estimated. ^p Preliminary. ^r Revised. W Withheld to avoid disclosing company proprietary data; excluded from "Total."

¹ Table includes data available through Apr. 25, 1990. Platinum-group metal production by the Federal Republic of Germany, Norway, and the United Kingdom is not included in this table because the production is derived wholly from imported metallurgical products and to include it would result in double counting.

² In addition to the countries listed, China, Indonesia, Papua New Guinea, and the Philippines are believed to produce platinum-group metals, and several other countries may also do so, but output is not reported quantitatively, and there is no reliable basis for the formulation of estimates of output levels. However, a part of this output not specifically reported by country is presumably included in this table credited to Japan. (See footnote 6).

³ Partial figure; excludes platinum-group metals recovered in other countries from nickel ore of Australian origin; however, a part of this output may be credited to Japan. (See footnote 6).

⁴ Reported figure.

⁵ Data are for years ending June 30 of that stated.

⁶ Japanese figures do not refer to Japanese mine production, but rather represent Japanese smelter-refinery recovery from ores originating in a number of countries; this output cannot be credited to the country of origin because of a lack of data. Countries producing and exporting such ores to Japan include (but are not necessarily limited to) Australia, Canada, Indonesia, Papua New Guinea, and the Philippines. Output from ores of Australian, Indonesian, Papua New Guinean, and Philippine origin are not duplicative, but output from Canadian material might duplicate a part of reported Canadian production.

⁷ Includes osmiridium produced in gold mines.

⁸ Estimates for the Stillwater Mine, from published sources.

⁹ Data may not add to totals shown because of independent rounding.

In the first quarter of 1990, the price of rhodium exceeded \$2,000 per ounce, a record high for this metal. In 1989, the average price of rhodium was only \$1,300. The immediate cause of the price rise was attributed to technical production difficulties at a newly commissioned refinery in the Republic of South Africa.

Futures contracts are traded on the New York Mercantile Exchange (NYMEX) and the Tokyo Commodity

Exchange for Industry (TOCOM), and to a lesser extent on the MidAmerica Exchange.¹² Futures contracts help consumers of platinum and palladium lock in prices and allow speculators an opportunity to make profits. By comparing the current price with the price for future delivery, one can surmise whether speculators expect prices to rise or fall.

Platinum and palladium futures contracts, specifying 99.9% metal content,

were traded on the NYMEX in units of 50 and 100 troy ounces, respectively. Table 8 shows the number of contracts traded, yearend, for 1986 through 1989.

Trading of platinum futures contracts on the TOCOM began in 1984. The contract unit was 500 grams, the quality specifications were 99.9%, and prices were quoted in Japanese yen per gram.

In London, physical prices of plati-

POTASH

By James P. Searls

Mr. Searls, a physical scientist, has been the commodity specialist for potash for 10 years. Domestic survey data were prepared by Carleen Militello, mineral data assistant; and international data were prepared by Giovanni P. Jacarepaqua, international data assistant.

U.S. potash production in terms of potassium oxide (K_2O) equivalent increased 5% relative to that of 1988, and apparent consumption declined 15%. Sales by U.S. producers increased 8% for the year. Average prices increased 5% over that of 1988 on the basis of K_2O equivalent, but there was a decline in the last 2 weeks of the year. Yearend stocks increased 24% from 1988 due to the increased production. U.S. net import reliance as a percentage of apparent consumption was 65%.

Canada provided an amount equal to 69% of domestic apparent consumption. U.S. exports increased 17%, with exports to Brazil, Japan, and Mexico showing the greatest improvement.

DOMESTIC DATA COVERAGE

The Bureau of Mines developed potash domestic data from voluntary semi-annual surveys of U.S. operations. Of

the 12 survey requests sent to operations, 11 responded, representing 98% of total production shown in table 1.

STRATEGIC CONSIDERATIONS

Strategic considerations concerning potash for the United States are relatively minor problems. Although the capacities of U.S. potash mines have not expanded to meet the expanding

U.S. demand for potash, large amounts of high-grade potash ore reserves are across the Canadian border in the Province of Saskatchewan. The United States has a long history of cooperation and friendship, even mutual investments, with Canada as indicated by the recent Free Trade Agreement between Canada and the United States. There is little to worry about concerning a potash cutoff by the Canadian producers. There are multiple pathways between the two countries that preclude the interdiction of trade by natural disaster or sabotage of railroad bridges or ports. The Canadian potash mine capacities were built with the expectation of sales to the U.S. market, especially in the Corn Belt. A cessation of trade with the United States would close at least 60% of the Canadian capacity until the offshore market for potash grew.

ISSUES

The Reilly-Wendover potash operation on the western end of the Bonneville Salt Flats came under question concerning the environmental impact of mining under the salt flats. The Carlsbad, NM, producers mine areas that oil and gas producers would like to drill on an exploratory basis. The potash producers are deeply concerned that the oil

and gas wells may leak natural gas into the potash mines. This would cause the potash mines to be declared "gassy" and would require major new investments in special equipment for gassy mines. This additional financial burden may cause potash producers to go out of business before the potash deposits are completely recovered. This would be a loss to the United States and would increase dependence on imported potash. The Carlsbad area would be severely impacted economically by the shutdowns and consequent loss of jobs.

PRODUCTION

Domestic potash production, in K₂O equivalents, increased 5% in 1989 compared with that of 1988. Of the total production for the year, 77% was standard, coarse, and granular muriate of potash, also known as potassium chloride, and 10% was sulfate of potash, also known as potassium sulfate. The remaining production included manure salts, soluble and chemical grades of muriate of potash, and sulfate of potash-magnesia, also known as potassium magnesium sulfate. The terms "standard," "coarse," and "granular" refer to the particle sizes of the finished product. "Standard," "coarse," and "granular" muriate of potash comprise

the "three muriates," a term that ignores the soluble and chemical grades of muriate of potash. "Sulfates" is a term for the addition of sulfate of potash data to sulfate of potash-magnesia data. "Manure salts" used to refer to high-grade "run-of-mine" ore; 25% K₂O ore is nearly 40% KCl which can be used on sugar beets. It now refers to a mixture of white muriate of potash and common table salt for industrial uses. The New Mexico potash producers accounted for 90% of the total marketable potash salts production. Production of crude salts in New Mexico was 14.2 million tons¹ with an average K₂O content of 13.9%. The producers were AMAX Potash Corp. of AMAX Inc., Eddy Potash Inc. of Trans-Resources Inc., International Minerals & Chemical Corp. of IMC Fertilizers Inc. (IMCF), Mississippi Chemical Corp., New Mexico Potash Corp. of Trans-Resources Inc., and Western Ag-Minerals Co. of Rayrock Resources Ltd. of Canada. All of the New Mexico producers, except Western Ag-Minerals, mined sylvinitic ore and beneficiated the ore into muriate of potash. Several beneficiation processes were used: The flotation of sylvite (potassium chloride) away from halite (sodium chloride) occurred at AMAX Potash, Eddy Potash, and Mississippi Chemical; the IMCF plant used heavy media separation, and New Mexico Potash used selective crystallization in their plant; Western Ag-Minerals and IMCF mined langbeinite ore and beneficiated the ore to sulfate of potash-magnesia. The IMCF personnel mined both types of ore and reacted fractions of each potash product to produce sulfate of potash.

One plant in Texas and one plant in Utah manufactured sulfate of potash. AMAX Potash operated the plant in Dumas, TX, and that production was reported in both the Bureau of Mines sulfate of potash mine production totals and the potash production totals shown in the tables. The Permian Chemical Corp. sulfate of potash plant in Odessa, TX, was closed for the year. The Climax Chemical Co. plant in Utah produced about 23,000 tons. This company's production was not included in either the Bureau of Mines sulfate of potash mine production totals or the total mine production of all types and grades of potash.

In Utah, Moab Salt Inc. produced muriate of potash for Texasgulf Chemical Co. from underground bedded deposits by solution mining and solar evaporation. The sylvinite salts from the solar ponds were beneficiated by flotation to separate the sylvite from the halite. Climax Chemical converted some of Moab Salt's potassium chloride to potassium sulfate for sale by Texasgulf. Great Salt Lake Minerals & Chemicals Corp. began production of sulfate of potash by solar evaporation and conversion from kainite. The Reilly-Wendover operation of Reilly Industries Inc. plant produced muriate of potash and manure salts by solar evaporation and flotation from near-surface brines at the west end of the Bonneville Salt Flats.

In California, Kerr-McGee Chemical Corp. continued to produce both muriate and sulfate of potash along with other products by selective crystallization from the underground brines of Searles Lake.

Near Hersey, MI, Kalium Chemical Ltd. of Sullivan and Proops Inc. commenced potash production by solution mining of an ore body, which was about 2,400 meters deep. Only minor amounts of muriate of potash were produced on a pilot plant scale.

Greensand, also known as glauconite, a natural silicate of potassium, aluminum, iron, and magnesium, was produced by Inversand Co., a subsidiary of Hungerford and Terry Inc., near Clayton, NJ. Contractors Sand & Gravel Co. near Middletown, DE, ceased production of greensand at the end of 1988. Production and sales information are withheld to avoid disclosing company proprietary data. Processed greensand continued to be sold as a filter media for the removal of manganese, iron, and hydrogen sulfide from drinking water supply systems. Classified raw greensand was resold by Zook and Ranck Inc. as a soil conditioner and as a source of slowly released potash, with a K₂O equivalent between 5% and 10%, to the organic farmers of North America.

CONSUMPTION AND USES

Apparent domestic consumption of all forms of potash in 1989 decreased

15% compared with that of 1988. This is an extremely difficult decrease to understand when compared to the Potash & Phosphate Institute's (PPI) report of a slight increase in potash consumption. The problem appears to be with the Bureau of Census' import data, which show a 19% decrease while PPI import data concerning Canada shows a 1% increase. Part of the answer may be in the amount of potash in warehouses not owned by potash producers over the winter of 1988-89. There may have been a problem with importers not listing the imported potash under the new Harmonized Code categories. If the Potash & Phosphate Institute aggregate imports figures were used, the apparent consumption of the United States would be 5.27 million metric tons or essentially level with last year.

According to the Potash & Phosphate Institute, the consumption of agricultural potash from Canadian and United States potash producers rose 3% from 1988 to 1989. The major States for consumption of agricultural potash from Canadian and United States potash producers, in decreasing order, were Illinois, Iowa, Ohio, Minnesota, Indiana, Missouri, and Wisconsin. These seven States consumed 59% of the total from Canadian and United States producers. Domestic producers provided 10% of Illinois' potash consumption, 8% of Iowa's consumption, 4% of Ohio's consumption, 2%

of Minnesota's consumption, 9% of Indiana's consumption, 59% of Missouri's consumption, and 1% of Wisconsin's consumption. The major agricultural consumers of domestically produced potash, in decreasing order, were Missouri, Texas, California, Illinois, Florida, and Arkansas. These six States accounted for 59% of the total. The major consumers of the domestically produced sulfates of potash, in decreasing order, were Florida, California, Georgia, Texas, North Carolina, Ohio, and Kentucky. These six States accounted for 65% of the total.

STOCKS

Yearend producers' stocks of potash increased 24% from that of 1988. Yearend stocks represented 19% of annual production or 10 weeks of average production.

PRICES

The average annual price, f.o.b. mine, of U.S. potash sales of all types and grades was up 5% compared with that of 1988 to \$176.74 per ton. The average price was \$181.36 per ton for the first one-half of the year and \$171.56 per ton for the second one-half of the year. The average annual price of

the three grades of muriate increased to \$137.05 per ton. Standard-grade muriate of potash averaged \$126.66 per ton, coarse-grade averaged \$141.91 per ton, and granular-grade averaged \$143.67 per ton. The average annual price for all grades of sulfate of potash averaged \$321.90 per ton.

The effect of the price agreement between the U.S. Department of Commerce and the Canadian potash producers in January 1988, can be seen in perspective in figure 1.

FOREIGN TRADE

Total U.S. potash exports as reported by the Bureau of the Census increased 17%, by ton K₂O. The major destinations of potash exports were to Latin America, which received 67%, by product tonnage, of the total exports. The individual countries were, in decreasing order, Brazil, Mexico, Colombia, Costa Rica, Dominican Republic, Peru, and Chile: These seven countries accounted for 89% of the exports to Latin America. Three countries represented 89% of the non-Latin American market: In decreasing order, these were Japan, China, and Canada. Exports of sulfate of potash declined 14% from that of 1988 and represented 18% of U.S. potash exports. For the nearly 13,000 tons decrease in sulfate of potash exports there was an increase of more than 20,000 tons (45%) of sulfate of potash-magnesia exports.

Potash imports for consumption as reported by the Bureau of the Census declined 19% by ton product. Muriate of potash imports declined 19%, and only Jordan showed an increase from those of 1988. Canada provided 91% of all potash imports by K₂O content but declined 18% from those of 1988. Canada provided 92% of all muriate of potash imports. Israel was the second largest source of imports with 5% of muriate of potash imports and 5%, by K₂O content, of total potash imports. Imports of potash from the U.S.S.R. declined 68% from those of 1988.

The PPI reported decrease of imports from offshore sources of 44%. Canada increased exports of potash to the United States by 1% for an aggregate decrease of 4% of potash imports.

¹ Average prices, f.o.b. mine, based on sales.² Excluding soluble and chemical muriates.**WORLD REVIEW**

World production decreased 7% below that of 1988. World prices, as exemplified by the per-ton price of standard muriate of potash, f.o.b. Vancouver, Canada, rose from approximately \$152 (about \$91 per ton product) in October 1988, to approximately \$165 (about \$99 per ton product) in January 1989, and stayed at that level until August. The price declined to approximately \$162 (about \$97 per ton product) by October. These prices were reported by British Sulphur Corp. Ltd. These prices reflect, in the first one-half of the year, the rising of the international price to meet the domestic price. After August, the less-than-expected spring and fall sales in the United States and the continued production by all of the North American producers lifted North American stocks to a level high enough to permit international market prices to decline. In the last 2 weeks of December, there was price cutting in the domestic market but this did not affect the international price.

Industry Structure

The two largest potash producing countries in the world are the U.S.S.R. and Canada with 10.5 million tons and 7.458 million tons of production, respectively. These two countries produce about 62% of the world total. The potash produced in the Soviet Union was delivered primarily to their domestic farms and eastern European neighbors leaving approximately 3.5 million tons for export. The Canadians sold only 315,000 tons domestically and sold about 6.8 million on the world market. As a result, Canada is the world leader and price setter in potash. Canada is also the swing producer, responsible for keeping stocks of finished product below a level that would lead to the lowering of potash price. The world price benchmark is set between Canada and a combination of China, India, and Japan. World prices are typically quoted in reference to standard product, f.o.b. Vancouver, British Columbia, the port from which most of Canada's potash is exported. The U.S.S.R. has sometimes sold potash at prices that are lower than the Canadian prices because the U.S.S.R. product quality has not always been up

TABLE 8

² Includes chemical and soluble muriates, manure salts, potassium magnesium sulfate, and before 1971, potassium sulfate.

³ Prior to 1971, potassium sulfate was included with "Other."

to international standards. The U.S.S.R. is the world's largest potash-consuming area. Outside of the U.S.S.R., the largest potash-consuming area is the corn-soybean belt in the Middle West. Illinois, Indiana, and Iowa consumed more potash than China in 1989.

Brazil

Petrobras Mineração S.A. expressed optimism concerning the ultimate viability of the Tarquari-Vassouras Mine by purchasing four continuous miners.² There is a report that the Rosario Mine has started trial production.³

Canada

Potash Corporation of Saskatchewan commenced a program to take the sales arm of the company private, with stock and bonds to be sold on the open market. Potash Company of America's new operation reopened in May. The new methodology involves solution mining and cold crystallization of pot-

ash in a pond from September to May. The Dead Sea Works of Israel entered into negotiations to purchase the 40% portion of Allan Mine in Saskatchewan. This portion is presently owned by Saskterra Fertilizer Ltd. of Canterra Energy.

Chile

Sociedad Chilena de Litio Ltda. commenced production of muriate of potash in its Salar de Atacama ponds in 1988.⁴ Because this product was sold to Sociedad Química y Minera de Chile (SOQUIMICH) for inclusion into SOQUIMICH's KNO₃ product, it is not clear whether there was double counting in Chile's total production figures.

China

The 120,000-ton-per-year First Phase of the Qinghai Fertilizer Factory commenced operation in the middle of the year.

Egypt

The BHP-Utah International Inc. firm signed an agreement with the Egyptian Geological Survey and Mining Authority to investigate a potash occurrence in Egypt.⁵

France

The potash workers held a strike for assurance of employment until the year 2004, the expected year of potash ore depletion for the Alsatian potash mines. Late in the year, the Government commenced public dialogue concerning rationalization of the French chemical industry, including the fertilizer industry. Enterprise Minière et Chimique, the sole potash producer in France, may be folded into Société Nationale Elf Aquitaine.

German Democratic Republic

During late winter, a mine collapse in the Ernst Thaelmann Mine of the Kalibetrieb Werra halted production at

that site.⁶ The shock waves also caused damage at the nearby Wilhelm Pieck Mine.

Israel

Dead Sea Works Ltd. (DSW) officials announced the discovery of a solid potash ore body, called Har Sdom, which was being investigated for underground mining.⁷ In the middle of the year, the Government of Israel announced plans to sell over 50% of the stock of the DSW. At the end of the year, the Knesset expressed hesitancy about losing control of the DSW.

Jordan

Modifications over the past 6 years to the Arab Potash Co. solar ponds and refinery have raised the capacity of the operation to 810,000 tons per year.⁸

Thailand

The Association of Southeast Asian Nations (ASEAN) Committee on In-

dustry, Minerals and Energy accepted the development of the Bamnet Narong resource as a project.⁹ The project cost was placed at \$300 million, but the finished product capacity has not been set. The Government of Thailand will finance 20% and the ASEAN organization will finance 40% of the project. The last 40% will be open to regional private industry. Kali und Salz AG of the Federal Republic of Germany will provide engineering.

U.S.S.R.

An agreement in principal has been reached with Minerals and Metals Trading Corp. of India whereby India would develop the Port of Muriupol on the Azov Sea,¹⁰ which connects to the Black Sea. The U.S.S.R. will ship 600,000 tons of potash per year for an unannounced period of time to pay for this development. This would be 60% of India's 1988 imports of potash.

OUTLOOK

United States Demand

The Bureau of Mines funded a study of the fertilizer market by The Wharton Econometric Forecasting Associates (WEFA) Group in 1988. Their model forecasted an increase in grain exports that resulted in a 2.6% increase in potash consumption out to 1995, at which time, the consumption would be 5.7 million tons K₂O.

For this Minerals Yearbook, the Bureau of Mines funded a macroeconomic forecast by DRI Inc. of some general macroeconomic series. By regressing the Bureau of Mines potash apparent consumption time series on several of these general macroeconomic series, a simple model was found with an R² = .74. The three series used were "food exports," "grain mill production," and "textile mill production." Using forecasts for 1995 of these three

series, a very optimistic forecast for 1995 was derived, however, it is not likely to be achieved. Historical data do not strongly support growth. Figure 2 shows the historical data since 1962, including the cusp in 1980.

World Demand

The WEFA Group model forecasts a

growth rate of 2% out to 1995 reaching a consumption rate of 30 million tons per year. The data in figure 3 portray a production history that was constant in growth up to 1975 and started to waiver, although the trend has continued upwards. The problem of the relationship between production and consumption is appreciated, but these are

in sedimentary-type areas. The original Stassfurt, German Democratic Republic, mines were discovered while digging a shaft for salt. The mines in New Brunswick, Canada, and Solikamsk, U.S.S.R., were found during searches for salt. The mines of the United States, Saskatchewan, Canada, and France were discovered during searches for oil wells. Potash has been found as a mineral outcropping only in the

Cisrarpethian area of the Western Ukraine.

Access.—Shaft sinking to allow worker-access to the ore zone is a relatively highly developed procedure that is done by specialists. The Canadian Elk Point Basin potash ore zone lies under a high-pressure aquifer that endangered any attempt to penetrate to the potash zone below. To successfully

sink a shaft in this area the water zone was frozen from above, and the shaft was dug through the frozen section. The shaft sinkers installed large cast-iron sections that bolted together to form a water-tight cylinder extending from above to below the frozen water zone. The top and bottom of this cylinder were sealed to the non-water-bearing country rock by driving wooden wedges between the cast-iron sections and the rock. These cast-iron sections are so precise that a constant temperature must be maintained in the shaft to prevent expansion and contraction, which might allow leaks to start. Shaft sinking through the Blairmore Aquifer in Canada is so expensive that only two shafts are sunk per mine. In most other potash mine shafts, the water problems were solved with grouting.

Carlsbad, NM, mine owners have had to add shafts to their mines because the mining faces have advanced miles away from the original shafts. The cost of moving workers to the mining face and back to the original shaft during an 8-hour shift becomes too high. It saves wages and produces more tons of ore per worker-shift to sink a shaft near the working face and quickly bring the miners to the face. The potash ore in these mines continues to travel to the original hoist shaft to be available to the refinery or mill. Mines may have as much as 20 miles of conveyor belts underground in both permanent (main line) and temporary (panel) placements. The Bergmans-segen-Hugo Mine in the Federal Republic of Germany uses a large spiral incline for personnel and equipment access by motor vehicle.

Mining.—Underground potash mining in the Carlsbad, NM, region and in Saskatchewan, Canada, is relatively clean and straightforward. The evaporite beds are regular, tabular, and essentially untitled. The Carlsbad beds are typically no deeper than 300 meters and are mined using classic room-and-pillar techniques. The room-and-pillar method of mining has been used extensively in the United States and the U.S.S.R. This method can be imagined by “looking down” on the ore zone from above and dividing the area to be mined into a checkerboard. Then, imagine mining out a large L-shaped portion of each square, leaving a square pillar at the same (for example, lower left-hand) corner of each square. The size of the square imagined for any ore and the relative size ratio of the pillar to the original square are determined by

FIGURE 4

NORMAL POTASH MINING, UNDERGROUND MINING WITH FLOTATION

the ore zone depth and rock mechanics, especially the mechanical strength and integrity of the layer just above the ore zone. The relatively shallow depth of Carlsbad potash means that the lithostatic pressure allows safe mining with a recovery rate of about 75%. Continuous miners are commonly used, sometimes connected directly to the conveyor belt and sometimes loading to a pair of shuttle cars that transport the ore to the conveyor belt. The Carlsbad mines that produce potassium magnesium sulfate have to use blasting agents to loosen the ore because the ore is too hard for mining machines. The potash mines in Saskatchewan, Canada, are much deeper, operating at between 975 and 1,040 meters. Lithostatic pressure on a potash ore zone is critical at this depth. Underground recovery is reduced to 35% to 45%, and, in some mines, the miners have to cut panels that collapse to protect the miners in other panels. One technique is to mine five parallel, 18-foot-wide panels each separated by about 20 feet of pillar. The outside panels collapse taking the stress off the inner three panels. The inner three panels are then used for conveying potash ore away from the face, access for workers and equipment, and bringing fresh air to and from the workings. Several of the mines that use multiple panels have collapsible, wheeled conveyor belts connecting between the boring machines and the head of the semipermanent conveyor belt leading to the hoist. The parallel panels are laterally connected by angled cuts that resemble "turkey tracks." These groups of parallel panels, called faces, are about 45 meters wide and leave a pillar that is about 45 meters between each face. The Boulby Mine in England is of the same depth and has adopted this five-panel entry pattern to permit mining at such depth. Miners in Saskatchewan, working at a location that is not quite as deep, found that they could mine panels that were 40 feet wide with safety. This mine has an extremely thick cover (back) of salt that provides more structural integrity at this panel width. Mine practice is a single panel that may extend a mile at 90° to the main passageway. Recovery is about 45% under these conditions.

The northern (Lower Saxony) potash beds of the Federal Republic of Germany are extremely folded, even vertical, because the deposits have been deformed by tectonics and the upflow

of the underlying salt formations into salt domes. Open sublevel stoping is the mining technology in large rooms. A stope panel is 200 meters high and several hundred meters long and wide. Funnel-shaped draw holes are excavated at the bottom of the panel for loading railcars below. Then blocks of ore are broken by blasting agents from the bottom of the stope to the top. The broken ore falls to the funnels and into cars for haulage to the skip. One of the benefits of this mining system is that mill tailings are returned to the mine instead of going to surface tailings piles. The French mines dip from west to east up to 25° and become hotter, approaching 135° F, at their eastern edge.¹¹ For this extreme heat, the owner has installed 700 kilowatts of air-conditioning capacity underground. The mining depth varies between about 460 meters and 1,070 meters. The French mines have converted to longwall mining for the highest recovery factor underground. They have driven roadways out to the extreme edges of their ore zones, installed continuous mining equipment, and are retreating to the shafts. The longwall miners are connected by several flexible chain conveyors to the mine's main conveyor belts, which lead to the ore shaft.

An important consideration in potash mines is the gassiness of the ore zone. The Boulby Mine in England and both mines in France are considered gassy mines. None of the mines in Carlsbad, NM, are considered gassy, according to 45 years of sampling records; nor are any of the mines in Canada. However, the Cane Creek Mine near Moab, UT, was abandoned as an underground mine due to a methane gas explosion.

Other technologies used in North America involve beneficiating naturally occurring brines or solution mining. Each site has its slight variations. The oldest potash-from-the-ground site in the United States is the Searles Lake site in southern California. Near-surface brines are pumped into a plant for mechanical crystallizing of potassium chloride, potassium sulfate, and boron. At Wendover, UT, near-surface brines are gathered in shallow trenches and pumped to solar ponds for crystallization by evaporation. One pond at a time is dewatered, and crystals of the resulting sylvinites are scraped from the

pond floor and taken to a flotation plant for beneficiation to potassium chloride. The site on the north arm of Great Salt Lake takes brine solely from the north arm of the lake and runs the brine through many solar ponds. The potash ore kainite is crystallized by solar energy in these ponds. One pond at a time is dewatered, and kainite is scraped from the floor of the pond and transported to the plant which converts the kainite to potassium sulfate. The potash mine outside of Moab, UT, was once an underground mine but proved too gassy and undulating. The mine was converted to a solution mine by sealing the shafts and drilling wells to both uphill and downhill locations on the side of a syncline. Fresh water is pumped underground updip of the lowest point mined. Brine pumped from the lowest point of the mine is passed to solar ponds for crystallization by solar evaporation. One pond at a time is dewatered, and the sylvinites are scraped out of the pond and transferred to the original flotation plant for beneficiation to potassium chloride. The solution mine near Belle Plaine, Saskatchewan, mines ore which is about 5,000 feet deep. Concentric pipes move brine down a single well to a cavity in the ore and return a saturated brine to the plant for crystallization using natural gas. The process is repeated in the many wells in this operation. This plant is able to separate the halite from the sylvite in the evaporators and does not have to use flotation to beneficiate the potassium chloride. The two firms using the waters from the Dead Sea in the Middle East use solar evaporation to crystallize the potash ore out of the brine. The water chemistry is such that a combination of carnallite and halite are harvested by the floating dredges.

A new process is rumored to have started in northern Mexico. The Cerro Prieto geothermal generating plant uses hot brines from geothermal wells to generate electricity. As the brines lose their heat to the power process, salts crystallize out. The process was designed to crystallize potassium chloride to a reasonably pure product. No information is available on the annual production at this time.

The newest process in North America is used in the recently flooded PCA Mine and the Kalium Mine in Saskatchewan, Canada. The ore zone is solution mined, but instead of using solar evap-

oration or heat-driven evaporators and crystallizers as other solution and brine operations do, potash is produced during the fall, winter, and spring from a large, outdoor pond by cooling the brine to near freezing temperatures. After the pure sylvite crystallizes at the bottom of the pond, it is collected by dredging. The mill is used only to dry and compact the crystals to several commercial sizes. This technology is also proposed in the Karlyuk Mine site in Turkmen S.S.R. where the first pilot plant of this process was operated in the mid-1980's.

Beneficiation.—Most sylvinite ores in the United States and elsewhere are beneficiated by froth flotation, after comminution to release the sylvite and halite particles from their agglomeration. The sylvite is floated from the halite in an aqueous solution that is saturated with both sodium and potassium chloride. Pulp densities are 20% to 35% solids. Common collectors are hydrochloride and acetate salts of aliphatic amines with a carbon chain length of 12 to 24. Frothers such as cresylic acid, pine oil, or alcohols are added before the slurry enters the flotation cell. The central point to this technology is to add a chemical to the slurry (pulp) of sylvite and halite that selectively attaches to both sylvite and air. By bubbling air through the slurry the chemical attaches to the rising air bubble and pulls the particle of sylvite to the surface. The froth of air bubbles containing potash on the surface is swept off the cell and passed on to the rest of the plant while the halite is drawn off the bottom of the cell. All the plants in Canada use froth flotation except for the two solution mines. Froth flotation is used exclusively in England and Spain. Plants in the U.S.S.R. using froth flotation are Beloruskaliy's Soligorsk 1, 2, and 3, and the Uralkaliy's Berezniiki 2 and 3. Froth flotation is used in less than one-half of the plants of the Federal Republic of Germany. Froth flotation is used in one plant, Theodore, in France and in the newest plant, Zielitz, in the German Democratic Republic.

The other technologies used in beneficiation are heavy media separation, electrostatic separation, leaching, and dissolution-recrystallization. Heavy media separation is used exclusively by one

company that operates potash mines in Carlsbad, NM, and Esterhazy, Saskatchewan. This technology uses a taconite solution to separate the sylvite, langbeinite, and halite by slight differences in density. Electrostatic separation is used in over one-half of the mills in the Federal Republic of Germany to separate the complex salts that are recovered from some of their mines. These ores contain sylvite, halite, carnallite, and kainite and are not well suited to aqueous separation. Leaching is used in Israel and Jordan to remove the magnesium chloride of the carnallite from the sylvite. There are hot leach and cold leach processes. The Israeli plant uses froth flotation, hot leach, and cold leach processes. Dissolution-recrystallization is much like solution mining except that the ore is conventionally mined and is brought to the surface as a solid. On entering the mill, the ore is dissolved in a hot NaCl saturated brine, which preferably dissolves potash and leaves the insolubles and the halite behind in the ore. Sylvite solubility in water doubles between 20° C and 80° C while halite solubility decreases slightly. As the water cools, only potassium chloride tends to crystallize out. Both French mills use this technology. Beneficiation by this technique is used in the Uralkaliy Combine in Soligorsk 1 and Berezniiki 1. It is used in one Carlsbad, NM, mill because the ore has 7% clay, and is also the method used by the PCA plant in Saskatchewan, Canada.

Physical Processing.—Once the sylvite is reasonably pure (95% or higher) the producer turns his attention to the final particle size. Many countries in the world have the tradition of hand-casting the potash onto the fields. They are happy with the particle size that emerges from the flotation cells. The United States, Canada, much of Europe, and other countries have developed technologies of spreading the potash over great acreages that could not be covered by one person walking and spreading the fertilizer by hand. These technologies require that the particles of potash be larger than is normally recovered from the ore. Part of the requirement is that the potash particle match the particle size of diammonium phosphate (DAP) or mono-ammonium phosphate (MAP) granules. Potash and

DAP are often mixed together to make a complete fertilizer application. If the two products were not the same size (and were mixed together in a fertilizer spreader), the smaller sized material would be segregated at the bottom of the spreader. During spreading, the material at the bottom of the spreader (the small sized material) would be applied primarily to the first part of the field and the larger material would be applied to the latter part of the field. Neither part of the field would receive a balanced application. The solution to this problem is to "compact" the fine potash between two rollers under high pressure to form a board of potash. This board is broken up with larger particles of potash coming out of the process. These larger particles are the desirable sizes, coarse and granular, that match the DAP and MAP particle sizes.

PUMICE AND PUMICITE

By Wallace P. Bolen

Mr. Bolen, a physical scientist, is a graduate of the University of Virginia and has been the acting commodity specialist for pumice and pumicite since September 1989. Domestic survey data were prepared by Blanche S. Hughes, mineral data assistant, and the international production table was prepared by Virginia Woodson, international minerals data assistant.

Domestic production of pumice and pumicite sold or used increased about 20% compared with that of 1988. Apparent consumption increased about 8%. Greece was the principal source of pumice imports with 71% of total imports compared to 86% in 1988.

DOMESTIC DATA COVERAGE

Domestic production data for pumice and pumicite were developed by the Bureau of Mines from one voluntary survey of U.S. operations. All 19 operations that received a survey form responded. Fourteen active operations contributed 100% of the quantity and value of sold and used pumice and pumicite as shown in table 1.

Large changes in production, unit value, and markets for pumice and pumicite were attributed to improved data collection rather than an indication of drastic changes in value or markets for this commodity.

PRODUCTION

Production of pumice and pumicite sold or used increased to 424,000 metric tons with a value of \$8.2 million. The States of Oregon, California, New Mexico, and Idaho, in order of decreasing production, accounted for nearly all of the pumice sold or used in the United States.

Principal domestic producers were Glass Mountain Pumice Inc., Siskiyou Co., CA; Hess Pumice Products, Malad City, ID; Producers Pumice, Meridan, ID; Copar Pumice Co. Inc., Santa Fe, NM; General Pumice Corp., Santa Fe,

NM; Utility Block Co., Albuquerque, NM; Cascade Pumice Co., Bend, OR; and Central Oregon Pumice Co., Bend, OR. These eight companies accounted for 94% of U.S. pumice and pumicite production.

CONSUMPTION AND USES

The most important market for pumice was building block, consuming 73% of the total. Compared to the marketing pattern in 1988, abrasive uses increased

12%, while landscaping uses of pumice decreased 68%. Other and unspecified uses of pumice and pumicite increased to over 60,000 tons.

QUARTZ CRYSTAL

By Joyce A. Ober

Mrs. Ober, a physical scientist with 12 years industry and Bureau of Mines experience, has been the commodity specialist for quartz crystal since 1986. Domestic survey data were prepared by Maureen Nash, mineral data assistant.

Cultured quartz crystal production and consumption increased in 1989 for the third consecutive year, and consumption of domestic lascas as feedstock for cultured quartz crystal increased also. The single domestic producer of lascas, the raw material from which cultured quartz crystal is produced, operated its mine to supply material to consumers. Demand for specimen-quality natural quartz continued; quartz crystal for this application is discussed in the Gem Stones chapter.

Electronic-grade quartz crystal is single-crystal silica that is free from all visible defects and has piezoelectric properties that permit its use in electronic circuits for accurate frequency control, timing, and filtration. These uses generate practically all the demand for electronic-grade quartz crystal.

Natural electronic-grade quartz crystal was the leading form of quartz until 1971 when cultured quartz crystal took the lead. Cultured (synthetic) quartz has replaced natural crystal in practically all applications. In 1989, synthetic quartz crystal producers consumed about 570,000 kilograms of lascas in their production and less than 500 kilograms of natural quartz crystal found application in electronic devices.

DOMESTIC DATA COVERAGE

The Bureau of Mines collected domestic production and consumption data for quartz crystal through a voluntary survey of U.S. operations. Seven companies responded to the canvass for the production of cultured quartz crystal, and the six active operations represented 100% of total production shown in table 1. Of the 34 operations canvassed concerning consumption of quartz crystal, 32 re-

sponded, 7 of which did not consume quartz crystal in 1989. These companies represented nearly 100% of total consumption, also shown in table 1. Consumption for the nonrespondents was estimated using reported prior-year consumption levels.

The metric system is the official system of measurement of most countries. The Bureau of Mines, in an effort to provide statistical data on quartz crystal that are consistent with international usage, will henceforth report data in kilo-

grams and metric tons unless otherwise noted.

LEGISLATION AND GOVERNMENT PROGRAMS

The National Defense Stockpile contained about 764,000 kilograms of natural quartz crystal, valued at \$10 million. This quantity represented an excess of about 492,000 kilograms

above the goal set for the stockpile. During the year, quartz crystal stockpile sales amounted to about 74,800 kilograms at \$368,000 to support the ferroalloys upgrading project. These were the first sales since 1985. The stockpile material, which primarily consists of large natural crystals, could be absorbed by the specimen and gem material industry. Very little, if any, of the material would be consumed in the same applications as synthetic quartz crystal.

STRATEGIC CONSIDERATIONS

Natural electronic-grade quartz crystal was initially designated after World War II as a strategic and critical material. At the time of U.S. stockpile acquisition, cultured quartz crystal was not commercially available. With the changing patterns of quartz consumption, the Federal Emergency Management Agency asked the National Materials Advisory Board to assess the requirements and related trends for stockpiling quartz. The final report was published in early 1985 and recommended changes in stockpile goals to reflect the declining dependence on natural quartz crystal.¹ Near yearend 1989, the President received authorization from Congress to further reduce the stockpile goal from about 272,000 kilograms to about 110,000 kilograms of quartz crystal.²

The National Defense Stockpile contains natural quartz in several weight classes and grades, including about 13,000 kilograms of material consisting of individual crystals weighing more than 10,000 grams each. Some of the individual quartz pieces in this weight class are suitable for generating mother seeds for cultured quartz crystal production. These large pieces were acquired from Brazil because similar materials were not available from a domestic source.³

PRODUCTION

Coleman Quartz Inc., Jessieville, AR, the only domestic company known to produce lascas, supplied the feed mate-

rial for cultured quartz crystal from mine production. Coleman mined only during the summer months, but processed lascas yearround. Lascas was mined, crushed, and sized. Crushed and sized material was transported to the processing plant where operators rinsed it in oxalic acid and then in deionized water to remove external contaminants. Finally, hand sorting, drying, and examination on a light table completed the necessary processing. The material was then shipped to cultured quartz crystal producers in 45-kilogram (100-pound) bags.

Production of cultured quartz crystal increased nearly 20% in 1989. Six companies were active. The two largest producers, Sawyer Research Products Inc. of Eastlake, OH, and Thermo Dynamics Corp. of Merriam, KS, were independent growers that produced crystal bars for domestic and foreign consumers in the crystal device fabrication industry. Motorola Inc. of Chicago, IL, produced quartz crystal for both internal consumption and the domestic device fabrication industry. P. R. Hoffman Material Processing Co. of Carlisle, PA, also reported outside sales. Bliley Electric Co. of Erie, PA, produced only for internal consumption. Electro Dynamics Corp. of Overland Park, KS, sold the quartz-crystal-growing portion of their operation to Thermo Dynamics in February 1989. Electro Dynamics continued to process synthetic quartz crystal.

These companies produced cultured quartz crystal using a hydrothermal process in large pressure vessels, known as autoclaves. Seed crystals, very thin crystals cut to exact dimensions, were mounted on racks and suspended in the upper growth region of the vessel. Lascas was loaded in an open-mesh wire basket that was placed in the bottom of the autoclave.

A solution of sodium hydroxide or sodium carbonate (the mineralizer), with additives such as lithium salts, and deionized or distilled water was used to fill the vessel to 75% to 85% of its volume. The bottom half of the growing vessel was heated to temperatures averaging between 350°C to 400°C; the temperature of the top portion is maintained at 10°C to 50°C less. At these temperatures, the solution expands and creates an internal pressure in the vessel between 10,000 and 30,000 psi. Under these conditions the lascas dissolves to

create a solution saturated with silica.

Through convection, the saturated solution transports dissolved silica to the cooler upper half of the vessel where it becomes supersaturated, and the excess dissolved quartz deposits on the seed crystals in the top half of the autoclave. The process continues until the growing crystals reach their desired size. The process may take 30 to 60 days, and sometimes even longer.

The processing of quartz crystals into various end uses is the same whether natural or cultured crystal is used. Before cutting, crystals are examined for physical defects. They are then cut, usually with diamond or slurry saws, along a predetermined crystallographic plane to a thickness slightly larger than that desired. Each wafer is inspected and diced into blanks of the desired dimensions. The blanks then progress through a series of lapping stages until they reach the final thickness; the electrodes are attached; and are mounted in suitable holders. The final assembly, called a quartz crystal unit, is ready for insertion into an electronic circuit.

CONSUMPTION AND USES

Consumption of lascas by the six domestic quartz crystal producers increased about 27%, from 451,000 kilograms in 1988 to 572,000 kilograms in 1989. The 25 active device-fabricating companies in 9 States consumed 12% more quartz crystal in 1989 than in 1988. Of these companies, 24 consumed only cultured quartz crystal. One company consumed only natural quartz crystal.

Lascas and quartz crystal were used in piezoelectric, optical, and glass industries. The piezoelectric effect is achieved when a suitable electrical signal is applied to a quartz wafer or blank with appropriate electroding and the wafer then vibrates mechanically throughout the bulk of the material at a characteristic natural resonance frequency. The quartz resonators are uniquely suitable for military-aerospace and commercial bandpass filter applications that require very high selectivity or in oscillator applications that require very high stability. In addition, for many applications requiring only moderate sta-

bility, a quartz resonator offers a unique combination of high performance, small size, and low cost. Quartz resonators were used for many less demanding applications such as providing timing signals for watches, clocks, and microprocessors in industrial, automotive, and consumer products.

For very high frequencies (above 100 megahertz), the quartz wafer becomes too thin for practical use. At these higher frequencies, quartz crystal structures that use surface vibrations, in which the frequency is determined by electrode dimensions rather than wafer thickness, have become more important. These structures are called surface acoustical wave (SAW) devices.

Most optical applications used quartz in the fused form as silica glass. Relatively small quantities of cultured quartz crystal were used directly for special optical considerations. Quartz's crystal properties are responsible for its uses that deal with normally polarized laser beams. Quartz retardation plates (especially quartz wave plates), Brewster windows and prisms, birefringent filters, and tuning elements are used in laser optics.

Sand and lascas were raw materials used by the majority of manufacturers in the silica glass industry. High-quality domestic silica sands were suitable for most uses, although lascas may be used as a feedstock material for manufacturing special large lenses, mirrors, and windows.

Historically, quartz crystal has been a material of strategic importance. During World War II, quartz was used principally in analog communications (e.g., in telephone multiplexing and in mobile military radios). Today, because of military emphasis on command, control, and communications (C³) surveillance and the growth of more sophisticated electronic systems, the importance of use of quartz crystal devices has grown. Many of the military applications are at the leading edge of technology. It has been U.S. Department of Defense policy to require that all military systems be hardened to nuclear radiation. To meet this special requirement, cultured quartz crystal must be radiation hardened by sweeping, a technique to remove certain impurities from the quartz.

Because of cost advantages, cultured quartz was used almost exclusively by

the crystal device industry. For resonator applications, raw quartz must be cut into thin wafers oriented precisely with the raw material crystal axes. The uniformity and convenience of cultured quartz have made its use almost universal. Unlike cultured quartz, natural electronic-grade quartz requires special orientation, cutting, grading, and sizing to produce a quartz wafer. As a result, most device manufacturers that cut natural in the past have discontinued use of natural quartz. One of the remaining uses of natural electronic-grade material was in pressure transducers used in deep wells.

STOCKS

Crystal growers' stocks of as-grown cultured quartz crystal were reported as 56,000 kilograms at the beginning of 1989. At yearend, these stocks had increased to 73,000 kilograms.

PRICES

The average value of as-grown cultured quartz, based on reported sales of about 340,000 kilograms, was \$30.67 per kilogram (\$13.91 per pound), an increase of 59% compared with that of 1988. Sales volume increased 22%. The average value of lumbered quartz, as-grown quartz that has been processed by sawing and grinding, increased 17% to \$140.97 per kilogram (\$63.94 per pound), based on reported sales of 40,000 kilograms. Sales volume decreased 37%.

FOREIGN TRADE

The Bureau of the Census began using the Harmonized Tariff Schedule in 1989 to identify material passing through U.S. customs. This system makes classification codes for imports and exports consistent internationally. With the adoption of the new codes, imports and export codes for quartz crystal changed, and some formerly listed details are no longer available. The import code for Brazilian crude pebble, which represented nearly all

lascas imports recorded, was eliminated. Although this material probably continued to enter the United States, the new code system aggregated several categories making information about specific materials unavailable. Likewise, the export data for natural electronic-grade quartz crystal were no longer available.

Because of these changes, foreign trade information for quartz crystal is limited. While information remained concerning exports of synthetic quartz crystal, comparison between the figures for 1988 and 1989 indicated that exports decreased nearly 70%. Reports for domestic producers indicated that these data may not be accurate. Reports indicated that exports were higher than those reported by Census.

OUTLOOK

Domestic production of cultured quartz crystal has grown steadily since 1986. Increased demand for crystal devices for electronic consumer products along with similar increases for all microprocessor controlled devices, indicated that quartz crystal production should remain strong well into the future. Because crystal devices continued to be used in an increasing variety of applications from kitchen appliances to military hardware in addition to the traditional items such as watches, demand should continue to increase and additional production capacity will be required worldwide.

RARE-EARTH MINERALS AND METALS

By James B. Hedrick and David A. Templeton

Messrs. Hedrick and Templeton are physical scientists with the Branch of Nonferrous Metals. Mr. Hedrick has covered rare earths for 9 years. Mr. Templeton has shared coverage of the commodity for 2 years. Domestic survey data were prepared by Ms. Imogene P. Bynum, Nonferrous Metals Data Section. International data were prepared by Mr. Harold Willis, International Data Section.

Domestic consumption of the rare earths was almost double the quantity used in 1988, mine production increased sharply, and the industry performed well amid increased international competition. Traditional markets of the rare earths, such as petroleum catalysts and metallurgical additives, continued a downward trend while new and emerging markets, such as neodymium-iron-boron permanent magnets, advanced ceramics, and automotive catalysts, showed strong growth. The television and lamp phosphors market was unchanged, and glass polishing applications increased markedly. Demand for rare earths consumed in high-temperature superconductors was small; however, technologic breakthroughs in 1989 increased the prospects for commercial development of rare-earth superconductors.

PRODUCTION

Bastnasite, a rare-earth fluocarbonate mineral, was mined by Molycorp, Inc. at its Mountain Pass, CA, open pit mine. Although mine output increased, Molycorp's sales of rare earths reportedly decreased slightly, mainly as a result of weak foreign demand and increased international competition. Molycorp completed an expansion of its separation facilities to produce additional quantities of dysprosium and neodymium oxides for the permanent magnet industry. The company also began production of erbium, an element used in glass coloration (pink), lasers that emit light in the blue wavelengths, and as a burnable poison in nuclear reactors. Monazite, a rare-earth phosphate mineral, was produced as a byproduct of titanium and zirconium minerals production by Associated Minerals (USA) Inc., a subsidiary of the Australian company Renison Goldfields Consolidated Ltd. (RGC).

¹Comprises only the rare earths derived from bastnasite, as reported in Unocal Corp. annual reports.

²Because of the implementation of the Harmonized Tariff System in Jan. 1989, import and export categories for 1989 are not necessarily comparable with those of previous years.

³Employment at a rare-earth mine in California and at a mineral sands operation in Florida. The latter mine produced monazite concentrate as a byproduct of mining ilmenite, rutile, and zircon, and employees were not assigned to specific commodities.

⁴Imports minus exports plus adjustments for Government and industry stock changes.

⁵Increase in industry stocks exceeded net imports.

⁶Net exporter.

Associated Minerals operated its placer dredging operation at Green Cove Springs, FL. The addition of a spud barge to the Florida operation has reportedly increased ore mining capability significantly and offset falling heavy-mineral sand grades. The barge addition allowed the floating concentrator to operate at design capacity. Monazite from all of RGC's mineral sands operations, including Green Cove Springs, was fully sold under long-term contracts.¹

Imperial Mining Co. produced minor amounts of a mixed monazite-xenotime-zircon concentrate at a gold and industrial

sand and gravel mine in North Carolina. To improve byproduct heavy-mineral sands recovery and delineate ore, Imperial was seeking a joint-venture partner to provide capital and expertise.

Scandium concentrate, produced in prior years in Utah, was processed by Sausville Chemical Co., Garfield, NJ, and Boulder Scientific Co., Mead, CO, into high-purity scandium oxide. Facilities to purify scandium compounds were operated by Research Chemicals Div. of Rhône-Poulenc Inc., Phoenix, AZ, and the Materials Preparation Center, Ames, IA.

Principal domestic producers of neodymium-iron-boron magnet alloys were Molycorp, Neomet Corp., and Research Chemicals. Leading U.S. producers of rare-earth magnets were the Delco Remy Div. of General Motors Corp., Hitachi Magnetics, Crucible Magnetic Materials, and IG Technologies.

In New Mexico, Molycorp and the Mescalero Apache Tribe announced a joint-venture agreement to develop a zirconium and yttrium-bearing deposit on the tribe's reservation. The deposit, identified by Molycorp in 1985, contains eudialyte, an yttrium-bearing zirconium silicate mineral. Reported reserves were 2.4 million tons grading 1.2% zirconium oxide and 0.18% yttrium oxide. Initial metallurgical tests by Molycorp indicate that the ore could be economically processed with conventional heap-leach technology.

In the southeastern United States, Associated Minerals and its parent company, RGC, announced completion of the exploration phase of the Old Hickory heavy-mineral sands deposit located southwest of Richmond, VA. The deposit reportedly contains 7.3 million metric tons of heavy minerals with minor amounts of monazite. Mining of the Old Hickory deposit could begin in 3 to 5 years.

CONSUMPTION AND USES

Domestic rare-earth processors consumed 72% more rare earths in 1989 than they consumed in 1988. Bastnasite consumption was 73% higher than in 1988, but monazite consumption was 42% lower. Shipments of rare-earth products from domestic processors of ore, concentrates, and intermediate concentrates was equivalent to 12,975 tons of rare earth oxide (REO), up 31% from the 9,867 tons shipped in 1988.

Consumption of mixed rare-earth compounds decreased 49% from the 1988 level, while consumption of purified compounds increased 98%. Higher consumption of purified compounds was the result of continued strong demand for neodymium, dysprosium, and certain other rare earths used in high-strength permanent magnets, cerium used in automotive catalytic converter materials and glass, and for yttrium used in a variety of ceramic and refractory applications.

The producers of mischmetal, rare-earth silicide, and other rare-earth alloys con-

sumed 30% more rare earths in 1989 than in 1988, while shipments of these goods fell 2% during the same period. Shipments of high-purity rare-earth metals increased 22% during the year.

The approximate distribution of rare earths by use, based on information supplied by primary processors and some consumers, was as follows: catalysts in petroleum, chemical, and pollution control applications, 42%; metallurgical uses as iron and steel additives, alloys, and mischmetal, 14%; ceramics and in glass polishing compounds and as glass additives, 43%; and miscellaneous uses in phosphors, electronics, permanent magnets, and in lighting and research applications, 1%.

The glass industry's principal use of rare earths, mainly cerium concentrate or cerium oxide, was as polishing compounds for lenses, mirrors, cut crystal, television and other cathode-ray tube (CRT) faceplates, gem stones, and plate glass. Rare-earth compounds were also used as additives to glass used in automobiles, food and beverage containers, television and CRT faceplates, radiation shielding windows, ophthalmic lenses, lasers, incandescent and fluorescent lights, and optical, photochromic, filter, and photographic lenses. The rare-earth additives acted as colorants, color correctors, and decolorizers, as stabilizers against discoloration from ultraviolet light and against browning caused by high-energy radiation, as dopants in laser glass, as modifiers to increase the refractive indices and decrease dispersion, and as absorbers of ultraviolet and visible light.

Phosphors containing rare earths were used in color television tubes, radar screens, avionic and data displays, X-ray intensifying screens, low- and high-pressure mercury vapor lights, electronic thermometers, and trichromatic fluorescent lamps.

The ceramics industry used purified rare earths in pigments, heating elements, dielectric and conductive ceramics, thermal and/or flash protective devices, stereoviewing systems, data printers, image storage devices, and as principal constituents and stabilizers in high-temperature refractories, such as yttria-stabilized zirconia, and in glasses and paints.

Rare-earth compounds had applications in petroleum fluid cracking catalysts, non-cracking catalysts, oxygen-sensing electrolytes, computer bubble domain memories, dyes and softeners for textiles, electronic components, nuclear fuel repro-

cessing, microwave applications, incandescent gas mantles, laser crystals, fiber optics, carbon arc lighting, synthetic gem stones, and superconductors.

Rare-earth permanent magnets were used in electric motors; alternators; generators; line printers; computer disk-drive actuators; proton linear accelerators; synchronous torque couples; eddy current brakes; microwave transmission focusing; magnetrons; klystrons; medical and dental applications, including nuclear magnetic resonance imaging; traveling wave tubes, metallic separators; aerospace applications, including electric actuators for ailerons and rudders; and in speakers, headphones, microphones, and tape drives.

Metallurgical applications of rare earths included alloys and additives in high-strength, low-alloy steels, gray and ductile iron, stainless and carbon steels, high-temperature and corrosion-resistant metals, hydrogen storage alloys used in heat exchangers and fuel cells, lighter flints, armaments, permanent magnets, neutron converter foils, special lead fuses, target materials for sealed-tube neutron generators, and high-voltage transmission cable.

STOCKS

Stocks of rare-earth ores and concentrates held by 19 producing, processing, and consuming companies decreased 54%. Bastnasite concentrate stocks held by the principal producer and six other processors decreased 59% from the 1988 level. Yearend stocks of monazite increased 35%, while stocks of yttrium concentrate decreased 10%.

Stocks of other rare-earth concentrates fell 43%. Stocks of mixed rare-earths compounds increased 12%, as stocks of purified compounds decreased 55%. Yearend stocks of mischmetal, rare-earth silicide, and other alloys containing rare earths gained 37%, as inventories of high-purity rare-earth metals were off 78%.

PRICES

Published prices for the rare earths were generally nominal and subject to change without notice. Increased foreign competition resulted in competitive pricing policies in the United States in 1989 with prices for most rare-earth products quoted on a daily basis.

Prices quoted by Molycorp for unleached, leached, and calcined bastnasite in standard quantities, containing 60%, 70%, and 85% REO, were \$1.15, \$1.20, and \$1.40 per pound of contained REO, respectively, at yearend 1989. These prices were respectively \$0.10 per pound more than at yearend 1988.

The price range of Australian monazite (minimum 55% rare-earth oxide, including thoria, f.o.b./f.i.d.),² as quoted in Australian dollars (A\$),³ increased from A\$700-A\$780 per ton at yearend 1988, to A\$780-A\$880 per ton by yearend 1989. The U.S. price range, converted from Australian dollars, increased from US\$598-US\$666⁴ in 1988 to US\$616-US\$695⁵ in 1989. The average declared value of imported monazite increased in 1989 to \$685 per ton, up \$85 from the 1988 value.

The yearend price quoted in Industrial Minerals (London) for yttrium concentrate (60% Y₂O₃, f.o.b. Malaysia) was \$32-\$33 per kilogram.

The price of cerium concentrate quoted by American Metal Market was \$1.55 per pound of contained cerium oxide at yearend 1989, an increase of \$0.15 from the previous year. The yearend price of lanthanum concentrate remained unchanged from the 1988 level at \$1.40 per pound of REO contained.

Mischmetal (99.8%, lots over 100 pounds, f.o.b. shipping point) prices for 1989, quoted by Reactive Metals and Alloys Co., were \$5.00 per pound.

The price for neodymium-iron-boron alloy, compiled by the Bureau of Mines, averaged \$15 per pound, f.o.b. shipping point, 1,000 pound minimum.

Molycorp quoted prices for lanthanide (rare earth) and yttrium oxides, net 30 days, f.o.b. Louviers, CO, Mountain Pass, CA, or York, PA, effective October 1, 1988, and throughout 1989, as follows:

Product (oxide)	Percent ¹ purity	Quantity (pounds)	Price per pound
Cerium	99.0	200.0	\$8.75
Europium	99.99	25.0	745.00
Gadolinium	99.99	55.0	65.00
Lanthanum	99.99	300.0	8.75
Neodymium	96.0	300.0	6.75
Do.	99.9	50.0	40.00
Praseodymium	96.0	300.0	16.80
Samarium	96.0	55.0	65.00
Terbium	99.9	44.1	375.00
Yttrium	99.99	50.0	52.50

¹Purity expressed as percent of total REO.

Molycorp also quoted prices for lanthanide (rare earth) compounds, net 30 days, f.o.b. York, PA, or Louviers, CO, effective November 15, 1989, as follows:

Product (compound)	Percent ¹ purity	Quantity (pounds)	Price ² per pound
Cerium carbonate	99.0	150	\$5.10
Cerium fluoride	Tech grade	250	3.00
Cerium nitrate	96.0	250	2.35
Lanthanide chloride	46.0	525	1.00
Lanthanum carbonate	99.9	175	5.90
Lanthanum-lanthanide chloride	46.0	525	.95
Lanthanum-lanthanide carbonate	60.0	200	2.45
Lanthanum-lanthanide nitrate	39.0	250	1.75
Neodymium carbonate	96.0	300	4.50

¹Purity expressed in terms of REO equivalent.

²Priced on a contained REO basis.

Rhône-Poulenc quoted rare-earth prices, per kilogram, net 30 days, f.o.b. New Brunswick, NJ, or duty paid at point of entry, as follows:

Product (oxide)	Percent purity	Quantity (kilograms)	Price per kilogram
Cerium	99.5	20	\$25.75
Dysprosium	95.0	20	132.00
Erbium	96.0	20	190.00
Europium	99.99	10	1,960.00
Gadolinium	99.99	50	136.50
Holmium	99.9	5	510.00
Lanthanum	99.99	25	23.00
Lutetium	99.99	2	7,000.00
Neodymium	95.0	20	20.00
Praseodymium	96.0	20	38.85
Samarium	96.0	25	175.00
Terbium	99.9	5	880.00
Thulium	99.9	5	3,600.00
Ytterbium	99.0	10	230.00
Yttrium	99.99	50	115.50

Nominal prices for various rare-earth oxides and metals were quoted by Research Chemicals, per kilogram, net 30 days, f.o.b. Phoenix, AZ, for yearend 1989 as follows:

Element	Oxide ¹ price per kilogram
Cerium	\$80.00
Dysprosium	230.00
Erbium	570.00
Europium	1,900.00
Gadolinium	180.00
Holmium	610.00
Lanthanum	55.00
Lutetium	9,000.00
Neodymium	130.00
Praseodymium	160.00
Samarium	380.00
Terbium	2,250.00
Thulium	7,200.00
Ytterbium	675.00
Yttrium	115.50

¹Minimum 99.9%-pure, 1- to 20-kilogram quantities.

No published prices for scandium oxide were available. Yearend nominal prices for scandium oxide per kilogram, compiled by the Bureau of Mines from information from several suppliers, were as follows: 99% purity, \$5,000; 99.9% purity, \$9,000; 99.99% purity, \$9,500; 99.999% purity, \$10,000. Scandium metal prices, as listed by the Johnson Matthey Aesar Group, were as follows: 99.99% purity, lump, sublimed dendritic, \$248.20 per gram; 99.9% purity, 250 micron powder, \$444.00 per 2 grams; and 99.9% purity, lump, vacuum remelted, \$322.00 per 2 grams.

FOREIGN TRADE

Rare-earth imports increased dramatically in 1989 from the previous year. Brazil, China, France, and India dominated the import market as shown in figure 1. Japan and Korea were the principal destinations of U.S. exports as shown in figure 2.

WORLD REVIEW

Bastnasite was the world's principal source of rare earths. It was mined as a primary product in the United States and as a byproduct of iron ore mining in China. Monazite was the second leading source of rare earths and was produced largely as a byproduct of processing minerals sands for titanium and zirconium minerals or tin minerals. The leading monazite producers were Australia, Brazil, China, India, Malaysia, the Republic of South Africa, Taiwan, and the United States. Xenotime

was the major source for yttrium and a minor source for the lanthanides. Xenotime was recovered primarily as a byproduct of processing for tin minerals in Indonesia, Malaysia, and Thailand, but was also produced as a byproduct of processing titanium and zirconium minerals in Australia and China. Increasing supplies of rare earths, including yttrium, were produced from rare-earth minerals in clay in China and from spent uranium leach solutions in Canada. Scandium was recovered as a byproduct of processing tungsten, tin, iron, and beryllium ores in China and was produced as a byproduct of uranium processing in the United States up to February 1989.

Capacity

Capacity to produce rare-earth minerals increased significantly in the 1980's. China and India installed the largest share of capacity during the decade.

Reserves

World reserves of rare earths were estimated by the Bureau of Mines at 45 million tons of contained REO, of which 23% is in market economy countries.⁶ China had the largest share of world reserves at 76%.

Australia

Newmont Australia Ltd. and Western Rare Earths NL (previously Golden Cue NL) entered a 60-40 venture, respectively, to assess the Yangibana rare-earth deposit in Western Australia. Located about 400 kilometers northeast of Carnarvon, Western Australia, the deposit reportedly contained 3.1 million tons of ore averaging 1.7% rare-earth oxide.⁷

See footnote at end of table.

Carr Boyd Minerals Ltd., owner of the Mount Weld rare-earth carbonatite deposit near Laverton, Western Australia, reportedly upgraded its measured reserves at a 20%-REO cutoff to 1.35 million tons of ore averaging 23.6% REO, including yttrium. At a 10%-REO cutoff grade, the reserves were 6.31 million tons at a grade of 16.2% REO.⁸

Rhône-Poulenc SA of France continued its quest to gain approval for a rare-earth separation plant at Pinjarra, Western Australia. Environmental concerns related to the disposal of naturally radioactive thorium have delayed the project. Rhône-Poulenc proposed a new plan to dispose of the thorium by injecting it into deep wells drilled into a saline aquifer.⁹

The Nissho Iwai Corp. of Japan purchased RZ Mines (Newcastle) Ltd. and Cable Sands Pty. Ltd. for A\$240 million from Pioneer International Ltd. Nissho had been importing rutile and zircon produced by RZ Mines for 20 years before the purchase. Nissho's purchase was reportedly in response to anticipated growth in demand for zircon resulting from Japan's increase in steel production and from expanding European markets for fine ceramics. Combined, Cable and RZ Mines produced about 1,200 tons of monazite per year.¹⁰

Cable Sands continued development of the Jangardup heavy-mineral deposit in southwestern Western Australia. The company expected to begin mining in 1990 or 1991.¹¹

An appeal to the Land and Environment Court concerning environmental issues delayed the startup of Australmin Holdings Ltd.'s mine at Newrybar, New South Wales. However, the appeal was not upheld, and the company expected production to begin in early 1990. Annual production of 30,000 tons of heavy-mineral concentrate was expected to yield 12,000 tons of rutile, 10,000 tons of zircon, and smaller quantities of monazite. Reserves at Newrybar were 22.3 million tons of ore averaging 1.1% heavy minerals.¹²

Renison Consolidated Goldfields subsidiary, Associated Minerals Consolidated, began development of the Eneabba West deposit in Western Australia. Initial mining was expected to start in 1990 or 1991. The deposit reportedly contained 230 million tons of sand with a heavy-mineral grade of 3.1%. Approximate annual production of monazite was expected to reach 2,500 tons.¹³

BHP-Utah Minerals International investigated the Beenup heavy-mineral sands

¹Table includes data available through June 27, 1990.

²In addition to the countries listed, China, Indonesia, North Korea, the Republic of Korea, Nigeria, and the U.S.S.R. may produce monazite, but output, if any, is not reported quantitatively, and available general information is inadequate for formulation of reliable estimates of output levels.

³Revised to zero.

⁴Reported figure.

deposit in the Scott River area of Western Australia. Initial studies indicated that the Beenup deposit could support dredging operations of up to 500,000 tons of heavy-mineral-bearing ore per year. Encouraging concentrations of heavy-mineral sands were reportedly found on Scott River area leases held by joint-venture partners Golden Plateau NL, Kingsgate Consolidated Ltd., and Wynarde Pty. Ltd.¹⁴

North Broken Hill Peko Ltd. was evaluating the feasibility of the Naracoopa mineral sands project on King Island, situated midway between Victoria and Tasmania in the Bass Strait. Reserves were

estimated to contain 25 million tons of ore grading 5.2% heavy minerals.¹⁵

Mineral Deposits Ltd. (MDL), a subsidiary of the Australian company Broken Hill Pty. Ltd., announced the development of a mineral sands deposit near Agnes Water, Queensland. Startup of the mine was scheduled for 1991.¹⁶

Minproc Chemicals Pty. Ltd. and KMCC Western Australia Pty. Ltd., a subsidiary of the U.S.-based Kerr-McGee Corp., planned to start mining the Cooljarloo heavy-mineral sand deposit near Cataby, Western Australia, in the first half of 1990. Reserves of 569 million tons of ore

containing 18.3 million tons of heavy minerals, including monazite, were reported.¹⁷

Brazil

Production of monazite concentrates in 1987 was 4,332 tons, with 177 tons from the State of Espírito Santo, a decrease from the 197 tons produced in 1986; 3,271 tons from the State of Rio de Janeiro, a decrease from the 1986 production of 3,421 tons; and 884 tons from the State of Bahia, which produced no monazite in 1986.

Measured reserves of monazite in 1987 were 36,806 tons. Estimated rare-earth oxide content based on these reserves was 18,376 tons. Monazite reserves were located in the States of Bahia, Espírito Santo, Minas Gerais, and Rio de Janeiro.¹⁸

Production of rare-earth compounds, as reported by the Government in 1987, was 22,500 kilograms of rare-earth carbonate, 2,422,000 kilograms of rare-earth chloride, and 66,000 kilograms of rare-earth oxides.¹⁹

Companhia Vale do Rio Doce (CVRD) planned to construct a rare-earth separation plant at Araxa, Minas Gerais, utilizing separation technology from Japan's Mitsubishi Corp. The company reportedly will be able to produce 3,000 tons of REO per year as byproducts from its titanium operation at Tapira.²⁰

Canada

Yttrium concentrate production in 1989 from uranium ores at the Elliot Lake Mine in Ontario, on an yttrium oxide content basis, increased from 50 tons to 100 tons. The yttrium operations were a joint venture of Unocal Canada Ltd., SM Yttrium Ltd., and Denison Mines Ltd.²¹

Joint-venture partners Hecla Mining Co. and Highwood Resources Ltd. decided not to develop the Thor Lake beryllium-niobium-rare-earth deposit in the Northwest Territories because of poor market outlook. The deposit reportedly contained 8,600 tons of yttrium oxide along with other rare earths.

China

China remained the world's leading producer of rare earths despite reduced output from southern mines.²² Decreased production was reportedly caused by a drop in domestic and foreign demand during the second half of 1989. Production of various mixed and separated rare-earth products reportedly reached 19,670 tons of equivalent

FIGURE 3
WORLD RESERVES OF RARE EARTHS
(REO CONTENT)

REO, an increase of 5.4% from 1988's level. Growth sectors for the rare earths in China were petroleum cracking catalysts, agricultural fertilizers, permanent magnets, and phosphors.

Scandium was produced at five locations in China and refined at four locations as follows:²³

Scandium mine locations	
1. Jiangxi Province, tungsten mines	
2. Guangxi Province, tin mines	
3. Guangdong Province, tin mines	
4. Fujian Province, iron (magnetite) mines	
5. Zhejiang Province, tungsten and beryllium mines	
Scandium processor locations	Principal product
1. Jiangxi Province Guizhou Cobalt Smelter	Tungsten
2. Guangxi Province, Pingkwa	NA
3. Hunan Province, Taujian, Rare-Earth Metal Smelter	NA
4. Hunan Province, Hunan Rare-Earth Metal Research Institute	Tin

NA Not available.

Denmark

Morstrøl Minerals investigated a heavy-mineral sands deposit near Hanstholm, northern Jutland. The deposit, covering 100 square kilometers, contains the minerals ilmenite, rutile, zircon, and monazite.²⁴

Greenland

Hecla Mining Co. (47%), Nuna Oil (50%), and Gewerkschaft Wilhelm Bergbaugesellschaft (3%) formed a consortium, named Sarfartoq, to explore for rare earths and niobium in southeastern Greenland.²⁵

Others, including A/S Carl Nielsen of Denmark and a Canadian triventure composed of Platinova Resources Ltd. (40%), Highwood Resources Ltd. (30%), and Aber Resources Ltd. (30%), explored a banded nepheline syenite (kakortokite) in the Ilimaussaq intrusive complex that contains the rare-earth and zirconium-bearing mineral eudialyte.²⁶

Guyana

An estimated 450 river-based diamond and gold dredges were reportedly processing heavy-mineral-containing resources. Other heavy minerals identified as potential byproducts of the dredging operations

were ilmenite, rutile, zircon, and, in some deposits, monazite.²⁷

Japan

Japanese demand for scandium was primarily for metal halide lamps, consuming about 50%. An estimated 30% is consumed in gadolinium-scandium-gallium garnets (GSGG) and the balance consumed in the electron guns of CRT's, automotive catalysts, and other uses.²⁸

Madagascar

QIT-Fer et Titane Inc. (QIT), a subsidiary of RTZ Corp. PLC (RTZ), announced that its joint-venture heavy-mineral sands project would be delayed at least until 1995, a result of problems encountered in negotiations with the Government.

Malawi

The French group, BRMG, investigated the well-known Kangankunde Hill rare-earth carbonatite in 1988, and was reportedly preparing a prefeasibility report.²⁹ Monazite in the carbonatite was environmentally acceptable because of its low thorium oxide content, 0.08%.

New Zealand

Fletcher Titanium Products Ltd. started production of heavy minerals at a pilot plant located on the west coast of South Island at yearend. Production of 400 tons per year of rutile, zircon, and monazite was planned.³⁰

South Africa, Republic of

General Mining Corp. Ltd. continued to produce byproduct monazite from its Naboomspruit fluorspar operations in the Transvaal. Monazite reportedly was separated during processing of the fluorspar by wet high-intensity magnetic separators.³¹

The Anglo American Corp. of South Africa Ltd. studied the feasibility of developing heavy-mineral sand deposits in Namaqualand. The deposits were on lands owned by De Beers Consolidated Mines near the west Cape coast, 30 miles north of the Olifants River. A wet concentration pilot plant was operated during the year. If a decision is made to proceed with the project, production was planned to commence in 1992, with an expected monazite output of 1,000 tons per year. Rutile and zircon production were expected to be

25,000 and 100,000 tons per year, respectively.³²

Severin Mining and Development Co. (Pty.) Ltd. conducted pilot plant tests on samples of a deposit 30 miles south of Richards Bay at Mitunzini. The deposit resembled the Richards Bay deposit and was reported to have a 10% heavy-mineral grade. A decision was expected in early 1990, following completion and analysis of pilot plant tests.³³

Richards Bay Minerals reportedly delayed exploration and development work on its project at Lake St. Lucia in the Natal Province because of environmental concerns.³⁴

Rio Tinto Minerals Development Ltd., a subsidiary of RTZ, acquired total ownership of QIT from BP Minerals Development Ltd., a subsidiary of British Petroleum. QIT holds a 50% interest in Richards Bay Minerals in the Republic of South Africa.³⁵

Taiwan

Pacific Ocean Rare Earth Industry Co. (POR), continued production of heavy minerals, including monazite, on the west coast. Monazite reserves in Yuanlin and Chiayi Counties were 50,000 tons. Ore from the area was shipped to Hsinchu for processing and separation of the rare earths from monazite. The POR rare-earth plant at Hsinchu was capable of processing 1,000 tons of monazite per year with annual separation capacity as follows: lanthanum oxide, 100 tons; cerium oxide, 240 tons; didymium oxide (Pr-Nd), 100 tons; samarium oxide, 12 tons; europium oxide, 2 tons; mixed gadolinium-terbium-dysprosium oxide, 20 tons; and yttrium oxide, 4 tons.³⁶

Thailand

The Office of Atomic Energy for Peace of Thailand was building a rare-earth separation plant to process 300 tons of monazite per year. The plant was scheduled for completion in late 1990.³⁷

CURRENT RESEARCH

Carr Boyd Minerals Ltd. reported a breakthrough in beneficiation of the rare earths. Company-funded research at the University of Western Australia discovered that mixed rare earths could be mechanically separated from the ore using high-energy ball mills instead of conventional chemical treatment. Rare earths produced from the new process can reportedly be reduced

directly to mischmetal or alloyed simultaneously without prior melting or heating.³⁸

Magnesium Elektron announced the development of a new rare-earth-magnesium alloy as a replacement for certain magnesium-thorium alloys. The new alloy, WE43, contains 3.75% to 4.05% yttrium, 2% to 2.5% neodymium, 0.75% to 1.25% heavy rare earths, a minimum 0.3% zirconium, and the balance magnesium. The alloy can reportedly substitute for the magnesium-thorium alloys presently used in several aerospace applications.³⁹

Researchers at the Aluminum Company of America created a high-temperature aluminum alloy using a rare earth. The rapidly cooled cerium-iron-aluminum alloy had an extremely fine-grained microstructure, in the 5 to 40 micron range. Designated Cu78, the new alloy reportedly has improved strength and fracture toughness up to 349° C. Cu78 was expected to be used in airframe structural parts and other aerospace components.⁴⁰

OUTLOOK

The outlook for rare earths was promising. Exhibiting a wide range of chemical and physical properties, the rare earths have found increased use in an expanding number of applications. The demand pattern was expected to continue to favor separated high-purity products. Although

a few traditional markets have been in decline (petroleum cracking catalysts and mixed metallurgical additives), increased rare earth use is expected in the near-term in permanent magnets, automotive catalytic converters, glass additives, and industrial, medical, and communications lasers. Recent advancements in high-temperature superconductor technology indicate a large potential for long-term growth.

World supplies of rare earths are expected to be adequate to meet demand, in part because increased demand for titanium and zirconium minerals has initiated expansions in both the mining and processing sectors. Australia, China, and the United States should continue as the principal sources of supply.

Economic projections forecast only a modest advance in the economy in 1990, followed by a resurgence of consumer demand in 1991.⁴¹ Rare-earth demand is predicted to outperform the domestic economy in 1990, especially in the non-traditional markets. Continued diversification in rare-earth markets is expected to provide increased stability to the industry.

BACKGROUND

Definition, Grades, and Specifications

The rare earths are a group of 17 elements comprised of scandium, yttrium, and the lanthanides.

⁴Byproduct of processing for phosphate rock.

⁵Byproduct of processing for tin minerals.

⁶Byproduct of processing for iron minerals.

⁷Residual weathering product in clay.

Scandium, atomic number 21, is the lightest rare-earth element. It is the 31st most abundant element in the Earth's crust with an average crustal abundance of 22 parts per million. Although it occurs in greater quantities in crustal rocks than lead, mercury, and the precious metals, scandium rarely occurs in concentrated quantities as a result of its aversion to combine with the common ore-forming anions.

Yttrium, atomic number 39, is chemically similar to the lanthanides and often occurs in the same minerals. Yttrium's average concentration in the Earth's crust is 33 parts per million and is the second most abundant rare earth in the Earth's crust.

The lanthanides comprise a group of 15 elements with atomic numbers 57 through 71, and include lanthanum, cerium, praseodymium, neodymium, promethium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, and lutetium. Cerium, the most abundant of the group at 60 parts per million, is more abundant than copper. Thulium, the least abundant of the lanthanides at 0.48 parts per million, occurs in the Earth's crust in higher concentrations than thallium, antimony, cadmium, and bismuth.

Largely because of differing ionic radii, the rare-earth elements are broadly classified into two groups: the light or cerium subgroup, comprised of the first seven lanthanides (atomic numbers 57 through 63), and the heavy or yttrium subgroup, comprised of the remaining lanthanides and yttrium (atomic numbers 64 through 71 and 39, respectively). Yttrium is classed with the heavy subgroup because of its occurrence, ionic radius, and other similar properties.

Bastnasite can theoretically contain 74.81% REO.⁴² Flotation concentrates of bastnasite average 60% REO, which can be upgraded to 70% REO by acid leaching, and to 85% REO by a combination of acid leaching and calcining.

Monazite theoretically can contain 69.73% REO. Monazite concentrate is usually sold at 55% minimum REO contained plus thorium, with most product grading 59% to 65% REO. Thorium contents are variable, but typically occur in the range of 4% to 10% equivalent thorium oxide. Monazite with a low thorium content commands a premium price.

Xenotime can theoretically contain 61.40% yttrium oxide. However, xenotime concentrates from Southeast Asia and

Australia typically contain 25% to 30% yttrium oxide. Xenotime is often upgraded by acid leaching to produce an yttrium concentrate grading 60% yttrium oxide and the balance primarily other rare earths.

The term "mischmetal" is used to denote a mixture of rare-earth elements in metallic form. It generally has the same ratio of rare-earth elements as that found in the ore. Ferrocenium is a pyrophoric alloy of mischmetal and iron. Rare-earth silicide is an alloy containing about one-third mischmetal, one-third iron, and one-third silicon. The rare-earth content in master alloys ranges from tenths of a percent in nodularizing alloys for ductile iron to 10% or more in inoculants for gray cast iron. Alloys containing nearly 100% rare-earth metals, such as mischmetal, are additives to certain steels.

The purity of separated rare-earth elements, produced primarily by solvent extraction or ion exchange, usually grade 96% or higher in purity. High-purity rare-earth compounds and metals are produced up to 99.9999% purity. Rare-earth products grading higher than 99.9% purity are often produced to specification. As a result of the wide range of products in which rare earths are consumed, many grades of rare-earth concentrates, compounds, alloys, and metals are marketed. Analyses of the rare-earth contents of selected ores are shown in table 8.

Industry Structure

Rare-earth ore minerals are sold by producers directly to processors, consumers, and commodity brokers, usually as a concentrate. Of the three principal ore minerals bastnasite, monazite, and xenotime, only bastnasite concentrate may be used in certain industrial applications with little or no processing. Most rare-earth concentrates undergo extensive processing to produce mixed or separated compounds and metals. Few companies in the rare-earth industry are fully integrated. Most companies that mine rare earths sell their concentrates to processors that separate the rare earths by chemical processing, primarily solvent extraction or ion exchange. Processors producing separated rare-earth products are often partially integrated, manufacturing fabricated and semifabricated products that are sold directly to manufacturers or end users. The distribution of the global mining industry is illustrated in figure 7.

FIGURE 5

MONAZITE
(PERCENT REO)**XENOTIME**
(PERCENT REO)**Geology-Resources**

Although the rare-earth elements are essential constituents in more than 100 minerals, only bastnasite, monazite, xenotime, and rare earth-bearing clay occur in concentrations high enough to be considered economic ore deposits. Other rare-earth-bearing minerals such as eudialyte, an yttrium-bearing zirconium silicate, may be considered an economic resource at some time in the future.

Monazite and xenotime originate as primary accessory minerals in many crustal rocks. Erosion of the crust breaks down the crust-forming rocks releasing monazite, xenotime, and other minerals. Eroded alluvial material then undergoes natural separation and sorting by rain and wind and dissolution of the soluble minerals. Further separation and concentration of heavy minerals, especially by specific gravity, is accomplished primarily by river and sea currents. Only the more chemically and physically stable minerals, including monazite and xenotime, survive transport to become concentrated in an economic heavy-mineral deposit.

Bastnasite occurs in greater abundance in crustal rocks than do monazite or xenotime. It is most frequently associated with rocks termed carbonatites. This name is derived from the high number of carbonate (e.g., calcite) minerals that make up the composition of the rock. Unlike sea shells, which form calcite from calcium and carbon dioxide taken from seawater, these carbonate minerals arise from molten magma originating from beneath the crust. The magma intrudes the crust at points of weakness and begins to crystallize as it ascends because of decreases in pressure and temperature. As crystallization (i.e., rock forming) progresses, the once-molten magma becomes increasingly more viscous, and the rise toward the surface is halted. If the carbonatite occurs at or near the surface at a sufficient grade it may be economic.

Technology

Exploration and Development.—The Mountain Pass deposit was discovered during exploration for radioactive minerals, a property typical of most rare-earth minerals or those associated with them. Exploration techniques employed to locate the rare earths include surface and airborne reconnaissance with magnetometric and radiometric equipment. It should be noted,

however, that very little exploration is conducted specifically for rare earths. Two world-class bastnasite deposits are developed and dozens of heavy mineral sand deposits are being worked for their combined mineral suite. Most of the mineral sand deposits were found during exploration conducted for ilmenite or other titanium minerals.

Mining.—Mountain Pass bastnasite is mined as a primary product from carbonatite, an intrusive igneous rock associated with alkaline intrusive igneous rocks. The hard rock is mined via bench-cut, open pit methods. Blasted ore is trucked to the mill where it is crushed, screened, and heated to improve flotation. Bastnasite recovered from the flotation circuit is thickened, filtered, and dried to produce a 60% REO concentrate. The concentrate can be upgraded to 70% REO by leaching with 10% hydrochloric acid to consume any remaining calcite. Subsequent roasting can further increase the REO content to 85% by liberating carbon dioxide from the carbonate portion of the mineral.

Heavy-mineral sands are the sources of most monazite and xenotime mined in the world. Almost all mining of these sands is done by floating dredges that concentrate the heavy minerals onboard and discharge the unwanted tailings back into the previously mined areas. Dredging is particularly well-suited for the mining of unconsolidated sands. Dredged ore is mined with either cutter-head suction dredges or bucketwheel excavators. The onboard wet mill separates the economic heavy minerals ("heavies") from the gangue through a series of equipment that may include hydrocyclones, screens, spirals, and cones. Indurated sand deposits that are too difficult to extricate by dredging are mined with typical earth-moving equipment (e.g., dozers, loaders, and/or scrapers).

Processing.—Bastnasite is processed by leaching 85% REO roasted calcine with hydrochloric acid to yield soluble chlorides. Cerium, oxidized during roasting to a higher valence, is insoluble and passes through a countercurrent decantation and thickening circuit. The thickened material is then filtered to collect the precipitate, containing about 70% REO, 90% of which is ceric oxide, which is dried and sold as cerium concentrate. The leach solution overflowing the thickener circuit contains the remaining rare earths in the form of chlorides and is put through a

solvent extraction process to separate the rare earths into two concentrates. One contains lanthanum, praseodymium, and neodymium and the other samarium, gadolinium, and europium. Each of these concentrates is then put through other solvent extraction circuits, and proprietary processes are used to separate the individual rare earths from each other.

Monazite and xenotime concentrates can be processed by dissolution in either sodium hydroxide or sulfuric acid. The first process is preferred because of its effectiveness in removing phosphate. In either method, thorium and certain other elements are separated, and the rare earths are subsequently recovered as mixed or individual compounds.

In the alkaline process, the concentrate is finely ground and reacted with a hot (140° to 150° C) solution of sodium hydroxide for several hours. The rare earths and thorium form insoluble hydroxides, and trisodium phosphate is dissolved. Water is added for thinning purposes, and after settling, the hydroxide precipitates are recovered by filtration, sodium hydroxide is recycled, and trisodium phosphate is recovered by crystallization.

The next processing step is to separate the rare earths and thorium. Two common methods exploit solubility differences for the separation. One way is to dissolve the mixed hydroxides in nitric or hydrochloric acid. Thorium can then be selectively precipitated by partially neutralizing the solution with the addition of sodium hydroxide or ammonium hydroxide. The solution is filtered to remove the thorium precipitate. Another method selectively dissolves the rare-earth hydroxides in hydrochloric acid. Rare-earth chlorides are dissolved, and thorium hydroxide is precipitated and separated by filtration. Solvent extraction also may be employed to separate the two materials. Tri-butyl phosphate or certain amine nonaqueous solvents can be used, but amine extractants are reported to perform best in sulfate solutions and form a high-purity thorium complex.

In the acid digestion process, monazite is finely ground and reacted with concentrated sulfuric acid at about 200° C. Temperature and acid concentration are controlled during digestion, and both rare-earth and thorium sulfates are formed. The sulfates are then dissolved in water and separated from the insoluble impurities by filtration. Thorium is then separated by precipitating with ammonia.

Byproduct Scandium.—There is no domestic exploration or mining conducted solely for scandium. This is because it occurs only in trace amounts ranging from about one part per million in uranium ores to between 500 and 800 part per million in tungsten concentrates. Scandium has recently been recovered as a secondary byproduct of copper mining at the Bingham Canyon Mine in Utah. It was recovered there from barren copper leach solutions that were processed by ion exchange and solvent extraction to produce uranium concentrates. Because of low uranium prices, recovery operations for this commodity and, hence, the byproduct scandium were placed on standby status in February 1989.

The leach solution, after completing its course through the copper recovery circuits, was obtained and processed by Energy Fuels Nuclear Corp. using an ion-exchange method to recover uranium. In this method, metal cations contained in the solution were adsorbed on resins in the ion exchange columns. Upon successive passes through this circuit, the solution was depleted of uranium, scandium, and other impurities. The resins were then stripped of their adsorbed materials via solvent extraction. Uranium products became entrained in the solvent and a sludge developed. Scandium was contained in the sludge in concentrations ranging from 5% to 10%. The sludge was then processed at a refinery to recover scandium oxide or other specific compound products.

Economic Factors

Prices.—Trends for bastnasite and monazite concentrate prices are shown in figures 8 and 9. Both concentrates exhibited a fairly steady growth in prices except for a few years following the 1979-81 economic recession. Time-price relationships, based on 1982 constant dollars, are shown in table 9.

Tariffs.—In 1989, the classification of imports to the United States was revised under the Harmonized Tariff Schedule of the United States. The new system of classification was enacted to facilitate trade between the United States and the rest of the world. The tariffs on imported rare-earth materials are shown in table 10.

Depletion Provisions.—The U.S. Government's tax depletion allowance on domestically produced monazite was 22% on the thorium content and 14% on the

FIGURE 8
BASTNASITE CONCENTRATE¹ PRICES

FIGURE 9
MONAZITE CONCENTRATE¹ PRICES

rare-earth content. Monazite produced in foreign countries was permitted a 14% depletion allowance. The domestic depletion allowance for U.S. and foreign production of bastnasite and xenotime was 14%.

Operating Factors

Environmental Requirements.—Domestic mines and processing plants were required to meet Federal and State environ-

mental guidelines for air, water, and soil quality. Reclamation of land currently mined for materials other than coal, including rare earths, was controlled by State authority. Requirements differed by State jurisdiction, with most requiring the mined land be returned to its original use or transformed into recreational and agricultural areas.

Naturally radioactive thorium-bearing rare-earth minerals and their byproducts were controlled by Federal and State regulatory agencies. State requirements differed by jurisdiction, but typically controlled the handling, shipping, and storage of materials containing thorium. Thorium-bearing residues were required to be disposed of only in Federally licensed fee-for-burial sites. The domestic rare-earth industry has incurred substantial costs to properly store and dispose of radioactive waste products.

Toxicity.—The rare-earth elements are considered only slightly toxic.⁴² However, the production of skin and lung granulomas after exposure to oxides, fluorides, chlorides, and metals by prolonged breathing, intradermal injection, or subcutaneous implantation requires extensive protection to prevent exposure through cuts and abrasions of the skin and inhalation. Symptoms of toxicity include writhing, ataxia, labored respiration, walking on the toes with arched back, and sedation. Research has shown males are less susceptible than females to the toxic effects of the rare earths. Extreme care must also be taken when exposed to finely divided rare-earth metals and metallic powders to avoid pyrophoric burns from rapid and possibly instantaneous oxidation, especially if inhaled. Certain finely divided rare-earth metals, alloys, and powders, may also present the additional hazard of oxidizing rapidly enough to explode.

Employment.—Rare-earth mine and mill employment, based on the quarterly average number of workers, is shown in figure 10. Data were furnished by the U.S. Department of Labor and compiled by the Bureau of Mines.

Productivity Trends.—The 11-year trend for U.S. rare-earth mine productivity, based on capacity utilization, shows a slight increase for monazite and a slight decrease for bastnasite. However, gains were made during the period as improved mining plans and recovery methods were initiated at the rare-earth mines in California and Florida.

RHENIUM

By John W. Blossom

Mr. Blossom, a physical scientist/engineer with 42 years industry and Government experience, has been the commodity specialist for rhenium since 1983.

In 1989, domestic demand for rhenium metal and other rhenium products was met by domestic recovery, domestic stocks, and imports.

Rhenium is a byproduct of molybdenite recovered as a byproduct of porphyry copper ore from seven mines in the Western United States. Consumption of rhenium increased about 6% in 1989. Imports for consumption apparently decreased about 23%. Some of this apparent decrease in imports was caused by category changes under the Harmonized Tariff Schedule, which became effective January 1, 1989. The major uses during the year were bimetallic platinum-rhenium catalysts and jet engine high-temperature components. The price of rhenium metal was about \$700 per pound, and the price for ammonium perrhenate about \$650 per pound of contained metal.

DOMESTIC DATA COVERAGE

Domestic mine production data for rhenium are developed by the Bureau of Mines from reported molybdenum production at the seven operating porphyry copper-molybdenum-rhenium mines in the United States.

^cEstimated.

¹Calculated rhenium contained in molybdenite concentrates.

CONSUMPTION AND USES

The major uses of rhenium are in petroleum-reforming catalysts and in high-temperature super alloys used in jet engine components. These two uses each represent about 45% of the total demand.

Rhenium is used in petroleum-reforming catalysts for the production of high-octane hydrocarbons which are used in the production of lead-free gasoline. Bimetallic platinum-rhenium catalysts have replaced

many of the monometallic catalysts. Rhenium catalysts tolerate greater amounts of carbon formation and make it possible to operate at lower pressures and higher temperatures, which leads to improved yields and octane ratings.

Catalytic units employing platinum-rhenium catalysts are used in about 80% of total U.S. reforming capacity. Platinum-rhenium catalysts are also used in the production of benzene, toluene, and xylenes, although this use is small compared with that used in gasoline production.

Source: Bureau of the Census

A significant property of rhenium is its ability to alloy with molybdenum and tungsten. Molybdenum alloys containing approximately 50 weight percent rhenium have greater ductility and can be fabricated by either warm or cold working. Unlike other molybdenum alloys, this alloy is ductile, even at temperatures down to 196° C, and can be welded. Also, alloys of tungsten with 24 weight percent rhenium have improved ductility and lower ductile-to-brittle transition temperature than pure tungsten. Rhenium improves the strength properties, at high temperatures (1,000° C), of nickel alloys. Some of the uses for these alloys are in thermocouples, temperature controls, heating elements, ionization gauges, mass

spectrographs, electron tubes and targets, electrical contacts, metallic coatings, vacuum tubes, crucibles, electromagnets, and semiconductors. These varied uses have represented only about 10% of total demand over the past year.

FOREIGN TRADE

Imports for consumption of ammonium perrhenate came from Chile, Sweden, and Switzerland, whereas Chile, the Federal Republic of Germany, France, Japan, Mexico and Sweden supplied rhenium metal.

World production of rhenium was estimated to be 75,000 pounds contained in

molybdenum concentrates; however, the quantity of rhenium actually recovered is much lower since not all concentrates are processed to recover the rhenium values. Rhenium was recovered from some byproduct molybdenite concentrates from porphyry copper deposits in Canada, Chile, China, Iran, Peru, the U.S.S.R., and the United States. In addition, the U.S.S.R. also recovered rhenium as a byproduct from the Dzhezkazgan sedimentary copper deposit in Kazakhstan. Rhenium metal and compounds were recovered from molybdenum concentrates in Chile, France, the Federal Republic of Germany, Sweden, the U.S.S.R., the United Kingdom, and the United States.

WORLD REVIEW

The definitions of reserves and reserve base are published in U.S. Geological Survey Circular 831, "Principles of a Resource/Reserve Classification For Minerals," which is reprinted in the introduction of "Mineral Facts and Problems, 1985 Edition" and "Mineral Commodity Summaries, 1990."

Estimated world reserves and reserve base of rhenium appear in table 5. They are contained primarily in molybdenite in porphyry copper deposits. U.S. reserves are concentrated in Arizona and Utah, but are also found in Montana, Nevada, and New Mexico. Canadian reserves are located in British Columbia, primarily on Vancouver Island. Chilean reserves are found primarily at four large porphyry copper mines and in lesser deposits in the northern half of the country. In Peru, reserves are concentrated primarily in the Toquepala open pit porphyry copper mine, and in about a dozen other deposits located in the southern half of the country.

Soviet reserves are in several porphyry copper deposits and one sedimentary copper deposit mainly in the south-central part of the country between the Caspian Sea and northwestern China. Other world reserves are located in Europe and in sedimentary copper-cobalt deposits in Zaire, in Africa.

OUTLOOK

In the next 5 years, demand for rhenium metal could double to about 45,000 pounds annually, with propulsion component needs at 60%, petroleum-reforming catalysts

30% and the various other uses consuming 10%. This increase in demand may be met by processing a greater amount of concentrates containing rhenium, and increasing the rate of recovery into the 90% range. Recycling of rhenium-bearing waste and scrap must be greatly improved. This area will require the development of new technologies.

SALT

By Dennis S. Kostick

Mr. Kostick, a physical scientist with 11 years Bureau of Mines experience, has been the commodity specialist for salt since 1980. Domestic survey data were prepared by Ms. Carleen Militello, mineral data assistant; and international data tables were prepared by Mr. Peter Roetzel, international data section.

The U.S. salt industry continued to restructure itself through consolidations, name changes, and domestic and foreign acquisitions to become a more integrated North American industry competing in the Western Hemisphere. The United States continued to be the world's largest producer of salt, accounting for about 18% of total world production. Production and trade of salt increased slightly compared with the previous year. World production of all types of salt rose about 4%. The greatest increase in production was in China, which reported a 27% increase in output, mainly for use in its expanding chemical industry. Environmental problems associated with emissions of chlorinated compounds may affect the short-term status of the domestic chloralkali industry, which is the largest single consumer of salt.

ISSUES

About one-half of the domestic production of salt is for use as feedstock by the chloralkali industry to manufacture chlorine and coproduct caustic soda. Environmental concerns regarding emissions of chlorine-base compounds, such as those used in chlorofluorocarbons (CFC's) and in paper bleaching, have reduced the demand of chlorine and caustic soda since 1988. A decrease in chlorine production because of demand changes will have a corresponding affect on salt production. The pulp and paper industry, which consumes about 14% and 24% of the domestic chlorine and caustic soda production, respectively, has been under investigation for discharging harmful effluents into the environment. Although dioxin investigations have been conducted since 1983, 104 bleached pulp mills were studied in April 1988 by the U.S. Environmental Protection Agency to determine the cumulative risk of a certain dioxin (2, 3, 7, 8 tetrachlorodibenzo-p-dioxin or TCDD) and a furan (2, 3, 7, 8, tetrachlorodibenzo

furan or -TCDF) released by the processes. Dioxins are toxic synthetic compounds that have been identified as carcinogenic to some animals, but their effect on humans is controversial and inconclusive. The issue is whether or not the quantity of dioxin that has migrated from milk carton stock into milk or from other paper products, such as paper towels, coffee filters, disposable diapers, and sanitary paper products is harmful. Some pulp mills are considering converting from chlorine-base bleaching chemicals to environmentally safe oxygen-base chemicals, such as hydrogen peroxide and sodium chlorate. Although less chlorine would be made, more sodium chlorate, which also uses salt as feedstock, would be produced.

The environmental issues that affected chlorine have caused a tightness in the caustic soda market that resulted in higher caustic soda prices. Since 1986, when there were large inventories of caustic soda in the world, prices have risen fourfold as demand increased. Although certain uses for chlorine are expected to decrease during the next several years, one major sector is anticipated to have favorable growth, polyvinyl chloride (PVC). PVC, which is the second most widely used plastic after low-density polyethylene, remained the main use for vinyl chloride, chlorine's primary market accounting for 24% of the end use. Although domestic demand for PVC pipe and fittings has been decreasing since 1988, which indicated a slowdown in domestic construction starts, exports of PVC have been strong. Demand for vinyl chloride is anticipated to grow by more than 4% through 1994, which should ease some of the tightness for caustic soda as more chlorine will be required. To alleviate some of the caustic soda shortages, some chlorine and caustic soda manufacturers reportedly are also evaluating the possibilities of producing caustic soda directly from trona, the ore of natural soda ash, or from soda ash directly. Production of caustic soda from soda ash was the

preferred method of manufacture until it was replaced by the electrolysis of salt around the turn of the century.

PRODUCTION

According to the Bureau of Mines survey for 1989, 31 companies operated 69 salt-producing plants in 13 States. Eight of the companies and 11 of the plants produced more than 1 million short tons each and accounted for 85% and 58%, respectively, of the U.S. total. Several companies and plants produced more than one type of salt. In 1989, 12 companies (16 operations) produced solar-evaporated salt; 6 companies (17 operations), vacuum pan salt; 10 companies (14 operations), rock salt; and 16 companies (30 operations), salt brine.

The five leading States in terms of total salt sold or used were Louisiana, 34%; Texas, 20%; New York, 14%; Ohio, 11%; and Kansas, 5%. Although Louisiana, New York, and Ohio were major rock salt-producing States, a substantial amount of salt was produced in Alabama, Kansas, Louisiana, New York, North Dakota, Ohio, Texas, Utah, and West Virginia as brine for the chemical industry.

The U.S. salt industry continued to restructure with changes of ownership, acquisitions, and name-change announcements. Great Salt Lake Minerals and Chemical Corp. (GSL) was acquired in March for \$34.5 million by D. George Harris and Associates and GSL senior management. Aside from salt, the Utah facility also produced potassium sulfate, sodium sulfate, and magnesium chloride. American Salt Co., which also is owned by Harris, markets GSL's salt. Domtar Inc.'s Sifto Salt Div. was tentatively sold at yearend, pending final approval by the U.S. Department of Justice, to Carey Salt Holdings Inc., the parent organization of American Salt Co. and Carey Salt Inc. The purchase was to include Domtar's rock salt mines in Goderich, Ontario, and Baldwin,

LA. The vacuum pan plants in Nappan, Nova Scotia; Goderich, Ontario; and Unity, Saskatchewan; were also included. The acquisition of Domtar, which was the third largest salt producer in North America, would double Carey's annual sales.

The salt division of Morton Thiokol was spunoff in July into Morton International, a separate business composed of other chemical operations. Another major U.S. salt producer, International Salt Co., was renamed to Akzo Salt Inc., as part of a worldwide name change by its parent corporation in the Netherlands. The change also affected International's solar salt subsidiary in Utah, which was renamed Akzo Salt of Utah, Inc.

CONSUMPTION AND USES

More than 43.8 million tons of domestic and imported salt was consumed in the United States in 1989, based on the annual survey of the U.S. salt producers. The reported percent distribution of salt by major end use was chemicals, 46%; ice control, 26%; distributors, 10%; food and agricultural, 6%; industrial, 5%; primary water treatment, 1%; and other combined with exports, 6%. For a more complete analysis of end-use markets, specific sectors of distribution in table 7 can be combined, such as agricultural and water conditioning with agricultural and water conditioning distribution, respectively. On an annual per capita basis, the average citizen consumes about 352 pounds, based on an estimated U.S. population of 247 million and total reported consumption data in table 7. This total includes the amount of salt used by everyone in the above categories. Using the data for the food processing and three-fourths of the grocery wholesalers sectors from table 7, the quantity of salt used for direct human consumption is about 16.6 pounds per person per year.

The chemical industry is the largest consumer of salt, primarily salt brine. Although most salt brine is captively produced by chemical producers, many chloralkali manufacturers now purchased brine from independent brine supply companies. In certain cases, brine is captively produced by one chemical company, and any excess brine is sold to neighboring competitors. According to a survey of domestic salt-base chlorine facilities, about 48% of the salt used to manufacture chlorine was captive, and 31% was purchased brine. Purchased solar or rock salt comprised 12%, and imported rock, solar, and vacuum pan salt was 9%.

FIGURE 1

U.S. SALT PRODUCTION LOCATIONS IN 1989

The chlorine and caustic soda industry consumed about 19.5 million tons of salt for feedstock, based on the industry average ratio of 1.75 tons of salt required to produce 1.0 ton of chlorine and 1.1 tons of coproduct sodium hydroxide. Reported consumption of domestic and imported salt for chlorine manufacture was 18.8 million tons, as noted in table 7. The difference between the calculated and reported quantities was the amount of salt unreported to the Bureau of Mines from imports or captive brine production of chloralkali producers. Production of chlorine gas and liquid sodium hydroxide, as reported by the Bureau of the Census and The Chlorine Institute, was as follows, in thousand short tons:

Organization	1988 ^f	1989
Bureau of the Census:		
Chlorine gas (100%)	11,257	11,161
Sodium hydroxide, liquid (100%)	10,527	11,075
The Chlorine Institute:		
Chlorine gas (100%)	11,597	11,909
Sodium hydroxide, liquid (100%)	12,262	12,507

^fRevised.

Table 16 lists the domestic chlorine-producing facilities that used only salt as feedstock. Based on these estimates and using Bureau of the Census chlorine production data, the U.S. salt-base chlorine industry operated at 88% of capacity. According to The Chlorine Institute, the industry operated at an average of 90% of nominal capacity and 95% of effective capacity in 1989. Because these capacities include chlorine produce from nonsalt sources, i.e., from the electrolysis of magnesium chloride and the oxidation of hydrochloric acid, this data may differ from other reported chlorine capacity utilization information.

STOCKS

Total yearend stocks reported by producers were 2.4 million tons. Most of these inventories were rock salt and solar salt. Many States, municipalities, distributors, and road-deicing contractors stockpiled additional quantities of salt in anticipation of adverse weather conditions.

PRICES

Price quotations are not synonymous with average values reported to the Bureau of Mines. The quotations do not necessarily represent prices at which transactions actually occurred, nor do they represent bid and asked prices. They are quoted here to serve only as a reference to yearend price levels. The following yearend prices were quoted in Chemical Marketing Reporter.

Salt, evaporated, common:	
80-pound bags, carlots or truckloads:	
North, works, 80 pounds	\$4.02
Bulk, same basis, per ton	60.00-61.20
Salt, chemical-grade, same basis:	
80 pounds	4.30
Salt, rock, medium, coarse:	
Same basis, 80 pounds	2.70
Bulk, same basis, per ton	8.00-25.00
Sodium chloride, USP:	
Granular bags, per pound	.29

FOREIGN TRADE

Section 1205 of the Omnibus Trade and Competitiveness Act of 1988 required the United States to adopt an international nomenclature and metric units for reporting trade information. On January 1, 1990, the Harmonized Commodity Description and Coding System (HTS) replaced the Tariff Schedule of the United States, Annotated, for import data and schedule B for exports. Previously, salt imports had three different categories—bulk, other (formerly known as bags, sacks, and barrels), and salt in brine. Exports had one classification, sodium chloride-salt. Under the new HTS nomenclature, imports only have one category known as "Salt (including table and denatured salt) and pure sodium chloride, whether or not in aqueous solution, seawater." The same classification also applies to exports. The trade tables in this report list the previous and current identification codes for salt.

The United States imported in 1989 nearly four times the quantity of salt that it exported. Although this would indicate that the United States is import reliant on salt to meet its salt requirements, the majority of imported salt was brought into the

NA Not available. XX Not applicable.

¹As reported at salt production locations. The term "sold or used" indicates that some salt, usually salt brine, is not sold but is used for captive purposes by the plant or company. Because data do not include salt imported, purchased, and/or sold from inventory from regional distribution centers, salt sold or used by type may differ totals shown in tables 7 and 8, which are derived from company reports.

²Data may not add to totals shown because of independent rounding.

country by foreign subsidiaries of major U.S. salt producers. Generally, imported salt can be purchased and delivered to many customers at costs lower than the comparable domestic product because production costs are less expensive abroad and currency exchange rates are more favorable.

The Journal of Commerce's Port Import/Export Reporting Service (PIERS) reported that Carey Salt Co., Cargill Inc., Domtar Industries Inc., International Salt Co., and Morton International imported 47% of the total imports of 4.9 million tons. Five companies that manufacture chlorine, which was the single largest domestic salt market, consumed 29% of total imports, which were primarily solar salt. These companies were Brunswick Pulp and Paper Co., LCP Chemical & Plastics Inc., Occidental Chemical Corp.,

Atochem North America (Pennwalt), and Weyerhaeuser Co. The salt and chloralkali producers imported 76% of total imports; the remainder were to many small direct buyers. Eight domestic salt producing companies exported 87% of the 588,306 tons exported in 1989, according to PIERS. The Journal of Commerce data contains only ocean commerce and no rail or truck trade between Canada and Mexico. These data may differ from total data reported by the Bureau of the Census. Tables 10 through 13 list the import and export statistics reported by the Bureau of the Census for 1988 and 1989.

WORLD REVIEW

Table 14 lists world salt production statistics for 97 countries based on reported

and estimated information. World production increased 4% in 1989 compared with that of the previous year. Since 1970, world salt production has increased more than 30%, whereas world population has risen 44%, from 3.63 billion to 5.19 billion individuals. Based on these statistics, the world annual per capita consumption has decreased from 89 pounds to 80 pounds.

Industry Structure

The United States remains the world's leading salt-producing nation, representing about one-fifth of total world production. The structure of the U.S. industry has changed throughout the years. In 1970, there were 50 companies operating 95 plants in the United States. Market competition, energy and labor costs, less expensive imports, and an excess of production

capacity reduced the size of the industry to 31 companies and 69 plants by 1989.

Most countries possess some form of salt production capability with production levels set to meet their own domestic demand requirements with additional quantities available for export. Many developing nations tend to develop their agricultural resources first to feed their population. Development of easily extractable mineral resources follows with salt being one of the first commodities to be

mined. Some countries, such as the United States, import a substantial amount of salt to meet total demand requirements because of economic factors.

Capacity

Each type of salt produced in the world has unique mining, processing, and marketing characteristics that determine the criteria for deriving rated capacities. The data shown in tables 15 through 17 are rated

capacities for mines and refineries and salt requirements for salt-base chlorine facilities as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with maximum capital expenditure. Tables 15 and 16 list the annual production capacities of domestic rock salt, solar salt, vacuum pan salt, and salt brine producers. Table 17 incorporates the domestic capacity data with foreign salt capacities. Capacity data were derived from industry sources, published reports, and estimates based on production trends.

Rock.—Because the majority of rock salt was used for deicing, the operating rate of rock salt facilities fluctuated with the demand for deicing salt, again dependent on the severity of winter weather conditions. During periods of strong demand, production levels often achieve, or exceed in certain situations, the rated capacities. Full mine capacity generally is a function of the hoisting capabilities of the mines. Assuming that the workweek is 5 days (250 workdays per year), two working shifts and one maintenance shift per day, and at least one short-term planned turnaround for the mine and mill per year, tables 15 and 17 list the production capacities for domestic and foreign rock salt operations.

Solar.—Solar salt, also known as marine and sea salt, is obtained from the solar evaporation of seawater, of landlocked bodies of saline water, and of discharged brines. Because evaporation rates must exceed the precipitation rates, the climatic conditions and geographic locations of solar evaporation facilities are critical to the successful production and harvesting of solar salt. Therefore, rated capacities generally are based on the historical evaporation patterns within a region and vary depending on the location and the surface areas of the evaporation ponds. Only unpredictable seasonal precipitation and market conditions usually affect the production, and market conditions usually affect the production rates of the facilities.

Vacuum Pan.—The mechanical evaporation of salt by the vacuum pan process is dependent on the number and size of the vacuum crystallizers operating in series. Rated capacities are usually easier to establish because of the proven design performance of the equipment.

Brine.—Brine capacities are difficult to derive because they are based on the variabilities of the injection rate of the solvent and the solubility rates of the underground salt bodies. Both determine the quantity of brine produced. In addition, production levels are dependent on the demand for the products that the brine is being used to manufacture. Therefore, individual company and country brine capacities are not included in tables 15 and 17, except in cases where capacities were derived from actual published brine statistics and the assumption made that brine capacity was equal to brine production. Table 16 lists the quantity, type, and source of the salt required to manufacture chlorine. The amount of brine purchased or used captively is close with the quantity of brine used for chloralkali production as noted in table 7.

Country capacities in table 17 may include data on solution-mined brine or naturally occurring brine, which were incorporated with other salt production statistics.

Brazil

The Government announced plans to construct a 138,000-ton-per-year chlorine facility in Sergipe that will use rock salt from nearby deposits. The plant was scheduled to come on-stream in the early 1990's.

Netherlands

Akzo NV, the world's largest producer of salt, will spend \$50 million to modernize its salt processing plant in Hengelo. The project, scheduled to commence in 1990 and be completed in 1992, will feature new automated control equipment.

OUTLOOK

The environmental concerns raised during 1989 will continue into the 1990's. Greater emphasis will be placed in stricter air and water quality controls. The deterioration of the ozone layer because of the breakdown of CFC molecules in the up-

Source: Bureau of the Census.

per atmosphere and dioxin contamination of surface waters from chlorine-base paper bleaching chemicals have begun to affect the future outlook of the chlorine industry, which uses a tremendous amount of salt

brine and also a lot of purchased rock and solar salt. Discharges of salt into ground water supplies will also be more thoroughly studied. Some releases are of natural origin, such as the dissolution and collapse

of certain underground salt formations in south-central Kansas, which led to contamination of fresh water wells and salinity increases in rivers. Other releases have been attributed to runoff from highway deicing and discharges from water softening units. Objective scientific investigations regarding the source of salt discharges can alleviate most of the public's concern about water quality without having to reduce sales of water conditioning salt, which is used to regenerate ion exchange water softening units, and highway salt.

The salt industry has been responsive to the public's awareness of the corrosion problems associated with highway deicing. Five of the major salt producers have developed corrosion inhibitors that, when added to rock salt, will reduce the corrosive action to bridges and roads using regular rock salt during the winter. Although calcium magnesium acetate (CMA) is a non-corrosive deicer, it is very expensive when compared with regular rock salt or the corrosion inhibitor-treated salt. The outlook for these treated-salt products is very favorable, especially in areas of the country that want to regulate the use of deicing salt.

Between 1970 and 1989, world salt production has increased about 1.3% per year, while the United States had a -1% per year rate of decline in production and -0.7% per year decline in consumption. The negative growth rate for the United States was for total salt. It should be noted that the dry salt component (vacuum pan, solar, and rock) grew at about 0.5% per year. Production and consumption of brine declined since 1970, causing the growth rate for the commodity to decline proportionally. Brine consumption decreased because of the demise of the synthetic soda ash industry, which used salt brine as feedstock. In 1970, there were eight synthetic soda ash plants in operation in the United States; only one was in existence by 1980. It closed in 1986.

In the 1980's, world production was 1.2% per year, while U.S. production declined -0.8% annually, and consumption decreased about -0.5% per year. As with the previous assessment of the industry, domestic dry salt usage grew 1.2% per year since 1980 while salt brine consumption decreased. Despite the adverse publicity in the 1980's regarding the use of salt (i.e., salt contributes to hypertension in some humans, corrosion from oversalting the highways, high sodium levels in drinking water), the dry salt industry has managed

to strengthen its position by developing sensible salting policies for deicing salt and working cooperatively with the food processing industry to address the salt in human nutrition issue. The Salt Institute,

which is the trade association for the majority of the producers, and the U.S. salt industry have worked closely and effectively with salt consumers and the public to educate and promote the benefits of salt.

The outlook for salt in the 1990's is optimistic. The major producers have diversified into all types of salt across the Nation and have developed reliable import sources in Canada, the Caribbean, and Mexico. Consolidations and restructuring within the U.S. salt industry have strengthened it into a competitive North American enterprise in the Western Hemisphere. Domestic salt consumption is forecast to grow about 1.3% to 1995.

BACKGROUND

Salt has been an important commodity throughout history. Its presence has determined the location of cities, migration of populations, and routes of trade caravans. One of the earliest accounts of using salt in political-economic societies was traced to about 2000 B.C. in China where Emperor Yu decreed that Shandong Province would supply the court with salt. The Phoenicians (1200 B.C.-300 B.C.) were one of the first maritime civilizations to trade salt. Salt became an important universal medium of exchange. The English word "salary" is derived from the Latin term "Salarium argentum," which were the salt rations that Roman soldiers were partially paid for their services. Aside from its use as a medium of monetary exchange, salt has also been used to signify hospitality. The custom of presenting newlyweds wine, bread, and salt shows salt as a lifegiving and sustaining substance. In many areas of the world, it is still the custom for the host to offer bread and salt upon entering the home. The custom is also practiced "out of this world"—it has been a tradition that all U.S.S.R. staffed spaceflights carry aloft bread and salt and leave them behind on the orbiting space station as presents for the next visiting crew.

The first production of salt in the United States was in 1614 by the Virginia colonists who evaporated seawater. The practice of extracting salt from subsurface brine was first employed in the United States at Onondaga, NY, in 1788. In 1862, the first rock salt mine in North America began operating at Avery Island, LA. Solution mining of salt began in about 1882 and consisted of drilling a small diameter well down to a salt bed, pumping freshwater down to dissolve the salt, and pumping the resultant brine to the surface for subsequent evaporation. In 1887, the vacuum pan was invented, which incorporated a vacuum

during evaporation to allow the water to boil from the brine at a lower temperature. This technological achievement reduced fuel consumption below that of direct-heated units.

Definitions, Grades, and Specifications

Technically, salt is a generic term that describes compounds formed by the partial or complete replacement of the hydronium ion of an acid by a metal or metallic radical. Water and salts are the end products from the chemical reaction between acids and bases. Through time, however, "salt" has become synonymous with sodium chloride (common salt) and will be considered equivalent throughout this chapter.

Naturally occurring sodium chloride is mineralogically known as halite. Pure salt contains 39.3% sodium and 60.7% chlorine by weight. Halite deposits usually contain between 1% and 4% impurities, mainly gypsum, shale, dolomite, and quartz. Rock salt is halite that is mined underground by conventional room-and-pillar techniques.

Evaporated salt is the term applied to fine crystals of salt obtained by evaporating brines, either natural or manufactured from solution mining, in large, vacuum-enclosed or open steam-heated kettles. Solar evaporated salt is the product harvested from shallow ponds after the brine has been exposed to solar and wind evaporation.

The physical characteristics of salt varies with the type of production process. Salt specifications from vacuum pan operations are the same because the process is similar throughout the country. Rock salt, however, can vary in color and composition with locality, and these characteristics influence the specification of the final product. Some impurities must be removed by chemical treatment or filtration to meet specifications for certain end uses.

There are various standards issued by different organizations that apply to salt. These standards may vary, depending on the intended end use. For example, salt for human consumption requires different specifications than those of salt for deicing highways.

Products for Trade and Industry

Salt for human consumption is packaged in different sized containers for several specialized purposes. Table salt can contain 0.01% potassium iodide as an additive that provides a source of iodine that is essential to the oxidation processes in the

body. Kosher salt, seasalt, condiment salt, and salt tablets are special varieties of salt.

Water conditioning and animal feedstock salt are made into 50-pound pressed blocks. Sulfur, iodine, trace elements, and vitamins are occasionally added to salt blocks to provide missing nutrients not found naturally in the diet of certain livestock. Salt is also compressed into pellets and used for water conditioning.

Geology-Resources

The definitions of reserves and reserve base are published in the U.S. Geological Survey Circular 831, "Principles of a Resource/Reserve Classification for Minerals."

The oceans are the world's largest resource of salt. Seawater contains 3.5% dissolved solids by weight with sodium chloride representing the major component, approximately 2.5% by weight. The world's oceans contain about 44×10^{15} tons of sodium chloride, which is equivalent to 4.5 million cubic miles in volume or a cube measuring 165 miles on edge.

Domestic salt resources are found mainly in four large depositional basins, covering an area totaling about 0.5 million square miles in 18 States. These basins are (1) the gulf coast, which covers part of Florida, Alabama, Mississippi, Arkansas, eastern Texas, and all of Louisiana; (2) the Permian, which is in part of New Mexico, Colorado, Kansas, Oklahoma, and Western Texas; (3) the Salina, covering part of New York, Pennsylvania, West Virginia, Ohio, and Michigan; and (4) the Williston, encompassing part of North and South Dakota, Montana, and Wyoming. The gulf coast and Permian basins extend into Mexico; the Salina and Williston both extend into Canada. The identified salt resources of the United States are estimated at 61×10^{12} tons and are being depleted at the rate of about 39 million tons annually. At the present level of production, the United States has enough salt to mine for more than 1.6 million years. Solar evaporation of coastal seawater would extend this rate virtually forever.

Salt can be geologically classified by its occurrence as evaporite deposits and in solutions.

Evaporite Deposits.—Bedded, diapiric flow, and playa salts are the major types of dry salt deposits. Bedded salt deposits were formed by the accumulation of

^eEstimated. ^pPreliminary. ¹Revised.

¹Table includes data available through June 13, 1990.

²Salt is produced in many other countries, but quantities are relatively insignificant and reliable production data are not available. Some salt brine production data for manufacture of chlorine, caustic soda and soda ash are not reported because of incomplete data reporting by many countries.

³Reported figure.

⁴Year ending June 30 of that stated.

⁵Less than 1/2 unit.

⁶Brine salt production as reported by the Burmese Government in short tons, was as follows: 1985—49,061; 1986—57,413; 1987—70,220; 1988—73,260; and 1989—65,000 (estimated).

⁷Revised to zero.

⁸Rock salt only for 1985.

⁹Marine salt and other for 1985.

¹⁰Data are for year beginning Mar. 21 of that stated.

¹¹Does not include production from Sardinia and Sicily, estimated at 220,000 short tons annually.

¹²Data captioned "Brine salt" for the United Kingdom are the quantities of salt obtained from the evaporation of brines; that captioned

"Other salt" are the salt content of brines used for purposes other than production of salt by evaporation.

precipitated salts on the seafloor of ancient landlocked marine bodies of water. Extensive and widespread evaporation was essential to form these massive rock salt deposits, some of which measure up to 3,000 feet in thickness.

Salt domes form when vertical or lateral pressures are applied to stratified salt deposits in which low-density salt will flow plastically through the surrounding rocks of higher density. The salt domes of Romania, the Federal Republic of Germany, and the gulf coast of the United States are examples of diapiric salt flows. The appearance is usually cylindrical with circular or elliptical diameters. A cap rock of anhydrite is common with overlying layers of gypsum and calcite. Oil, gas, and sulfur are associated with many domes and represent large mineral resources. There are 329 proven salt domes in the gulf coastal province and offshore regions of the United States. Louisiana has 183 domes onshore and offshore; Texas, 83; Mississippi, 61; and Alabama, 2.

Playas are flat, vegetation-free floors of an undrained desert basin that may occasionally be covered by water. Post evaporation minerals such as sodium carbonate, sodium sulfate, sodium chloride, borates, nitrates, phosphates, and potash result from the leaching of the rocks surrounding the basin by water flowing into the playa. Searles Lake in California is a classic example of a salt-bearing playa lake.

Salt in Solution.—Ocean, lake, and ground water are the primary aqueous mediums in which salt is dissolved. Seawater contains many dissolved minerals, the major one being sodium chloride. Other dissolved minerals include various sulfate, magnesium, calcium, and potassium compounds.

Water tends to accumulate on land in topographic depressions created by tectonic uplifts or subsidences of the Earth's upper crust. As mineralized solutions from upland sources drain into these basins, solar evaporation concentrates the salts to form saline lakes. The Aral Sea in the U.S.S.R., Great Salt Lake in Utah, and the Dead Sea between Jordan and Israel are examples of this process.

Ground water is composed of mineralized connate and meteoric water found in permeable sedimentary formations. In some areas, sodium chloride-rich brines migrate to the surface through intersecting fractures and joints in the rock strata to form local salt springs.

³Includes brine for sale and for captive use. Brine production capacity is assumed to be equal to the quantity of annual brine production, as shown in tables 2 and 3. Brine producers include those chloralkali manufacturers that purchase brine or use captive brine, as listed in table 16.

Note.—Cargill's Freedom, OK, solar plant; Akzo's Williston, ND, vacuum pan plant; and Morton's Trona, CA, solar plant have been closed.

Technology

Exploration.—Exploring for new salt deposits is based on examination of various geochemical and geophysical information. Analysis of the underlying strata by core drilling, oil and water well logs, or other techniques is the basis for establishing the size of the deposit. Usually the most favorable areas for mine development will be located near the market regions and convenient transportation routes.

The development of mines incorporates strict safety precautions while permitting for the maximum economic recovery of salt. During shaft sinking, water-bearing strata may be encountered, and waterproofing techniques must be employed to prevent mine flooding. At least two access shafts are constructed in room-and-pillar mines to provide adequate safety and ventilation.

Mining.—Rock Salt.—Rock salt is mined by the room-and-pillar method, which is similar to that used in coal and trona mining. The salt is drilled, cut, blasted, mucked, crushed, and transported to the surface for processing, which usually involves removing the impurities and screening the material to finer size fractions.

Underground mining practices of bedded rock salt and domal salt formations are similar except for the height differences within the mines of the two types of operations. For example, bedded formations usually are laterally extensive but are vertically restricted. Salt domes are laterally restrictive but are vertically extensive. Many salt domes have depths in excess of 20,000 feet, yet many outcrop at the surface. Most gulf coast salt mining operations are generally less than 1,000 feet below the surface. Working at deeper depths is difficult because of higher temperatures and denser rock.

Solar Evaporation.—Solar evaporation is an effective method of producing solar salt in areas of high evaporation and low precipitation. Along coastal margins in many parts of the world, seawater is collected and allowed to evaporate in specially constructed evaporating ponds. Saline lakewater is also processed using this method. The ponds are separated by levees that isolate the brine during different stages of fractional crystallization.

The initial step concentrates the brine to increase the salinity and allow many calcium, magnesium, and iron compounds

to precipitate from solution. The brine is circulated among a network of interconnecting ponds, with salinity increasing with each transfer. The brine is then treated with lime to remove excess calcium sulfate and then pumped to evaporation ponds and then transferred to harvesting ponds to permit the salt to crystallize. After about 85% of the salt is precipitated, the remaining supernatant liquid, called "bitterns," can be drained to adjacent ponds for subsequent extraction of magnesium, potassium, bromine, and sodium compounds. The harvesting pond is flooded again with new brine from the lime pond to repeat the cycle. It takes about 5 years once seawater is first introduced into the system for the completion of the crystallization process. The salt is harvested by special tractors equipped with scrapers and ready for processing.

Solution Mining.—The first reported use of solution mining was about 250 B.C. in China when holes were drilled into deep salt deposits. The brine was brought to the surface by pipes made of bamboo. The brine was evaporated over fires fueled with wood, coal, or natural gas. The basis of current technology began in France around A.D. 858. An injection well is sunk, and pressurized freshwater is introduced to hydraulically fracture the bedded salt. Once communication with the production well is established, the brine is pumped to the surface for treatment.

Roof collapse of the overlying strata and surface subsidence are potential problems associated with solution mining; however, producers have taken precautions to minimize these hazards. One method that had been used was injecting air with the water into the salt caverns. The air formed a protective cover between the water and the top of the cavity that reduced the amount of dissolution of the roof.

Beneficiation.—Rock Salt.—About 68% of total rock salt produced and imported is for highway deicing. Crushing and screening to the proper physical size is usually the only processing that road salt undergoes. In many operations, these steps are done underground in the mine to minimize haulage and storage costs. In addition, the extremely fine fraction, which often is unusable, remains underground rather than on the surface, which would represent a waste product to be disposed.

Solar Salt.—After harvesting, the salt crystals are washed with dilute brine to remove residual bitterns and impurities. The salt is transferred to processing facilities where it is washed with saline water, dried for about 8 minutes at approximately 300° F, and screened into fine to coarse sizes, depending on the end use of the salt to be sold. Most operations ship solar salt in bags and in bulk, using barges, truck, and rail transportation.

Mechanical Evaporation.—Salt obtained by dehydrating brine using heat alone or in combination with a vacuum is vacuum pan salt. The vacuum pan process conserves energy by utilizing multiple-effect evaporators connected to vacuum pumps. A saturated salt solution will boil at a higher temperature than pure water. When a vacuum is applied, the brine boils at a lower temperature, enabling the superheated vapor that is generated to act as the heating medium for the next evaporator.

The grainer or open pan process uses open, rectangular pans with steam-heated immersion coils to evaporate the water in the brine. Rotating rakes scrape the salt precipitate into a sump or up a ramp, depending on the method, and onto conveyors for debriining and drying treatment. The final product is usually flake shaped rather than the typical cubic form. Flake salt is preferred for production of cheese, butter, and baked goods.

The Alberger process is a modified grainer operation that produces cubic salt with some flake salt. The pans are shallow, circular units with external heating units, rather than heating coils. The open pan process cannot be operated successfully in regions with high humidities because the evaporation rate is too slow and more energy is required to evaporate the brine.

Desalination.—The conversion of saline water into freshwater has important municipal, industrial, and agricultural applications. Aside from obtaining pure water, desalination also produces byproduct salt. There are four processes presently employed in water desalinization and each has different cost and energy factors. The processes are distillation, membrane, freezing, and ion exchange. Some salt from these processes is used by the chemical industry. In some regions, salt is returned to the saline water source. Seawater typically contains 3.5% to 4.5% salt, or 35,000 to 45,000 parts per million.

NA Not available, although production is known to occur.

¹Capacities were derived from industry sources, published reports, and estimates based on production trends. Salt brine capacities are not meaningful because they vary with production levels of brine feedstock to chemical plants. Therefore, salt brine capacities are not included in the list, except for certain countries that incorporate brine statistics with other types of salt. In these exceptions, brine capacities are assumed to be equal to the quantity of brine produced in 1988.

²Also known as marine salt.

³Some countries report "refined salt," which may or may not be vacuum pan salt, but washed or screened rock or solar salt. Efforts were made to categorize refined salt into the appropriate type of salt.

⁴May include brine or salt from undisclosed sources.

⁵Contains salt produced as a byproduct or coproduct from potash mining. Additional salt may be recovered but discharged as a waste product.

⁶Contains salt produced as a byproduct or coproduct from sulfur mining.

⁷Contains salt produced as a byproduct or coproduct from gypsum mining.

⁸Salt is imported, washed, repackaged, and exported.

⁹Byproduct salt from potash mining is 8.5 million tons, of which only about 880,000 tons are sold and the remainder discharged.

¹⁰Recovered from geothermal brines.

¹¹Less than 1/2 unit.

¹²Byproduct salt from potash mining is 2.65 million tons, of which only about 500,000 tons are sold and the remainder discharged.

¹³Includes about 220,000 tons of sea salt recovered using open pan process.

¹⁴From evaporating brine from salt springs or wells over wood fires.

¹⁵Plants from brine marshes are washed to obtain a salt solution, which is heated in containers to recover salt.

¹⁶From mechanical evaporation of seawater at petrochemical complex.

¹⁷Salt is obtained from several seawater desalination plants but amount of recovery is uncertain.

Economic Factors

Energy and labor costs are important factors that affect production costs, and ultimately the selling price, for all types of salt. After the salt is produced, shipping costs become very important when attempting to sell to a customer that is in proximity to other salt producers. Industry sources indicate that within the United States, a 300-mile radius is an effective limit of competition for a producing location before the influence of other competitors is noticed. Some of the major U.S. producers also have foreign subsidiaries that produce salt, which is imported at prices favorable to many consumers because transportation costs are less.

Capital investment and energy costs are important factors that influence the selling price of the type of salt produced. Vacuum pan and open pan processing requires more equipment and energy than solution mining, and consequently, the average value of evaporated salt is considerably higher than that of salt in brine.

Prices.—The four types of salt that are produced each have unique production, processing, and packaging factors that determine the selling prices. Generally, salt sold in bulk is less expensive than salt that has been packaged, pelletized, or pressed. Salt in brine is the least expensive salt sold because costs are less. Vacuum pan salt is the most expensive because of the energy costs involved in processing. Table 19 lists the historical values of the different types of salt since 1970. The data are compared with 1989 constant dollars to show the effect of inflation and general economic conditions on the values.

Tariffs.—The United States imports about four to six times the quantity of salt that it exports. Imports from countries having most favored nation (MFN) status enter duty free. However, salt imported from non-MFN countries have a 26% ad valorem tax imposed.

Operating Factors

Environmental Requirements.—The environmental problems associated with salt mining are few and tend to be localized without major impacts on the environment. A major concern in solution mining is the potential of land subsidence. As the salt is dissolved, some roof collapse may occur, causing sections of the surface to partially

The standard for drinking water in the United States is 500 parts per million.

Byproducts and Coproducts

Salt is a coproduct from various seawater and saline lake operations. Depending on the cost of recovery and processing, certain magnesium, potassium, and bromine

compounds can be produced from the bitterns. Subterranean brines also contain borax, calcium chloride, sodium carbonate, and sodium sulfate in addition to the above. Certain potash operations in the world also produce salt as a coproduct. When discharged to tailing ponds as a byproduct of potash mining, salt is often harvested and sold by second parties.

^cEstimated.

¹Represents that amount sold or used captively within the industry, from the quantity produced and any sold from inventory. Accurate data on beginning and yearend inventories of salt are unavailable and often are underreported because of additional storage underground at mines, warehouses, terminals, etc. However, about 2.5 million tons are estimated to be stored annually nationwide.

²The total quantities of salt in inventory are underreported and are excluded in determining the supply-demand balance relationship for salt. However, the difference between production and sold or used is assumed to be because of changes in inventory.

³Includes imports for consumption.

⁴Includes salt used in rubber; tanning; other industrial; institutional wholesales and/or retailers; U.S. Government resale; other wholesalers; some exports for consumption in overseas territories administered by the United States; and other various minor uses.

⁵Represents the difference between the quantity reported to the Bureau of Mines and total U.S. primary demand. The amount of discrepancy is attributed to variances in inventory and import statistics.

⁶Values are based on the average of all salt producers' valuations reported for bulk, f.o.b. plant, and includes all processing costs, depreciation of equipment, taxes, and profit.

Source: U.S. Bureau of Mines.

FIGURE 2
U.S. SALT SOLD OR USED, BY TYPE

or totally fill the cavity. Subsidence is unpredictable, and once the process begins, it must be allowed to finish and reach equilibrium. Another issue pertaining to solution mining is the potential problem of well casing leakage. Any excursion of salt brine could affect groundwater supplies, which are protected by various State and Federal water quality regulations. Solar evaporation facilities may substantially disturb coastal marsh areas because of the large extent of the lagoons needed for efficient operation.

Employment.—According to the Bureau of Mines salt survey, 4,284 people were employed in the mining and processing of salt in 1988. The quantity employed by type of salt and by mine and mill activity was as follows: rock salt, 1,021 in the mine and 278 in the mill; solar salt, 105 in harvesting and 610 in the processing plant; vacuum pan salt, 2,197 in the processing plant; and salt brine, 54 in solution mining and 19 in the processing plant.

¹E-534-75 is an analytical standard that is necessary for a meaningful salt specification.

²Input regarding food and table salt specification is necessary to maintain quality products in these areas.

³Work has been done with medical salt standards to obtain reasonable specifications.

⁴The ANSI Packaging Standard is a voluntary standard for primary salt containers, secondary containers, and pelletized shipping units.

⁵UU-S-48F gives Federal Sack Specifications. An effort has been made in this area to obtain a reasonable standard.

Source: Salt Institute.

Transportation.—The locations of the salt supplies often are not in proximity of the consumers location, and transportation can become an important cost. Pumping salt brine through pipelines is an economic means of transportation, but cannot be used for dry salt. Large bulk shipments of dry salt in ocean freighters or river barges are low in cost, but are restricted in points of origin and consumption. River and lake movement of salt in winter is often severely curtailed because of frozen waterways. As salt is packaged, handled, and shipped in smaller units, the costs are increased and are reflected in higher selling prices.

Ocean borne imports of salt have been increasing in some areas of the United States because they are less expensive with respect to transportation costs than what could be purchased from many domestic suppliers using rail transportation. Salt continued to be one of the most heavily traded chemical industry ores in the world, representing about 66% of world seaborne mineral trade.

CONSTRUCTION SAND AND GRAVEL

By Valentin V. Tepordei

Mr. Tepordei, a geological engineer with more than 20 years industry experience, has been the construction sand and gravel commodity specialist with the Bureau of Mines since 1979. Domestic survey data were prepared by Olga E. Valdes, mineral data assistant.

A total of 897 million short tons of construction sand and gravel was estimated to have been produced in the United States in 1989, a 2.8% decrease compared with that of 1988. This tonnage represents the fourth consecutive year of production over 880 million tons, indicating a continuation of the strong demand for construction aggregates.

Foreign trade of construction sand and gravel remained relatively minor. Exports increased 16.6% to 1.1 million tons, while value increased 23% to \$13.6 million. Imports increased 21.7% to 427,000 tons, while the value increased 109% to \$6.6 million. Domestic apparent consumption of construction sand and gravel was 897 million tons.

The new regulatory requirements being proposed by the Occupational Safety and Health Administration (OSHA) regarding its revised asbestos standards governing occupational exposure to non-asbestiform varieties of actinolite, tremolite, and anthophyllite (AT&A) minerals, and the final promulgation of the permissible exposure limit for crystalline silica, measured as respirable silica, constitute major areas of concern for the industry.

DOMESTIC DATA COVERAGE

Domestic production data for construction sand and gravel are developed by the Bureau of Mines from voluntary surveys of U.S. producers. Full surveys of construction sand and gravel producers are conducted for even-numbered years only. For odd-numbered years, a preliminary survey that collects production information on a sample basis is used to generate only annual estimates for each State. In addition, a new quarterly sample survey for crushed stone and sand

and gravel was implemented by the Bureau of Mines in 1989, providing for the first time production estimates by quarters for each State and the nine geographic regions. The results of this survey are published each quarter in a separate publication, the Quarterly Mineral Industry Survey. Both sample surveys canvass most of the large companies in each State, accounting for up to 80% of each State's total tonnage.

LEGISLATION AND GOVERNMENT PROGRAMS

On January 13, 1989, OSHA announced the final promulgation of exposure limits for 400 air contaminants, establishing a permissible exposure limit (PEL) of 0.1 milligrams per cubic meter (mg/m³) for crystalline silica, measured as respirable silica.¹ Despite this ruling, some statements in the preamble indicate that OSHA may in the future consider the need to lower the

standard, based on "emerging developments in this area."

On August 29, 1989, the Mine Safety and Health Administration (MSHA) published a new proposed rule that revises MSHA's existing standards for air quality and chemical substances at coal and metal nonmetal mines. The proposed rule contains permissible exposure limits for substances that may pose health hazards at these operations. In addition, the proposed rule contains revised requirements for exposure monitoring, carcinogens, and respiratory protection programs. The original deadline for receiving comments about the proposed ruling was November 27, 1989, and was extended to March 2, 1990.²

On July 21, 1989, OSHA announced another extension, through November 30, 1990, of the stay for the new provisions of its revised asbestos standards governing occupational exposure to nonasbestiform varieties of AT&A minerals. The revised asbestos exposure standards were originally published by

OSHA on June 20, 1986. The former asbestos standard remains in effect for the extent of the stay. Based on OSHA's Hazard Communication Standard, a product is considered carcinogenic if it contains 0.1% or more of an OSHA-designated carcinogen. The inclusion of nonasbestiform AT&A minerals in the asbestos exposure standards effectively designates large areas of the United States as containing carcinogenic minerals. The revised OSHA regulations for airborne asbestos standards, if implemented, are expected to have a significant impact on the aggregates and the construction industries that could include increased mining and construction costs and disruption of the supply of aggregates in most areas.

In 1989, MSHA established a new program to combat illegal mining. The program will be enforced through an Illegal Mining Task Force, as well as MSHA officials at the local level. MSHA considers a mining site illegal when the operator fails to register the site with the agency.

ISSUES

On June 20, 1986, OSHA published a final rule titled "Occupational Exposure to Asbestos, Tremolite, Anthophyllite, and Actinolite; Final Rules." The regulation, which was amended in September 1988, established exposure limits for asbestos and nonasbestiform varieties of the amphibole minerals AT&A. Under OSHA regulation, all products containing a specified concentration of these minerals must be labeled as having a constituent that is a carcinogen.

In an effort to assist OSHA in its decision regarding implementation of the final asbestos standard, the Bureau of Mines completed in August 1989 a study entitled, "Analysis of the Cost Effectiveness of the OSHA Regulation of Nonasbestiform Amphiboles with Respect to Selected Sectors of the Domestic Minerals Industry." The Bureau's analysis questions "whether OSHA has conclusively demonstrated a health risk associated with AT&A and, consequently, that these minerals should be regulated at all, given that no discernible net benefits will result." The study has also "identified a basic inconsistency between OSHA's

definition of asbestos and its asbestos standard," and found that "the regulation will result in economic impacts on several minerals industry sectors."

"The economic impact of the OSHA regulation is expected to be greatest on the aggregates industry. Due to product liability considerations," it is suggested that "every sand and gravel deposit in the United States would have to be examined at least at the cursory level, at a minimum cost of \$1,000 per deposit. Sales losses in the aggregates industry are possible and would be contingent on the availability and cost of material that is essentially free of AT&A, and the liability concerns associated with using products containing AT&A."

In the concluding section of the study, "it is recommended that OSHA not regulate AT&A as asbestos unless medical data conclusively show that these minerals present a health risk which would be reduced through regulations;" that "OSHA should revise its asbestos and fiber definitions, to make the two terms consistent from a mineralogical standpoint;" and that "OSHA should specifically address the economic impact of its proposed regulation on the minerals industry and weigh these costs against possible benefits."

PRODUCTION

The production estimates indicate that in 1989 the U.S. production of construction sand and gravel was 897 million tons, a 2.8% decrease compared with that of 1988. Of the four major geographic regions, the West again led the Nation in production of construction sand and gravel with 330 million tons, or 36.7% of the U.S. total, followed by the Midwest with 271 million tons, or 30.3% of the total; the South with 188 million tons, or 20.9%; and the Northeast with 109 million tons, or 12.1%. Compared with 1988, production by major geographic regions decreased 16.2% in the Northeast and 7% in the South, but increased 2.8% in the West and only 0.1% in the Midwest.

Of the nine geographic regions, the Pacific again led the Nation with 208 million tons, or 23.2% of the U.S. total. Next was the East North Central with 177 million tons, or 19.7% of the

total, followed by the Mountain with 121 million tons, or 13.5% of the total. Compared with 1988, production increased in three of the nine regions, the largest increases being recorded in the Mountain region, 5.9%; the West North Central, 4.6%; and the Pacific region with only 1.1%. The production decreased in the remaining six geographic regions with the major decreases occurring in New England, 26.6%; West South Central, 9.9%; and Middle Atlantic, 8%.

The estimated production by quarters for 1989 indicated that most of the construction sand and gravel in the United States was produced in the third quarter of 1989, followed by the second quarter and the fourth quarter. Estimated production by each quarter of 1989 was also available for most of the States.

Construction sand and gravel was produced in every State, and the 10 leading States were, in descending order of tonnage, California, Michigan, Ohio, Texas, Washington, Arizona, Minnesota, Illinois, New York, and Indiana. Their combined production represented 52.9% of the national total.

Compared with 1988, production increased in only 16 States, including 4 of the top 10 States. The increases were significant in Washington, 21.3%; Indiana, 14.2%; and Illinois, 9.6%.

Fewer acquisitions by foreign or domestic companies and mergers occurred in the construction sand and gravel industry in 1989. Lone Star Industries Inc., of Greenwich, CT, completed in January 1989 the sale of its remaining 40% interest in Tarmac-Lone Star joint venture to Tarmac America of Herndon, VA, a division of Tarmac PLC of Wolverhampton, United Kingdom. The original joint venture was established in 1986. The latest transaction included remaining interest in aggregates, cement, concrete, and concrete products operations located in North Carolina, South Carolina, and Virginia.

Great Lakes Dredge & Dock Co. of Chicago, IL, sold 25% of its 75% interest in McCormack Aggregates Co. of South Amboy, NJ, to Ralph Clayton & Sons Materials of Lakewood, NJ. Clayton also bought McCormack Sand Co.'s entire 25% stake in the company and changed its name to Amboy Aggregates. McCormack, presently the largest offshore producer of sand and

gravel in the United States, will continue to supply sand and gravel in Connecticut, New Jersey, and New York.

Redland PLC of Gorby, United Kingdom, acquired through its subsidiary, Western-Mobile Inc. of Denver, CO, Flatiron Sand & Gravel Co. of Boulder, CO. The transaction included the assets of Flatiron Sand & Gravel, Flatiron Paving, Flatiron Premix Concrete, and Plains Aggregate Co. Redland also owns in the United States Genstar Stone Products Co. of Hunt Valley, MD, and Redland-Worth Corp. of San Antonio, TX.

CalMat Co. of Los Angeles, CA, formed a joint venture with Owl Rock of Arcadia, CA, to acquire Kirst Construction Co., the owners and operators of Azusa Rock of Fish Canyon, CA.

ARC America Corp., of Newport Beach, CA, a subsidiary of ARC Ltd. of Bristol, United Kingdom, and one of the major sand and gravel and crushed stone producers in the United States, was acquired by Hanson Trust PLC of London, United Kingdom. The change in ownership followed the acquisition by Hanson PLC of the Consolidated Gold Fields

PLC, of London, United Kingdom, the parent company of ARC Ltd. At the end of 1989, Hansen PLC was in the process of selling all ARC America operations to Colonial Sugar Refineries (CSR) Ltd. of Sydney, Australia, a major sugar and building-material producer. The transaction includes American Aggregates Co. of Greenville, OH; Associated Sand and Gravel Co. of Everett, WA; and WMK Co. of Las Vegas, NV. CSR already owns Rinker Materials Corp. of West Palm Beach, FL.

Limited information about the production of construction sand and gravel in foreign countries may be found in the Bureau of Mines "Minerals Yearbook, Volume III, Area Reports: International." For nonreporting countries, estimates of sand and gravel and crushed stone outputs can be based on indirect sources such as the level of cement consumption.

CONSUMPTION AND USES

Sand and gravel reported by producers to the Bureau of Mines is actually

material that is "sold or used" by the companies and is defined as such. Stockpiled production is not reported until it is sold to a user or consumed by the producer outside its own operation. Because no consumption surveys are conducted by the Bureau of Mines, the "sold or used" tonnage is assumed to represent the amount produced for domestic consumption and export.

The largest use of construction sand and gravel is as aggregate for the production of concrete, used in nearly all residential, commercial, and industrial buildings and in most public works projects such as highways and roads, bridges, dams, airport runways, sewer systems, tunnels, etc. Over the past several years this use represented about 28% of the total. The second largest use is as base material in the construction and repair of highways, railways, runways, etc; it represented about 15% of the total. Other major uses are as aggregate in asphaltic concrete used for paving highways, streets, and parking lots, about 9%, and as fill in highway construction, earth dams, and other applications where recontouring of the original land surface is required, about

See footnote at end of table.

7%. The above percentages were calculated based on the information provided by the producers. It should be noted that over the past several years, about 39% of the total U.S. production was included in "unspecified uses—actual and estimated" because some producers reported only total production or did not report at all, and then their production was estimated. The percentage of estimated amounts for nonrespondents decreased from 23.5% in 1984 to 13.1% in 1988, while the percentage of production reported only as totals increased from 16.2% in 1984 to 25.9% in 1988.

Sand and gravel are usually used mixed, but some uses require only sand or only gravel. Sand is used in mortar, plaster, and gunite and for snow and ice control. Gravel is used to improve or control drainage and as covering and stabilizer on load-bearing surfaces such as unpaved roads, driveways, and parking areas. In 1989, only production estimates were generated for construction sand and gravel, and, therefore, no information by end uses is available for this year.

PRICES

As a result of rising costs of labor, energy, and mining and processing equipment, the average unit value of construction sand and gravel increased from \$1.11 per ton, f.o.b. plant, in 1970 to \$3.62 in 1989. However, the constant dollar value fluctuated between \$2.63 and \$3.06 per ton for the same period. Increased productivity achieved through increased use of automation and more efficient equipment were mainly responsible for these trends.

FOREIGN TRADE

The widespread distribution of domestic sand and gravel deposits and the high cost of transportation limits foreign trade, mostly to local transactions across international boundaries. U.S. imports and exports are small, representing only about 1% of the domestic consumption.

TABLE 4—Continued
**CONSTRUCTION SAND AND GRAVEL SOLD OR USED BY
 PRODUCERS IN THE UNITED STATES, BY STATE**

(Thousand short tons and thousand dollars)

State	1988		1989 ^c	
	Quantity	Value	Quantity	Value
West Virginia	1,653	6,099	2,300	6,700
Wisconsin	25,048	60,080	21,700	56,400
Wyoming	3,413	11,351	4,500	15,400

^c Estimated.

¹ Data may not add to totals shown because of independent rounding.

Exports

Exports of construction sand decreased 46% to 273,000 tons compared with that of 1988, while value increased 21% to \$5.9 million. Mexico was the

major destination, receiving about 36.3% of the total, followed by Canada with 22.7%. Exports of construction gravel increased 85.6% to 852,000 tons, while value increased 115.7% to \$7.7

million. Canada was the major destination, with 85% of the total, followed by Mexico with 3%.

Imports

Imports of construction sand and gravel increased 21.7% to 427,000 tons compared with that of 1988, while the value increased 109% to \$6.6 million. The Bahamas was the major source of imported construction sand and gravel with 54.3% of the total, followed by Japan with 11.9%, and Canada and Norway with 9.6% each.

reached its midpoint in 1989. Management of ongoing research, rather than the initiation of contracts, became the focus of SHRP's activities. SHRP's mission is to produce usable research results targeted toward technical areas where there is potential for rapid progress that could yield significant cost savings. The four areas of research

are Asphalt, Concrete and Structures, Highway Operations, and Long-Term Pavement Performance Programs.

SHRP's main objective in asphalt research is to produce new performance-based specifications for asphalt binders.³ A wide range of advanced materials characterization techniques like nuclear magnetic resonance and spectroscopy

and computer-aided tomography (CAT) scans are being tested. The CAT scan research conducted at the University of Southern California at Los Angeles could provide a powerful new nondestructive test technique for diagnosing problems in asphalt pavements.

The concrete and structure program includes research in the area of im-

proved concrete materials and corrosion of concrete structures. Under this program, a rapid laboratory test that will determine aggregate reactivity in less than 2 weeks has been developed. Current tests require 9 months to 3 years.

About \$20 billion is spent on highway maintenance in the United States each year, which represents about one-third of total highway spending. This expenditure is growing at a rate of about 9% annually. More cost-effective maintenance methods, equipment, and materials are badly needed. SHRP is addressing this problem through its Highway Operations Program by conducting a series of nationwide field performance tests. Texas A&M Research Foundation has designed an experiment to compare the cost-effectiveness of six preventive maintenance methods to be tested under various climate and traffic conditions. The performance of the maintenance methods will be monitored over 5 years at specially constructed side-by-side test sections on inservice roads throughout the country. The snow-and-ice control is another area of interest for the Highway Operations

Program. The Department of Mechanical Engineering of the University of Wyoming is using computer simulation, model studies, and full-scale prototyping to design and test more efficient and flexible snow-and-ice control equipment and methods.

The University of Washington is developing a rapid laboratory test method for identifying aggregates that are susceptible to freeze-thaw damage. Concrete bridge corrosion is a major problem, affecting a large number of structures around the country. The evaluation of the effectiveness of electrochemical chloride removal technology, an experimental but promising technique for extracting chloride from concrete using electrical current, is advancing under SHRP's Concrete Structure Program.

SHRP's Long-Term Pavement Performance (LTPP) Program is a first-ever major effort to measure pavement performance in different climate and soil conditions at about 1,000 in-service test sections in all 50 States and in Canada. The LTPP program has been planned to run for 20 years, SHRP funding the first 5 years of data gathering and analysis. The data collected as part of the SHRP program is expected to provide sufficient information to refine pavement design that will significantly improve the performance of new pavements.

The Third International Symposium on Unbound Aggregates in Roads (UNBAR3) was held on April 11 through 13, 1989, at the University of Nottingham, United Kingdom.⁴ These symposiums are dedicated entirely to the utilization and characterization of unbound aggregate bases. The in situ testing of compacted pavement layers, innovative methods for placing unbound aggregates to obtain a more uniform end product with a leveled surface, and the use of vibrating hammers or computerized vibratory rollers for compacting both unbound base material and asphalt concrete were some of the topics discussed at this year's symposium.

In response to growing concern over rutting of asphalt concrete pavements, in July 1987, the American Association of State Highway and Transportation Officials (AASHTO) organized a joint taskforce of Federal, State, and industry representatives to study the problem. Participating agencies included

AASHTO, the National Asphalt Pavement Association (NAPA), the Asphalt Institute, the National Stone Association (NSA), the National Aggregates Association (NAA), the Construction Industry Manufacturers Association (CIMA), the National Cooperative Highway Research Program (NCHRP), SHRP, and the Federal Highway Administration (FHWA).⁵

About 70% of all paved public roads and streets and 57% of the interstate highways are surfaced with flexible pavements (asphalt). Asphalt concrete rutting is a longitudinal deformation that develops under the action of channelized loads. It occurs because of consolidation or shear failure in the subgrade or pavement structure. Aggregates make up about 95% of the weight of asphalt concrete and provide most of the pavement's load carrying capacity. The quality and physical properties of aggregates, especially gradation, are critical in preventing rutting and in improving pavement performance in general.

One way to make a mix more resistant to rutting is to increase friction between the particles by using more crushed aggregates. FHWA Technical Advisory T5040.27, "Asphalt Concrete Mix Design and Field Control," recom-

mends that natural sands be limited to 15% to 20% of the total weight of aggregates for high-volume roads.

Another gradation problem that causes rutting is an excessive amount of minus No. 200 material in the mix. FHWA's Technical Advisory recommends that mixes be designed with dust to asphalt ratio between 0.6 and 1.2. The Task Force final report was published in February 1989. It concludes that most of the causes of rutting are known and the solutions to the rutting problem are now available. The report also indicates that FHWA Technical Advisory T5040.27 is a state-of-the-art technical document.

About 240,000 highway bridges in the United States are currently classified as "structurally deficient," mainly because of bridge-deck deterioration. Reinforced concrete bridge decks and piers are particularly vulnerable to salt penetration. The salt affecting the reinforced concrete structures comes from deicing salts as well as from seawater. The combination of chloride ions from the salt, reinforcing bars, and moisture leads to an electrochemical process that causes the rebars to corrode and expand in size. As the bars expand, they

exert internal pressure on the concrete, which splits along the rebars and leads to rapid deterioration of the concrete. The deterioration process of reinforced concrete can be significantly reduced through cathodic protection that reverses the flow of electrical current developed when corrosion occurs. Several anode systems for cathodic protection of bridges now available were evaluated in two reports published by FHWA.⁶

OUTLOOK

The demand for construction sand and gravel in 1990 is expected to be about 900 million tons, a slight increase from 1989. The weakness in the non-residential and multifamily residential building construction markets is expected to be compensated by a stronger demand in road construction and repair work. Gradual increases in demand for construction aggregates are anticipated after 1990, based on increased volume of work on the infrastructure. It is estimated that the demand for construction sand and gravel will reach 1 billion tons in 1995. The projected increases will be influenced by construction activity primarily in the public construction sector.

The release of the Department of Transportation comprehensive report on national transportation policy⁷ indicates that a significant increase in the volume of work on the infrastructure should be expected in the next 5 to 10 years. The value of public construction work as part of the gross national product (GNP) has declined constantly from about 3% in the 1950's and 1960's to less than 2% in the 1980's. If this trend begins to reverse in the 1990's, a significant increase in spending for public construction work could be expected that will dramatically alter the above forecasts.

Construction sand and gravel f.o.b. prices are not expected to increase significantly, even if the demand for construction aggregates will rise over the above forecasts. However, the delivered prices of construction sand and gravel are expected to increase significantly, especially in and near metropolitan areas, mainly because more and more aggregates are transported from distant sources.

BACKGROUND

Sand and gravel is a granular, unconsolidated, and usually rounded agglomeration of particles of rocks and minerals, resulting primarily from the natural disintegration and abrasion of rocks through weathering or erosion. Sand and gravel, as one of the most accessible natural resources, has been used since the earliest days of civilization, mostly as a construction material. At the beginning of the 20th century, the U.S. production of construction sand and gravel, the sand and gravel used mostly for construction purposes, was relatively small and its uses limited. Today, annual sand and gravel production tonnage ranks second in the nonfuel minerals industry after crushed stone and is the only mineral commodity produced in all 50 States. The United States is, in general, self-sufficient in sand and gravel, producing enough to meet all domestic needs and to be a small net exporter, mainly to consumption points along the United States-Canadian and United States-Mexican borders.

Most of sand and gravel is used for construction purposes, mainly as aggregate in concrete; as road base material in the construction and repair of highways, railways, and runways; and as aggregate in asphaltic concrete for paving highways, streets, etc. Construction sand and gravel has one of the lowest average per ton values of all mineral commodities. The constant dollar price has changed relatively little over the past 20 years. Increased operating costs have been partially offset by automation and other means of increasing operating efficiency.

Although construction sand and gravel resources are widespread and in adequate supply nationally, local shortages exist. Land use conflicts and environmental problems associated with rapid urban expansion are major factors contributing to these shortages. In addition, in some geographic areas with sufficient resources, some shortages occur because the proportions of various size fractions of sand or gravel may not meet size specifications of the construction industry. Demand pressures, land use regulations, and the cost of meeting environmental and reclamation requirements are factors that will cause a rising price trend. Larger operations with more effi-

cient equipment, more automation, and better planning and design will be the trend of the industry in the future. This will permit increased use of less accessible and lower quality deposits and will keep prices at competitive levels.

Definitions, Grades, and Specifications

Sand is defined throughout the industry and by the American Society for Testing and Materials (ASTM) as naturally occurring unconsolidated or poorly consolidated rock particles that pass through a No. 4-mesh (4.75-millimeter) U.S. standard sieve and are retained on a No. 200-mesh (75-micrometers) U.S. standard sieve. Gravel consists of naturally occurring unconsolidated or poorly consolidated rock particles that pass through a sieve with 3-inch (76.2-millimeters) square openings and are retained on a No. 4-mesh U.S. standard sieve.

Sand and gravel is made up of varying amounts of different rock types and is, therefore, of varying chemical composition. Silica is the major constituent of most commercial sands, and lesser amounts of feldspar, mica, iron oxides, and heavy minerals are common. Most applications of sand and gravel have specifications for size, physical characteristics, and chemical composition. A compilation of 42 ASTM Specifications and Test Methods, including the latest revisions and updates pertaining to aggregates, concrete, and admixtures, was reprinted by the NAA.⁸

Specifications for sand and gravel used in roadbuilding and concrete construction are often rigid regarding particle size gradation and shape and include physical as well as some chemical properties. However, these specifications can differ in detail from State to State or even from city to city within the State. Soil conditions, climate, and peculiarities in different deposits may necessitate adjustments of requirements of sand and gravel mixtures and chemical composition.

Specifications are written by commercial users; Government agencies, including Federal, State, county, and city construction and highway departments; and the ASTM. Problems arise for the producers of construction aggregates when their product is sold or used in several different cities, counties, or States, many of which may have

different specifications. Some progress is being made toward the standardization of aggregate sizes for similar requirements. A need exists for a more active interchange of data and experience among aggregate consumers and producers.

Products for Trade and Industry

Concrete is made by mixing properly sized aggregate, portland cement, and water into a slurry. Chemical action between the cement and the water results in the crystallization of hydrous calcium aluminum silicates, which causes the mass to bind and harden. Round particles in the aggregate are desirable because they improve the workability of the concrete as it is poured. If broken material is used and angular or flattish fragments exceed about 15% of the total volume, workability can be maintained only by increasing the amount of sand and water, thus reducing strength, or by adding more cement, thus increasing the cost of the concrete.

Sized and broken sand and gravel is used to make asphaltic concrete aggregate and road bases. Broken surfaces adhere to the hot asphaltic mixture better than do rounded surfaces and provide interlocking surfaces that tend to strengthen the asphaltic concrete. Broken particles pack better and tend to move less under load than do rounded particles and, therefore, make better road bases for highway and road construction. This is essential because bases and asphaltic concrete tend to flow when placed under great or long duration stresses.

Industry Structure

Because of the low unit value, construction sand and gravel is produced near the point of use; therefore, the industry is concentrated in or nearby large, rapidly expanding urban areas and, on a transitory basis, in areas where highways, dams, and other large-scale public and private works are under construction. In the United States, sand and gravel is produced in every State. The largest operations tend to be concentrated in the States with the largest population and largest production of sand and gravel.

Construction sand and gravel is produced in virtually all countries, but relatively few of them survey this indus-

try and even fewer regularly publish official statistics on sand and gravel.

On the basis of tonnage, the construction sand and gravel industry is the second largest nonfuel mineral industry in the United States. In 1988, the last year when a full survey was conducted, there were 4,175 companies producing construction sand and gravel operating 5,687 pits. The individual operations range in size from those producing millions of tons annually to those reporting less than 25,000 tons per year. Most operations are small, turning out one product or a limited range of products, but most of the tonnage comes from large operations. For example, the 26 operations reporting more than 2.0 million tons each in 1988 represented only 0.4% of the total number of operations, but produced 9.5% of the total tonnage, while 95 operations reporting between 1 and 2 million tons each, representing only 1.6% of the total number of operations, produced 13.6% of the total tonnage. For the same year, most of the construction sand and gravel was produced by operations reporting between 200,000 and 1 million tons each—1,109 operations, representing 19.5%, produced 50.3% of the total tonnage.

The leading companies producing construction sand and gravel, in descending order of tonnage, based on the 1988 survey, were CalMat Co. of Los Angeles, CA; Beazer U.S.A. Inc. of Pittsburgh, PA; ARC America Corp. now CSR Ltd., of Sydney, Australia; Granite Construction Co. of Watsonville, CA; and Dravo Corp. of Kenner, LA. The top 5 companies operated 118 pits and produced 10% of the U.S. total. Two of these five companies are subsidiaries of foreign companies. Many producers are in the sand and gravel business exclusively, but others are diversified in various degrees in the production of other mineral raw materials, intermediate construction products such as ready-mixed concrete and concrete blocks, final manufactured products, or construction of buildings, roads, and other structures. At the same time, construction companies are entering more and more into the sand and gravel business to integrate their operations.

Geology-Resources

The processes of formation and dep-

osition impart to sands and gravels the physical characteristics that largely determine the commercial value for a particular use and influence the manner of development. The principal types, based on origin, are stream, glacial, residual, marine, and lake. Windblown deposits are of minor importance. Much of the commercial production is from stream deposits, many of which are deficient in the fines required by present-day grading specifications for concrete aggregates. Stream deposits usually exhibit stratification and often large size gradation. The beds vary in thickness and sometimes have interspersed lenses of clay or fine sand. The degree of roundness and the particle size varies with the hardness and distance transported. Glacial deposits have the least sorting of all transported deposits, while marine and lake deposits exhibit the best sorting with coarse and fine particles, often well segregated. Residual deposits are found overlying the parent rock and are unstratified mixtures of pebbles, boulders, sand, and clay. They often contain much soft material that prohibits commercial production. Marine or offshore deposits could become more important as inland deposits become depleted or environmentally less desirable to extract. A comprehensive report showing geologic occurrences of potential sources of sand and gravel and crushed stone of the conterminous United States for use as natural aggregates was published by the U.S. Geological Survey.⁹

On the basis of geologic evidence, world reserves are sufficient to meet demands, although not necessarily at precisely the locations where needed. Reserves, which are measurable amounts of sand and gravel that can be produced profitably with current technology under existing economic and political conditions, are controlled mostly by land-use and/or environmental constraints. The total sand and gravel resources of the United States are very large. However, the geographic distribution and/or quality of the reserve base often does not match market patterns or requirements.

Technology

Major technological developments that have been instrumental in maintaining adequate production at relatively stable real costs include use of larger operating units, more efficient portable and semiportable plants, unit-

ized plants for versatility of plant capacity, new prospecting methods utilizing aerial and geophysical surveying methods, and greatly increased rehabilitation and resale of mined areas. Use of mined-out pits as lake beds and as sanitary landfill areas has been successful at numerous localities. Automatic controls, along with monitoring by closed-circuit television coordinated with automated counting and recording and radio communications systems, have been installed in many of the larger and newer operations; these, along with the use of improved equipment, have permitted recovery of salable fractions from deposits previously considered too low in quality for profitable exploitation. These practices will increase as pressures build to increase productivity and minimize environmental conflicts.

Exploration.—Sand and gravel deposits, like any mineral deposit, must be explored and evaluated before development. Preliminary examination can establish the extent and nature of the deposits. This is followed by a detailed exploration program aimed at obtaining reasonably accurate information on the quantity of material available, the degree of uniformity throughout the deposit, and especially, variations in particle size, both vertically and horizontally. Also, the nature and amount of waste materials and the economic feasibility of their removal must be studied.

Geophysical methods are of value in preliminary surveys. Detailed exploration may be achieved by a systematic arrangement of test pits, trenches, boreholes, or other procedures designed to obtain a cross section of the deposit in conjunction with sampling and testing. Advances in interpretation of aerial photographs and increased application of geophysical techniques have made evaluation of sand and gravel deposits more quantitative. For underwater exploration, mining devices such as dredges and draglines are used. Pilot runs are necessary to determine if required specifications can be met consistently and economically.

Much of the sand and gravel that is being mined in stream, flood plain, alluvial fan, riverbeds and terrain, and glacial deposits is good quality material with nearly equal amounts of gravel and sand and small amounts of unusable material. As these deposits become depleted in future years, less de-

sirable and more expensive sources will have to be developed where mining, reserves, ratio of sand to gravel, quality of material, waste factors, and environmental factors such as waste disposal will present more problems.

Exploration and planning will become more important in assessing deposits, particularly hillslope deposits of older sand and gravel. Grading to meet required slope and setback requirements at hillslope sites may necessitate leaving large tonnages of material unmined. Many millions of tons of material are available, but it may not be of proper quality or ratio of sand to gravel. More deposits of marginal quality will have to be developed to provide for future demand.

Mining.—Sand and gravel generally occur in the same deposit, but the relative proportions of each vary greatly within most deposits. Consequently, the control problem of producing aggregate to rigid specifications involves combinations of many types of equipment like screens, washers, classifiers, crushers, and grinding mills. The two basic sand and gravel mining methods are open pit excavation and dredging. Open pit excavation and processing has four major steps: (1) site clearing—removing trees and vegetation, stripping overburden and topsoil, and transporting, redepositing, or stockpiling it at or off the site; (2) mining—removing the sand and gravel from the deposit; (3) processing—screening, washing, crushing, blending, and stockpiling the mined material to conform to standards and specifications; and (4) reclamation of the extraction area. Processing may or may not take place at the mining site. Mining equipment ranges from small, simple units such as tractor-mounted high-loaders and dump trucks to more sophisticated systems involving large power shovels, draglines, bucketwheel excavators, and belt conveyors. Increasingly, mining systems are being designed to provide for more efficient and economical land reclamation.

Mining with a dredge usually involves mounting the equipment on boats or barges. Suction or bucket-type dredges are used most commonly to harvest sand and gravel from the bottom of a body of water. The sand and gravel is processed either on board or transported to land for processing.

Processing.—Although small amounts of unprocessed bank-run sand and gravel are used for fill, most of the U.S. production is processed in some way. Present methods include washing with water during the screening process, in some cases followed by crushing of the larger particles in cone or gyratory crushers. Secondary crushing may be done by roll crushers. Sizing is done, in most plants by horizontal or sloped single or multideck vibratory screens. If necessary, heavy-media separation or jigging is used to remove heavy, unusable materials. Sand for use in construction is freed from clay by log washers or rotary scrubbers. The scrubbing is followed by classification, use of separatory cones or hydroseparators to remove water, and fine screening for grading. Rodmilling is often required for production of small-sized fractions of sand. Transfer of processed sand and gravel from the processing plant to stockpiles or bins is accomplished by flexible combinations of conveyor belts, bucket elevators, and screw conveyors.

Permanent installations are built when large deposits are to be operated for many years. Portable and semiportable units are used in many pits that have an intermediate working life. Several such units can be tied together to obtain large initial production capacity or to add capacity as needed. Mobile screening plants can be quickly moved from one deposit to another without undue interruption or loss of production.

Recycling.—As the Nation moves into an age of increased environmental consciousness, recycling of old concrete and asphalt, used mostly in pavements, is increasing. Local scarcity or high cost of construction aggregates in some areas as well as waste disposal problems are making recycling more attractive economically. In some States, limited recycling, especially in road construction, is either encouraged or required by law. The best utilization for recycled cement concrete is as road base material, because the matrix of concrete cannot be converted back to cement, and also because of the lower strength of concrete compared with that of natural aggregates. Sound crushed concrete can make good coarse aggregate, but the fines produced in crushing the concrete have a higher absorption, are more friable, and will

require a higher amount of asphalt in asphaltic concrete and a higher amount of mixing water in portland cement.¹⁰ The amount of asphalt roads recycled is significantly larger than that of concrete roads, mainly because asphalt can be rejuvenated with oil additives and used in pavements, significantly reducing the cost of the finished road. Experience has shown that about 35% of crushed asphalt pavement can be recycled into new asphalt mixtures. Proper testing under engineering supervision in all construction projects using recycled materials as aggregates should be performed to ensure that the technical specifications are met.

Byproducts and Coproducts

Small amounts of gold and silver are recovered as a byproduct or coproduct of sand and gravel extraction, particularly in highly sorted deposits.

Economic Factors

Construction sand and gravel is a high-volume, low-value commodity. The industry is highly competitive and is characterized by thousands of operations serving local or regional markets. Production costs vary widely depending on geographic location, the nature of the deposit, and the number and type of products produced. Constant dollar unit values have been quite steady during the past 20 years. Modernization, automation at newer, larger plants, and competition from crushed stone have helped to keep production costs and prices from escalating. Constant dollar prices are expected to rise in the future because of decreased deposit quality and more stringent environmental and land use regulations.

Accessibility is a problem for the construction sand and gravel industry. The high-volume and low-unit value of sand and gravel requires that operations be close to the market location. Markets for sand and gravel are construction sites that are mostly in areas of high population density. New operations, close to population centers, are difficult to develop because the land is often attractive for other uses such as housing, shopping centers, agriculture, parks or recreational areas, and because of public dislike for mining operations close to populated areas. Existing operations in expanding communities face increasing costs because of increasing land

values and increasing restrictions on operations as suburban development comes closer. Deposits are often small and, once exhausted, the operation must be moved to a new site that invariably is farther from the market because closer sites are being used for other purposes.

The industry also faces increasing competition from crushed stone that can substitute for sand and gravel in most of its applications. Stone operations are generally longer-lived, can afford greater capital investment for higher efficiency, and are often located where competing land use pressures are less severe. The topographically rugged stone-bearing areas are usually less desirable for construction purposes than sand-and-gravel-bearing areas, which are generally flatter.

Depletion Provisions.—A 5%-depletion allowance based on gross income is allowed for construction sand and gravel. There are no import tariffs.

Operating Factors

Many States, counties, and cities in the United States have zoning laws, and land within each governmental unit is usually zoned to indicate acceptable land uses. If mining is permitted in a zone and a sand and gravel company owns or leases land within that zone, the company may apply for a use permit or its equivalent to begin an operation. If the parcels to be quarried are on lands under both city and county jurisdiction, permits usually must be obtained from each. An acceptable reclamation plan that meets the guidelines or regulations of the appropriate governmental agency must also be approved. Environmental concerns such as noise, dust, beautification, and storage of wastes must be accounted for in a manner satisfactory to the governmental entity involved. Wastewater discharge requirements must be planned for and met. If the deposit to be worked is on a river or land controlled by a river or water or flood control agency, whether municipal, State, or Federal, that agency's requirement must also be satisfied.

In most States, permits for sand and gravel operations require an Environmental Impact Report (EIR) or Statement (EIS). A reclamation plan and a use permit application may also be required, with considerable overlap of

subject matter with the EIS. A complete EIS may cover all the problem areas at once and facilitate acceptance.

Environmental Requirements.—Two main points are involved in environmental land use and reclamation factors. First, the industry must be concerned about any practices that can affect the community environment. An effective effort must be made to reduce noise, air, and water pollution; to reclaim pits after the operation is complete; and to improve the overall appearance of the operating mine, processing plant, and transportation facilities. Second, the industry and community must recognize the time and costs required to protect the environment and the importance of agreeing on fair and realistic environmental standards.

Because sand and gravel is a local commodity, the effect of supply deficiencies and cost of material will affect the local community first. Undue delay and unreasonably high cost can strongly affect the movement of sand and gravel into the marketplace. Also, stringent controls by the local government that prevent permits being issued to operators can have adverse economic effects on the communities around them. These conditions can make it difficult to assess the timing and even the possibility of plants going on-stream and can therefore affect the supply of sand and gravel into the marketplace.

Although much progress is being made through premining planning, the sand and gravel industry continues to have problems with environmental controls, land use conflicts, and reclamation practices. Many of these problems are acute because extraction areas and plants must be reasonably near to consumers who are largely in metropolitan areas. Major environmental considerations that must be dealt with in mining and processing sand and gravel are emission of particulate matter into the air, processing water discharge, noise abatement, and employee and public health and safety.

Transportation.—Transportation is a major factor in the delivered price of construction sand and gravel. The cost of moving construction sand and gravel from the plant to the market often exceeds the sales price of the product at the plant. Because of the high cost of

transportation, construction sand and gravel continues to be marketed locally. Economies of scale, which might be realized if fewer, larger operations served larger marketing areas, would probably not offset the increased transportation costs.

Truck haulage is the main form of transportation used in the construction sand and gravel industry. Many producers have their own truck fleet and deliver their own raw materials and products. A significant and increasing amount of sand and gravel, however, is being hauled by independent truckers because of the cost of maintaining a truck fleet, particularly when the market is highly variable or down. Rail and water transportation combined account for about 10% to 20% of total construction sand and gravel shipments.

INDUSTRIAL SAND AND GRAVEL

By Wallace P. Bolen

Mr. Bolen, a physical scientist, is a graduate of the University of Virginia and has been the commodity specialist for industrial sand and gravel since October 1988. Domestic survey data were prepared by Howard L. Sullivan, mineral data assistant, and the international production table was prepared by William Zajac, Chief, Branch of Geographic Data.

Production of industrial sand and gravel in 1989 increased to 29.2 million tons, about a 3% increase over that of 1988.

Production increased for the third consecutive year and was attributable to increased silica usage for fiber and specialty glasses, chemicals, roofing granules, and hydraulic fracturing (frac sand).

Exports of silica sand and gravel increased about 94% in quantity and 31% in average value per ton, compared with that of 1988. Imports of industrial sand and gravel decreased about 19% in quantity, but the associated value increased 7%. Domestic apparent consumption of industrial sand and gravel in 1989 was 27.2 million short tons, a small decrease from 1988.

Domestic production data for industrial sand and gravel were developed by the Bureau of Mines from voluntary surveys of U.S. producers. Of the 160 industrial sand and gravel operations surveyed, 153 (96%) reported to the Bureau of Mines. Their combined production represented about 99% of the U.S. total published in table 1. The production of nonrespondents was estimated mostly using employment data. Of the 160 operations, 153 (96%) were active and 7 idle.

LEGISLATION AND GOVERNMENT PROGRAMS

The Department of Labor's Mine Safety and Health Administration (MSHA) issued a proposed rule titled "Air Quality, Chemical Substances, and Respiratory Protection Standards" on August 29, 1989. A section of the proposed rule would revise standards for air quality at metal-nonmetal mines.

For silica, the revision proposed accepting a 0.1 milligram per cubic meter

(mg/m³) of respirable silica (quartz) exposure limit in place of the former formula that measured and limited exposure. This change did not effectively alter the standard but rather conformed the silica exposure limit to the format used for all other hazardous dusts. For cristobalite and tridymite, the less common forms of silica (SiO₂), the proposed exposure limit was 0.05 mg/m³. Additionally, the proposed rule reviewed current standards on dust control and detailed the use and maintenance of respirators.¹

ISSUES

A major issue of concern for the silica industry revolved around the 1986 International Agency for Research on

Cancer (IARC) findings that there was limited evidence that silica is a carcinogen to humans. A hazard communication statement was required by the Occupational Health and Safety Administration (OSHA) because respirable silica is known to induce silicosis, a non-cancerous lung disease, and is considered a probable carcinogen. This meant that employers must inform and train their employees about the proper handling of silica due to its potential hazards.

Additionally, MSHA recommended that producers label products that contain respirable silica to alert their customers of the hazards associated with silica. Many producers have begun this practice, and training of employees has been regular and continuous at most operations. The greatest concern for producers of silica was negative reaction from consuming industries and

possible additional restrictive legislation and penalties from MSHA and OSHA.

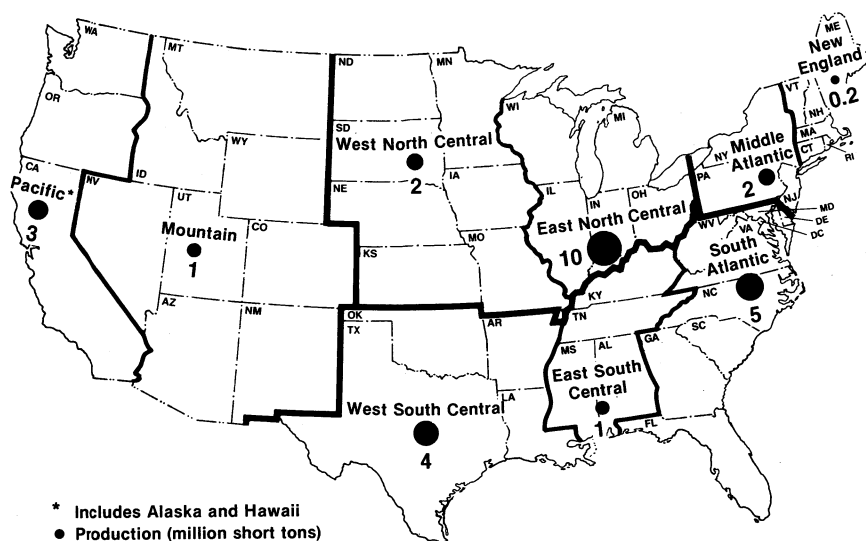

PRODUCTION

The Midwest (East and West North Central regions) continued to lead the Nation in production with about 42% of the 29.2 million tons produced in the United States, followed by the South (South Atlantic, East and West South Central regions) with about 35% and the West (Pacific and Mountain regions) with 14%. Compared with 1988, the output of industrial sand and gravel increased 5% in the South and 3% in the Midwest, but decreased 4% in the Northeast (Middle Atlantic and New England regions) while the West's production increased slightly.

Based on the 1988 census estimations on population, 1989 U.S. per capita industrial sand and gravel production was 0.12 ton. Per capita production by major geographic region was 0.21 ton in the Midwest, 0.12 ton in the South, 0.08 ton in the West, and 0.05 ton in the Northeast.

The five leading States in the production of industrial sand and gravel, in descending order of volume, were Illinois, Michigan, California, New Jer-

FIGURE 1
PRODUCTION OF INDUSTRIAL SAND AND GRAVEL IN THE UNITED STATES IN 1989, BY GEOGRAPHIC REGION

sey, and Texas. Their combined production represented 46% of the national total. Significant changes within the five major producing States included Illinois, where production increased 6%, and Michigan, where production

decreased by 6%.

The Bureau of Mines canvassed 87 producers of industrial sand and gravel with 153 active operations. About 75% of the industrial sand and gravel was produced by 46 operations, each with

¹ Data may not add to totals shown because of independent rounding.

an annual production of more than 200,000 tons. The 10 leading producers of industrial sand and gravel were, in descending order of tonnage, Unimin Corp., U.S. Silica Co., Fairmount Minerals Ltd., The Morie Co. Inc., Manley Brothers of Indiana, Badger Mining Corp., Oglebay Norton Co., Construction Aggregates Corp., Simplot Industries, Inc., and W. R. Bonsal and Co. Their combined production, from 59 operations, represented 71% of the U.S. total.

Green River Silica Co. in Hart County, KY, began operations in 1989 and produced sand for blasting, filtration, and golf courses.

U.S. Silica, based in Berkeley Springs, WV, purchased Card Silica Co., IN, and after renovations expected to begin production in early 1990.

Bonsal, Lilesville, NC, a major producer of industrial gravel for the production of silicon metal, neared completion of another lump silica production facility at Beech Island, SC. The rural dredging operation was located near the Savannah River and Augusta, GA.

The Monterrey City Council refused to renew a mining permit for Monterrey Sand Co., Monterrey County, CA; and, after 46 years of production, the operation ceased activities at its Sand City and Marina beaches locations.

Manley Brothers ceased its operation at Michigan City, IN, because it was unable to obtain additional adjacent reserves as a result of high property costs in the area.

Additionally, 11 small producers of silica sand for industrial uses either ceased operations or moved out of industrial sand production and became solely construction sand producers.

CONSUMPTION AND USES

Sand and gravel production reported by producers to the Bureau of Mines was actually material used by the companies or sold to their customers. Stockpiled material was not reported until consumed or sold.

Of the 29.2 million tons of industrial sand and gravel sold or used, 42% was consumed as glassmaking sand and 24% as foundry sand. Other important uses were abrasive sand (8%) and frac sand (5%). Because some producers

did not report a breakdown by end use, their total production as well as the estimated production for nonrespondents were included in "Other uses, unspecified," which represented about 3% of the U.S. total.

On the regional level, more than one-third of the glassmaking sand was produced in the South (38%), followed by the Midwest (29%), and the West (18%). Three-fourths of the foundry sand was produced in the Midwest

(75%). About three-fourths of the hydraulic fracturing sand was produced in the Midwest (74%), and about one-half of the abrasive sand was produced in the South (51%).

Northeast

Cumberland County, NJ, continued to be the largest source for the glass, foundry, and blast sand markets in the region. Unimin, U.S. Silica, Morie, and WHIBCO, Inc., all of which oper-

ated plants in the county, were among the largest producers of sand for these markets. U.S. Silica's plant in Huntingdon County, PA, also produced significant amounts of sand for the glass market. Morie's plant in Cumberland County produced a major percentage of the abrasive blast sand in the region.

Midwest

Unimin's plants in LaSalle and Ogle Counties, IL; LeSueur County, MN; and Columbia County, WI; were among the leaders in producing sand for the glass, foundry, frac sand, and blasting markets. Fairmount Minerals, operating plants in Geauga County, OH, and La Salle County, IL, was a major producer for the foundry and glass markets in the region. U.S. Silica's plant in La Salle County, IL, and Badger Mining's plant in Jackson County, WI, were large producers for the glass and frac sand markets, respectively. Construction Aggregates Corp. in Ottawa County, MI, and Manley Brothers in Van Buren County, MI, were major producers of foundry sand in the region. Unimin's Ogle County and Badger Mining's Green Lake County operations were also large producers for the foundry industry.

South

Unimin and U.S. Silica Co. were two of the largest producers of sand for the glass and foundry markets. Unimin's major plants were in Frederick County, VA; Richmond County, NC; Pontotoc County, OK; and Izard County, AR. U.S. Silica's Bullock County, AL; Morgan County, WV; and Johnston County, OK, operations were the major contributors for these markets. Morie's Tuscaloosa County, AL, and Tennessee plants were large producers of foundry and glass sand, respectively, in the region. Pioneer Concrete of Texas, Inc., Southern Silica of Louisiana, Specialty Sand Co., LA, and Foster-Dixiana, SC, produced the bulk of the blasting sand. Bonsal and B. V. Hedrick Sand and Gravel, both in Anson County, NC, produced most of the industrial gravel used in the processing of silicon and ferrosilicon. Bonsal also produced large quantities of material for roofing granules.

West

Owens-Illinois, Simplot Industries, and Unimin were the three largest pro-

W Withheld to avoid disclosing company proprietary data; included with "Other uses, specified;" also included in "U.S. total" by use. XX Not applicable.

¹ Data may not add to totals shown because of independent rounding.

² Mostly estimated total production plus other uses (small quantities) as reported by producers.

FIGURE 2
SAND USED IN SELECTED END USES, 1989

ducers of glass sand in the region, with major operations in Amador County, CA; Clark County, NV; and Contra Costa County, CA; respectively. Corona Industrial Sand Co., Riverside County, CA, supplied the majority of sand for the sand blasting industry in the region. Simplot Industries also supplied a large portion of the foundry sand consumed.

TRANSPORTATION

Of the total industrial sand and gravel produced, 58% was transported by truck from the plant to the site of first sale or use, up from 56% in 1988; 34% was transported by rail, unchanged from 1988; 3% by waterway, down from 4% in 1988; and 5% not transported, down from 6% in 1988. Because most of the producers did not report shipping distances or cost per ton per mile, no transportation cost data were available.

TABLE 7

**TRANSPORTATION OF
INDUSTRIAL SAND AND
GRAVEL IN THE UNITED STATES
IN 1989 TO SITE OF
FIRST SALE OR USE**

Method of shipment	Quantity (thousand short tons)	Percent of total
Truck	16,863	58
Rail	9,949	34
Waterway	825	3
Not transported	1,568	5
Total	29,205	100

PRICES

Compared with 1988, the average value, f.o.b. plant, of U.S. industrial sand and gravel increased nearly 3% to \$14.05 per ton. Average unit values for industrial sand and industrial gravel were \$14.23 and \$10.39 per ton, respectively. Nationally, industrial sand used as fillers for rubber, paint, and putty, etc., had the highest value per ton (\$65.75), followed by silica sand used in ceramics (\$31.67), coal washing (\$28.36), molding and core facings (\$26.93), scouring cleansers (\$26.51), silica flour (\$26.19), and fiberglass (ground) (\$26.17).

The average value per ton of industrial sand was highest in the West (\$17.48), followed by the Northeast (\$15.44), the South (\$15.15), and the Midwest (\$12.29). Glass sand average value per ton varied markedly, from \$16.50 in the West to \$10.11 in the Midwest. Tighter supplies and higher production and transportation cost in the West increased the cost of sand and gravel in this region.

FOREIGN TRADE

Exports

Exports of industrial sand, compared with 1988, increased 94% to 2,060,000 tons, and the value increased 154% to \$78.3 million. Of this, 51% went to Canada, 21% went to the Netherlands, 7% went to Japan, and the remainder went to numerous other countries throughout the world.

Imports

Compared with 1988, imports for consumption of industrial sand decreased 19% to 35,000 tons valued at \$2.1 million. Of this, 91% came from Australia and 6% came from Japan. Small amounts of specially prepared silica sand from Canada, the Federal Republic of Germany, France, Japan, Mexico, and the United Kingdom sold for very high values per ton.

WORLD REVIEW

World production of industrial sand and gravel, based on information usually provided by foreign Governments, was estimated to be 137.5 million short tons. The United States was the leading producer followed by, in descending order, the Netherlands, Argentina, France, and the Federal Republic of Germany. Most countries in the world had some production and consumption of industrial sand and gravel because of its basic uses in glass and foundries. However, because of variation in descriptions and usage for silica sand and gravel, it was difficult to get reliable information. Beyond those countries listed in table 10, many other countries, including the U.S.S.R. and other Eastern European nations, were believed to have had some type of silica production and consumption.

CURRENT RESEARCH

Research related to the industrial sand and gravel industry continued to advance on many fronts. Newly fabricated materials, including chemicals, ceramics, and other related materials, provided new markets for silica producers while simultaneously placing more stringent requirements on silica as a raw material.

During 1989, several articles were centered on the use of silicon nitride (Si_3N_4), a ceramic, for engine components. Si_3N_4 components had begun to replace traditional metals in engines, functioning in many applications, including turbocharger rotors, valves, and ball bearings. Advantages of Si_3N_4 included improved durability, lower wear and friction, increased fuel effi-

ciency, and greater impact resistance. As materials and production costs come down, usage of Si_3N_4 and other ceramics, such as silicon carbide, could become commonplace.^{2 3}

Advances in glass melting technologies will be necessary for the glass industry to remain competitive with alternate materials. Partially funded by the Department of Energy (DOE), Air Products and Chemicals, Allentown, PA, experimented with using oxygen in place of air to improve the efficiency of the furnaces used in glassmaking. Improved efficiency was realized because oxygen raises the flame temperature and minimizes heat losses to the flue.⁴ Additionally, KTG Glassworks Technology Inc., Pittsburgh, PA, worked to improve thermal efficiency through the use of segmented furnaces. The system, called Seg-Melt, maintained the separate processing of batch and cullet at the furnace. According to KTG, this method will cut the cost of container glass by 11%.⁵

The DOE continued work on the Defense Waste Processing Facility near Aiken, SC. The operation will use a vitrification process to secure waste of radioactive liquid plutonium by fusing the waste with borosilicate particles to form a glass. The glass will be poured into stainless steel canisters and then sealed before being moved to the glass waste storage building. Eventually the canisters will be stored in the DOE's

permanent underground waste facility at Yucca Mountain, NV. Commencement of the process was scheduled for 1992 and should continue for at least 20 years.^{6 7}

OUTLOOK

Demand

The forecast range of total U.S. demand in the year 2000 was expected to be 30 to 41 million short tons for industrial sand and gravel. Probable demand was expected to be about 36 million tons, which corresponded with an average annual growth rate of 1.9%. All forecasts were based on previous performances for this commodity within various end uses and contingency factors considered relevant to the future of the commodity.

Glass Sand

Since 1984, annual demand for glass sand had fluctuated between 10.3 and 12.1 million tons. Sand consumed for container glass had decreased since 1987 mainly because some glass containers were being replaced by aluminum cans and plastic containers and also because the amount of glass being recycled was increasing. Additionally, many manufacturers of container glass were using thinner walls in glass containers, and this process had cut down

See footnotes at end of table.

the amount of sand used. Also, a new, thinner and lighter safety glass was used in automobiles and its use was growing. As a result of these contingency factors, demand for glass sand was expected to grow slowly until the year 2000. Probable demand for glass sand for the year 2000 was forecast to be 14 million tons, with a range of 12 to 16 million tons. The probable forecast indicated a modest annual growth rate of 0.8%.

Foundry Sand

The probable forecast for foundry sands was expected to be 9.5 million tons, and the range was expected to be 9 to 11 million tons. The probable forecast indicated an average annual growth rate of 2.6%. The use of foundry sand was seen to be dependent mainly on automobile production. Recently, many foreign auto makers have opened plants in the United States, and this should support growth in sales of foundry sands as a greater percentage of cars sold in the United States will also be made in this country.

Hydraulic Fracturing Sand

This end use showed a strong growth in 1989, surging to over 1.5 million tons. The amount of hydraulic fracturing sand used in each oil and gas well increased, and this trend was expected to be maintained in the future. Therefore, demand was expected to grow for this end use. Probable demand for hydraulic fracturing sand for the year 2000 was expected to be 2.3 million tons, with a range of 1.7 to 2.7 million tons. The probable forecast indicated an annual growth rate of 4%.

Adequacy of Supply

Domestic production was expected to continue to meet more than 99% of demand through the year 2000. Imports, mostly from Australia, the Bahamas, and Canada, were expected to remain minor.

The United States was the largest producer and consumer of silica sand among the market economy countries and was self-sufficient in this commodity. Most of it was produced in the eastern part of the United States where the largest deposits and major markets were located. A significant amount of silica sand was also produced in the West and Southwest, mostly in Califor-

^e Estimated. ^p Preliminary.¹ Table includes data available through June 15, 1990.² In addition to the countries listed, Angola, Antigua and Barbuda, the Bahamas, China, Israel, New Caledonia, Panama, and the U.S.S.R., among others, produce industrial sand, but current available information is not adequate to formulate estimates of production levels.³ Fiscal years beginning July 1 of that stated.⁴ Reported figure.⁵ Less than 1/2 unit.⁶ Data may not add to totals shown because of independent rounding.

nia and Texas.

Because the unit price of silica sand was relatively low, except for a few end uses that required a high degree of processing, the location of silica sand deposits in relation to the market was an important factor that may work for or against a sand producer. Consequently, a significant number of relatively small operations supplied local markets with a limited number of products.

The constant-dollar price of domestic silica sand had fluctuated since 1983 and was expected to continue fluctuating because of strong competition among producers for retention of dwindling markets.

Possible Supply-Demand Changes

Several factors could affect supply-demand relationships for silica sand. Further increases in the development of substitute materials for glass and cast metals could reduce demand for glass sand and foundry sand but would increase demand for silica flour, which is used as a filler in plastics, and for glass fibers, which are used in reinforced plastics. Also, increased efforts to reduce waste and increase recycling could hinder glass sand demand. Although these developments could cause demand for silica sand to decrease, the total value of production could increase because of the increased unit value of the new specialized sands.

An increase in the price of oil on the international market would stimulate domestic drilling and extraction from new and old oil deposits. This would increase demand for domestic hydraulic fracturing sand.

Concern over the use of silica as an abrasive due to health concerns and the imposition of stricter legislative and regulatory measures concerning silica exposure could decrease demands in many silica markets.

Development of more efficient mining and processing methods were expected to continue. This will enhance development of lower grade silica sand deposits located closer to markets but not presently mined. Such developments were expected to increase silica sand reserves.

BACKGROUND

Probably no other nonmetallic mineral has more diversified uses than silica sand, mainly because of its common occurrence around the world and its distinctive physical characteristics, including hardness, resistance to high temperature and chemical action, and relatively low price. One of the first industries to use silica sand was the glass industry. At least 4,000 years ago, long before iron was smelted, glassmaking was already a known craft. Although the place and date of the first manufactured glass are not known, the oldest known specimens of glass are from Babylon (ca.2600 B.C.) and from Egypt (ca.2500 B.C.), where the industry was well established by around 1500 B.C. Many varieties of glass were known during Roman times. Little is known of the glassmaking methods used in Europe from the fall of Rome until the 10th century, when stained

glass was produced in Venice. After this, Venice remained the leader in fine glassware for the next four or five centuries. In the 17th century, a process for casting glass was invented in France, and later England began to make flint glass, marking the beginning of modern glass technology.

Glassmaking was apparently the first industry to be transplanted from Europe to North America, first to Mexico, and later to the British colonies. The first manufacturing establishment in what is now the United States was a glass factory at Jamestown, VA, built in 1608. The 1885 edition of "Mineral Resources of the United States," the predecessor of today's Bureau of Mines "Minerals Yearbook," reported a total of 317,000 tons of silica sand produced in 1884 in the United States, under "Glass Materials." In 1989, a total of 29.2 million tons of silica sand was produced in the United States for a variety of uses, of which 12.3 million tons was for glassmaking. Today, glass has become an invaluable product with a multitude of forms and applications.

1989	14.23	13.67

Metals casting was probably the second industry that used silica sand. Today, the casting industry provides vital components for most modern manufacturing industries. The number of industries using silica sand is growing constantly, as are the products made by using silica sand.

Definitions, Grades, and Specifications

Sand is defined throughout the industry and by the American Society for Testing and Materials (ASTM) as granular rock particles that pass through a No. 4 mesh (0.187-inch) U.S. standard sieve and are retained on a No. 200 mesh (0.0029-inch) sieve, and are the result of natural disintegration or comminution of cemented rock. Industrial sand or silica sand is the term used by the industry for sands that have a very high percentage of silicon dioxide (SiO_2), and are essential materials in glass manufacture, in ferrous and non-ferrous foundry operations, in certain chemical and metallurgical processes, for hydraulic fracturing of oil and gas deposits, and in many manufactured products as fillers or extenders.

Most industrial sands have been named for their specific uses; for example, glass, foundry, abrasive, filler, and hydraulic fracturing sands. Almost in-

TABLE 12
PROJECTIONS AND FORECASTS FOR U.S. INDUSTRIAL SAND,
BY END USE, IN THE YEAR 2000

(Million short tons)

End use	1989	Year 2000		
		Forecast range		Probable
		Low	High	
Glass sand	12.3	12.0	16.0	14.0

Total	29.2	30.7	40.7	35.8

variably these sands, in addition to being high in silica, consist mostly of quartz grains.

Products for Trade and Industry

Silica sand had a wide range of uses in a significant number of industries, the most important being glass and foundry. Other uses were metallurgical and as abrasives, as fillers, for filtration, and for hydraulic fracturing of rock formations to improve recovery in oil wells.

Glass sand was used as a main constituent for manufacturing glass containers, flat glass, safety glass, pressed and blown glass, fiberglass, and a wide

variety of specialty glasses such as optical glass and industrial glass.

Glass sand had to meet rigid specifications with respect to purity and silica content, depending on the kind of glass being manufactured. Only a very small amount of iron oxide and chromium compounds could be tolerated, and a high percentage of aluminum, calcium, or magnesium oxides was undesirable. The standards of the American Ceramic Society for glass sand indicated that all grains should pass through a No. 20 mesh screen, between 40% and 60% should be retained on a No. 60 screen, between 10% and 20% on a No. 80 screen, and not more than 5%

should pass a No. 100 screen. Sand for first-quality optical glass should contain 99.8% SiO₂ and a maximum of 0.1% Al₂O₃ and 0.02% Fe₂O₃. Third-quality flint glass could contain only 95% SiO₂ and as high as 4% Al₂O₃. Only in the low-quality amber glass was the content of Fe₂O₃ permitted to reach 1%.

Most glass manufacturers established their own specifications for the physical size and chemical purity of the raw materials that have to be met by the suppliers of glass sand. In the past 10 years, glass manufacturers showed an increased interest in finer glass sands because processing of smaller particles required lower temperatures and, therefore, reduced the consumption of energy.

Foundry sands included molding sand and core sand that were used for casting iron-, aluminum-, and copper-base alloys. Required properties included cohesiveness sufficient to hold together the mold or core when moist, which is achieved by a bonding agent; refractoriness to withstand the high temperature of the molten metal; strength to resist the weight of the metal; permeability to release vapors and gases generated during cooling of the metal; and proper texture and composition to produce a smooth casting that will not react with the metal. Most metals were cast in "green sand," which is a mixture of silica and clay, although to a lesser extent, resins or oils were also used as a bonding agent instead of clays. In the case of naturally bonded foundry sands, the amount of clay minerals present affected their usefulness. Standard tests and specifications for foundry sands were published by the American Foundrymen's Society.^{8,9}

Refractory sands were used in the manufacture of silica brick and tile, quartzite (gannister) being the commonly used raw material. Required properties were "the capability of maintaining the desired degree of chemical and physical identity at high temperatures" and resistance to abrasion, impact, thermal shock, and high level of load. Refractory silica materials were classified based on their general composition and on their distinctive properties. Standard classifications and specifications for Silica Refractory Brick were published by the ASTM.^{10,11}

Abrasive sands were quartz sands used in stone sawing, glass grinding, metal

polishing, and sand blasting. No rigid specifications existed for these sands, but sound, clean, hard, and closely sized sand grains were required. Purity and grain-shape specifications varied with the type of abrasive action and the requirements of the final product. An angular particle shape with sharp cutting edges was generally required.

Hydraulic fracturing sand was pumped into oil or natural gas wells as a sand-liquid mixture to break up petroleum-bearing formations and act as a propping agent, allowing oil or gas to move more freely toward the producing wells. Some of the major requirements for fracturing sands were spherical, well-rounded grains of clean, dried, and well-screened quartz sand, free of any materials such as feldspar, calcite, and clay. The most common size was 20/40 mesh; other sizes included 6/12, 8/16, 12/20, 40/70, and 70/140, but these sands represented only about 15% of the total sand used as proppant. "Recommended Practices for Testing Sand Used in Hydraulic Fracturing Operations," published by the American Petroleum Institute, was used as a guide by industry.¹²

Ground sand or silica flour is found wide industrial application as a filler in paint, plastics, rubber, ceramics, and a variety of other products. Mainly because of the diversity of its uses, no standard specifications existed for the silica flour used in most of these applications except grain size and chemical composition.

Metallurgical sand was used as a fluxing agent for basic oxides in various smelting operations and as a source of silicon in ferrosilicon manufacture. The ferrosilicon was a steel alloying additive. Filter sand was used extensively in filtering water for municipal and industrial use and swimming pools and in sewage treatment plants. Engine sand was used in locomotive haulage to improve traction. Other sands were used in special cements, in manufacturing silica brick and tiles for furnace linings and beds, for coal washing, and in manufacturing pottery.

Industry Structure

In 1989, 87 U.S. companies with 153 active operations produced silica sand. The individual industrial sand and gravel operations ranged in size from those producing about 1 million tons

annually to those reporting less than 10,000 tons per year. Most of the production came from large operations that were mostly owned or operated by a small number of companies. In the past 10 to 15 years, there was a gradual trend toward larger operations, mostly because small plants were becoming less economical. The viability of small operations was dependent on demand in local markets, mining conditions, and the degree of processing required to supply the final product.

During the past 10 years, changes within the structure of the industrial sand industry occurred, primarily caused by mergers and acquisitions, some resulting from an influx of foreign capital, mostly from Europe.

Geology-Resources

U.S. resources of industrial sand were expected to be sufficient to meet domestic demand in the foreseeable future, although their geographic distribution and quality often did not match market requirements. The availability of these reserves was controlled to a significant degree by land-use and/or environmental constraints. Reserves of industrial sand owned or controlled by domestic producers were estimated to total about 3 to 4 billion tons.

Although industrial sand reserve data for the rest of the world were not available, it could be assumed, on the basis of geologic evidence, that world reserves were sufficient to meet demand, even if not always at the locations where needed.

Industrial sand or silica sand was produced in the United States from a variety of geological formations ranging in age from late Precambrian to mid-Tertiary. About 70 stratigraphic units were known as having an economic potential for this industry. Lithologically, these deposits ranged from quartzites, sandstones with different degrees of cementation, quartz conglomerates, chert deposits, and quartz pegmatites to terrace sands and gravels and dune sands. Most of the high-quality industrial sand was produced from a few geological formations in the eastern United States. Oriskany sandstone, or more precisely the Ridgeley formation of Early Devonian age, was one important source of silica sand. It extended from New York State to southern Virginia and eastern Ohio but

was being mined only in central Pennsylvania, northwestern Maryland, and northern West Virginia, where the formation was thick enough to be of commercial value. It was a hard white orthoquartzite with medium to fine, angular and subangular, and well-sorted grains. The St. Peter sandstone of Middle Ordovician age, extending from Wisconsin and Minnesota through Iowa, Illinois, and east-central Missouri, was another major source of industrial sand. The best known center of production of silica sand from this formation was the Ottawa district of La Salle county, IL, where it was known as "Ottawa sand," and to a lesser degree in southern Wisconsin and east-central Missouri. It was a soft and poorly cemented high-purity orthoquartzite with coarse, rounded grains. The weak cement holding the silica grains together was mostly a light-colored clay.

In addition to the two formations just mentioned, the most important sources of industrial sand in the United States, numerous other deposits were also being mined for silica sand in different parts of the country, including the Jordan sandstone of Upper Cambrian age in Minnesota and Wisconsin, a primary source of hydraulic fracturing sand; the Raritan formation of Upper Cretaceous age in central New Jersey and the Cohansey sand of probable Miocene age in southern New Jersey; the Tuscarora quartzite of Lower Silurian age in Pennsylvania and Virginia used for the manufacture of refractory bricks; the Sylvania sandstone of Devonian age in the Detroit area; the Oil Creek and McLish formations of Lower Ordovician age in Oklahoma, a southwestward extension of the St. Peter sandstone; and the Hickory sandstone of Cambrian age in central Texas that produced mostly hydraulic fracturing sand.

In the west, the most important sources of industrial sand were the Ione formation of Eocene age in northern California, the Silverado (Paleocene) and Tejon (Eocene) formations in southern California, and the Eureka quartzite of Middle Ordovician age in central California.

Approximately two-thirds of the U.S. industrial sand or silica sand was produced east of the Mississippi River, especially in the industrialized areas of the East North Central, South Atlan-

tic, and Middle Atlantic regions. Of the top five producing States that accounted for about one-half of 1989 production, three—Illinois, Michigan, and New Jersey—were in the East and the other two—California and Texas—were in the West. The concentration of the industrial sand operations in the eastern part of the United States resulted from the existence of high-quality geologic deposits in close proximity to the major consuming industries, glass and foundry.

Technology

Exploration.—A large number of geologic formations with economic potential as a source of industrial sand have been mapped and described in the literature over many years and were, therefore, well known. Consequently, detailed exploration and development work for new industrial sand operations was expected to occur on some of these formations. The qualities of a silica deposit necessary for a viable operation should include proper particle size, chemical composition, degree of cementation, and deposit uniformity. Also, the nature and amount of waste material and the economic feasibility of its removal and possible use or disposal should be studied. The evaluation of the new deposit should also include an environmental impact study as required by most local or State agencies before authorizing a new mining operation.

If the raw material should prove to meet the requirements and adequate reserves are demonstrated, the development stage of the operation could be started. Economic feasibility and marketing studies should be performed by analyzing all factors important for any such mining operations, including the availability of power and water supply, mining and processing costs and requirements, the condition of nearby roads and highways, the proximity of rail haulage, the cost of compliance with local, State, and Federal regulations, and the proximity and density of local population as well as its attitude toward such a project.

Mining.—Most industrial sand was mined from open quarries, but a few underground operations existed, mostly because of an exceptionally thick over-

burden or environmental limitations. Surface mining methods and equipment varied with the type of the geologic formation, size and configuration of the deposit, production capacity, estimated life of the operation, and location of the deposit with respect to urban centers. The mining methods depended primarily on the degree of cementation of the rock, but most open pit mining operations included site clearing and removal of the overburden; mining of the silica rock or sand; processing of the material, including crushing, screening, and classification; and reclamation of the extraction area. Unconsolidated sands, such as the Cohansey of New Jersey, if below the ground water level were dredged. Much of the St. Peter sandstone was first loosened by light blasting and then washed down by hydraulic jets or "monitors" into sumps, from which it was pumped to the processing plants. Harder rock such as the Oriskany sandstone required blasting and primary and secondary crushing before it could be processed.

Beneficiation.—Processing of mined silica sand required specialized operations that varied considerably with the nature of the deposit and the physical and chemical requirements of the desired product. Depending on the degree of cementation, several stages of crushing were necessary to achieve the desired size reduction. Gyratory crushers, jaw crushers, impact mills, or roll crushers were used as primary or secondary crushers, and smooth rolls, media mills, autogenous mills, high-speed hammer mills, or fluid energy jet mills were used for grinding the product down to 50 microns and finer. Dry or wet screening was used to separate particles of sizes down to about 150 microns, and wet or air classifiers processed particles from 250 microns into the submicron range. Vibratory screens and gyratory screens in addition to mechanical, hydraulic, or air classifiers were used, depending on the size distribution required.

Research for the silica mining industry related not only to new methods that increased output and reduced production costs but also to health and safety problems as well as exploration, land management, and reclamation. Equipment manufacturers and some government agencies were constantly working on improving exploration, mining, and proc-

essing plant technology.

Significant technological developments instrumental in maintaining adequate production at relatively stable real costs were mostly in the processing plant technology. The use of computerized systems in plant operation and quality control increased; and this, along with improved mining and processing equipment, permitted the recovery of salable fractions that were previously considered uneconomical.

Recycling.—Recycling of silica sands was limited to some foundry sands, particularly those used for making cores and molds with no-bake resin-bonded sands, some abrasive and air-blasting sands, and some scrap glass that substitutes for glass sand. International trends toward increased recycling of glass and foundries sands and innovative ideas on recycling other materials should influence increased recycling of silica products.

Byproducts and Coproducts

Small amounts of gold and silver were recovered occasionally as a byproduct or coproduct from some unconsolidated silica sand deposits. Also, during the processing of some silica resources, other minerals, including clays, feldspars, mica, and quartz crystals, were produced as byproducts and coproducts.

Economic Factors

Silica sand deposits are nonrenewable resources. New mining methods combined with advances in mineral processing that were introduced during the past decade have increased the number of silica deposits that can be commercially developed.

The industrial sand industry was very competitive largely because silica sand is a relatively abundant mineral, with supply usually exceeding demand. The delivered price of the product, in addition to quality, was a very important element in any major transaction. The producer with an operation closest to the market had a significant advantage over competitors. Combining sophisticated (and therefore expensive) processing equipment backed by technical knowledge and solid sales expertise was important. For this reason, only a small number of large companies were able to

compete successfully and succeed in the silica sand business and supply a wide variety of products. Smaller, less efficient operations became uneconomical as operating costs, as well as costs associated with meeting various Federal, State, and local regulations, continued to increase. The only alternatives they had were to either limit the range of products they supplied to closely located markets or go out of business.

Prices.—As a result of rapidly rising costs of labor, energy, and mining and processing equipment, 1988 constant dollar prices of industrial sand rose steadily between 1973 to 1983. From 1984 to 1989, 1988 constant dollar prices fluctuated in the 13.50 to 14.50 range. Prices should be expected to continue to fluctuate although they should slowly rise as a result of the cost of compliance with more stringent environmental, land use, and safety regulations.

Costs.—Production costs for silica sand were determined to a large extent by the cost of labor, equipment, energy supply, water availability, and the additional burden of compliance with environmental and safety regulations. Production costs varied widely depending upon the nature of the geologic deposit, the geographic location, and the type and number of products produced. Profits were relatively small for most producers, total production costs being close to the f.o.b. selling price per ton.

Tariffs.—There has been no tariff on imported silica sand, containing 95% or more SiO_2 and not more than 0.6% iron oxide, from most favored nations since January 1, 1987. For all other countries, the tariff for imported silica sand remains \$1.94 per long ton.

Depletion Provisions.—The depletion allowance for industrial sand and gravel was 14%.

Operating Factors

Environmental Requirements.—Major environmental considerations that had to be dealt with in mining and processing of industrial sand and gravel were emission of particulate matter into the air, discharge of processing water,

and noise abatement. Air pollution constituted a major problem in the processing plants, especially in the drying and packaging stages of finer products like silica flour, silicosis being the major disease that can be contracted as a result of long-term exposure to silica dust. Because of the high cost of compliance with the environmental regulations designed to reduce this health hazard and possible long-term liabilities associated with it, some companies were no longer producing silica flour or did not plan to produce it in the future. Both wet and dry methods of dust control were used. The most important water pollutant was clay in suspension as a result of washing and screening silica sand. Because of the large quantities of water used to process silica sands and the need of compliance with stringent regulations, the treatment of discharge water by the sand producer was expected to require increasingly sophisticated and expensive processing methods. Significant progress was made in reducing noise pollution both inside and outside of the operations, including noise and vibration produced by blasting and movement of heavy trucks.

Sand producers had to obtain mining permits from the appropriate governmental agency, which sometimes also required an Environmental Impact Statement (EIS) and a reclamation plan that met its guidelines or regulations. More and more emphasis was being put by local communities on improving the overall appearance of the operating mines as well as on land reclamation after mining was completed. At the same time, industry and the communities had to recognize the time and costs required to protect the environment and the importance of agreeing on fair and realistic environmental standards. Many States, counties, and towns had zoning laws that regulated land use.

Most of the active silica sand quarries as well as the known deposits were on private land, which was either owned or leased on a long-term basis by the producers. These deposits contained high-quality silica sand and were in the best locations with respect to markets. Unlike the construction sand and gravel industry, the industrial sand industry was usually not significantly affected by increasing land values near populated areas.

Transportation.—Transportation costs for silica sand were often equal or considerably greater than the cost of the product at the processing plant. Because of the large variety and number of consumers of silica sand, long-distance haulage was not uncommon. The largest tonnage, 58% of all industrial sand, was shipped by truck because most users require a versatile and rapid delivery system. Substantial quantities, 34% of the total, were also shipped by rail, especially when large volumes were sent long distances.

SELENIUM AND TELLURIUM

By Daniel Edelstein

Mr. Edelstein is a physical scientist (geologist) with more than 15 years of combined experience working for the Bureau of Mines in minerals processing research, process evaluation, and mineral commodities. He has been a commodity specialist for selenium, tellurium, and copper for 7 years.

Domestic demand for selenium and tellurium declined in 1989 owing to weakness in demand for selenium used in photo-receptors and tellurium used in ferroalloys. The apparent world demand for selenium increased, and that for tellurium remained unchanged. World demand for selenium continued to be strong and stocks of refined selenium declined. However, prices continued to fall from the high level experienced in 1987. World production and shipments of tellurium were nearly balanced, and the price for refined tellurium was essentially unchanged throughout the year.

STRATEGIC CONSIDERATIONS

In August 1987, under contract to the Federal Emergency Management Agency (FEMA), ASM International convened a panel of industry representatives to assess the quality and material form of minor metals for the National Defense Stockpile. In their report issued in 1989, the panel recognized important specialized military applications for high-purity selenium and tellurium in the manufacture of hardware for infrared imaging systems for night vision and navigation systems. These applications included germanium-arsenic-selenium glass for infrared optical components and cadmium-mercury-telluride infrared detectors. The panel concluded that domestic capacity for commercial and detector grades of tellurium was adequate to meet emergency requirements, but they recognized a potential for an emergency shortage of high-purity selenium for strategic uses. However, owing to the possibilities of conservation, the availability of selenium from domestic and Canadian sources, and the ability to substitute other materials in a number of metallurgical applications, the panel felt that the supply of selenium should be reasonably secure in an

emergency and thus recommended against stockpiling of selenium. Government stockpiles of selenium, which exceeded 400,000 pounds in the 1960's when selenium rectifiers were of significant strategic importance, were liquidated by 1974.¹

ISSUES

Selenium and tellurium and their compounds are considered toxic in large doses. Though there are no clear indications of long-term systemic effects among industrial workers, selenium and tellurium exposure is monitored and regulated by the Occupa-

tional Safety and Health Administration (OSHA), and the Environmental Protection Agency (EPA) regulates their discharge in air, water, and solid wastes. The occurrence and toxicity of selenium in the environment from nonindustrial sources has been reported in considerable detail. Agricultural irrigation practice in the San Joaquin Valley of California and other arid regions of the Western United States leached selenium compounds from the soil. Selenium accumulated in the evaporation ponds and catch basins from agricultural drainage water. The high selenium levels in the water and aquatic vegetation had significant detrimental effect on waterfowl nesting in these areas.

While selenium is toxic in high doses, it is an essential micronutrient in the diet of humans and livestock. In April 1987, the Food and Drug Administration (FDA), U.S. Department of Health and Human Resources, published new regulations concerning the use of selenium as an additive in feed for major food-producing animals. The new regulations increased the maximum allowable selenium supplementation level in complete animal feed from 0.1 to 0.3 part per million, as well as proportional increases in feed and mineral supplements. Five organizations subsequently filed objections to the 1987 amendments over concern that the environmental impact had not been adequately addressed. The organizations contended that the new limits increased the potential for bioaccumulation or concentration of selenium, thereby creating potential environmental problems, particularly in aquatic ecosystems. In July 1989 FDA published its analysis of the objections to the 1987 rule and invited written comments on its analysis.²

In May 1989 EPA repropoed maximum contaminant level goals (MCLGs) and National Primary Drinking Water Standards (NPDWRs) for 38 chemicals including selenium. EPA first proposed new standards in 1985. The MCLG for selenium of 0.05 milligram per liter, unchanged from the new standard proposed in 1985, was five times greater than the existing 0.01 milligram per liter standard. In proposing the new standard, EPA recognized that selenium was an essential micronutrient and that a standard below the proposed level might result in selenium deficiency in the human diet. EPA believed that the proposed standard would adequately balance the potential deficiency and toxicity effects of selenium.³

According to the Bevill Amendment to the Resource Conservation and Recovery Act (RCRA) solid wastes from the extraction, beneficiation, and processing of ores and minerals were exempted from regulation as hazardous waste under Subtitle C of RCRA, pending completion of certain studies by EPA. In 1980, EPA interpreted this exemption, on a temporary basis, to include all solid wastes from exploration, mining, milling, smelting, and refining of ores and minerals. However, in July 1988, a Federal Court of Appeals, directed EPA to confine the exclusion to only those special wastes that met certain high-volume and low-hazard criteria. A list published by EPA in April 1989, conditionally retained process wastewater from primary

selenium processing within the Bevill exclusion. However, the Notice of Proposed Rulemaking (NPRM), released in September, excluded this waste stream from the list of waste streams being conditionally retained within the Bevill exclusion. A final NPRM was required by mid-January 1990.⁴

A significant operating problem that has affected domestic selenium and tellurium production indirectly has been the control of air pollution at copper smelters. As of January 1988, smelters were to comply with the ultimate control standards for sulfur dioxide emissions as stated in the 1977 amendments to the Clean Air Act of 1970. ASARCO Incorporated decided not to retrofit its Tacoma, WA, smelter with the necessary engineering controls to bring it into compliance with arsenic and sulfur dioxide emissions regulations, and in 1985 closed the smelter. Owing to the high arsenic content of the ores, the Tacoma smelter was the only domestic smelter capable of processing high-selenium-tellurium concentrates imported from the Philippines. Closure of several other non-compliance primary domestic copper smelters further reduced smelting capacity. Consequently, the United States has become a net exporter of copper concentrates, which effectively reduces the potential domestic recovery of byproduct selenium and tellurium.

PRODUCTION

Primary selenium was recovered in the United States at three electrolytic copper refineries: Asarco at Amarillo, TX; Phelps Dodge Refining Corp. at El Paso, TX; and Rio Tinto Zinc Corp. Ltd. (formerly BP Minerals America Corp.) at its Kennecott refinery at Magna, UT. Commercial-grade tellurium metal and tellurium dioxide were produced by Asarco. Selenium- and tellurium-containing anode slimes or residues generated at other domestic primary copper refineries were exported for processing.

Domestic production of refined selenium declined despite an increase in primary refined copper production. In the United States most of the increase in refined copper production was from solvent extraction/electrowinning, which precluded recovery of selenium. Domestic shipments of selenium continued to outstrip production, and stocks of refined selenium con-

tinued to drop. Most domestic selenium production was as commercial-grade material, averaging a minimum of 99.5% selenium, and available in various forms including shot, powder, and lumps, or as pigment-grade powder having a minimum 99.8% selenium content. There was no domestic production of high-purity selenium suitable for electronic applications.

About 150 to 200 metric tons of selenium contained in scrap derived from the manufacture of photoconductor drums and from used photoreceptor drums was exported for processing. There was no domestic production of secondary selenium.

Domestic production of refined tellurium declined markedly during 1989 in response to a decline in domestic demand. Stocks of semirefined feedstock rose slightly from the low level established in 1988.

CONSUMPTION AND USES

Selenium demand by end use can be divided broadly into five applications: electronics (includes photoconductor uses), glass and ceramics manufacturing, pigments, chemicals, and metallurgical. In electronics, the largest end-use market, high-purity selenium was used principally as a photoconductor on the drums of plain paper copiers. Other electronics uses include rectifier and photoelectric applications. In glass manufacturing, selenium was used principally as a decolorant to compensate for the yellow-green tint imparted by ferrous ions. Selenium was also used to reduce solar heat transmission in architectural plate glass. Cadmium sulfoselenide red pigments have good heat stability and are used in ceramics and plastics.

Chemical uses of selenium included industrial, pharmaceutical, agricultural, and biological uses, such as rubber compounding chemicals, gun bluing, catalysts, antidandruff shampoos, animal feed supplements, and vitamin supplements for humans. In metallurgical applications, selenium was added to steel, copper, and lead alloys to improve machinability and casting and forming properties.

Domestic demand for selenium in 1989 declined slightly from that of 1989 owing to a decline in photoreceptor demand and to weakness in the automotive industry. Demand for selenium by end use was estimated as follows: Electronics, 35%;

pigments and chemicals, 20%; glass manufacturing, 25%; and other, including agriculture and metallurgy, 20%.

Tellurium was used principally as an alloying element in the production of free-machining low-carbon steels, where additions of up to 0.1% tellurium, usually in conjunction with lead, greatly improve machinability. Similarly, the addition of tellurium to copper and other nonferrous alloys improves their machinability, strength, and corrosion resistance. Tellurium catalysts were used chiefly for oxidation of organic compounds, but were also used in hydrogenation, halogenation, and chlorination reactions. Tellurium chemicals were used as curing and accelerating agents in rubber compounding. Electronic semiconductor applications for high-purity tellurium included its use with selenium as a photoconductor in plain paper copiers, as an infrared sensing material in mercury-cadmium-tellurium (MCT) thermal imaging devices, and in thermoelectric and photoelectric devices.

Apparent domestic demand for tellurium and its compounds, as calculated from production, trade, and stock data, declined markedly. The decrease in apparent demand was largely attributed to reduced shipments to manufacturers of free-machining steels. A drawdown of unreported merchant and consumer inventories, which had been accumulated during 1988, was believed to account for some of the fall-off in calculated demand. Substitution of other free-machining alloys may have been stimulated by the high price of tellurium and environmental concerns over lead, which is used in conjunction with tellurium in some free-machining alloys.

In 1989 iron and steel products remained the largest end use, followed by nonferrous metals, chemicals, and other uses.

PRICES

The merchant price for commercial-grade refined selenium, quoted by Metals Week on a weekly basis, continued to decline during the first 6 months of 1989 before stabilizing during the third quarter at \$6.50 to \$7.00 per pound. Prices had peaked during the first half of 1988 at about \$11.00 per pound. The price decline occurred despite continued strong world demand for selenium and an almost 30% decline in reported world stocks of refined sele-

nium. Significant premiums were charged for higher purity forms of selenium.

The price for commercial-grade tellurium metal remained at or near the high price established during 1988, more than triple the 1986 price. The yearend price quote for tellurium by the only domestic producer was \$34 per pound.

FOREIGN TRADE

Imports of selenium metal were at about the same level as in 1988. Though Canada remained the largest source of imports, Canadian imports declined by about 37%. Exports of selenium metal, waste, and scrap rose by over 50%. It is believed that between 200 and 250 tons of that material were either scrap materials for reprocessing, or unrefined anode slimes or residues. Under the Harmonized Tariff System (HTS) adopted in 1989, imports of sodium selenite and other selenium compounds were no longer distinct categories. Similarly, imports of tellurium compounds and salts were no longer distinguishable. Though imports of unwrought tellurium, waste, and scrap, were included with imports of boron metal under the HTS, imports of boron were thought to be negligible.

WORLD REVIEW

World production of refined selenium was at about the same level as in 1988. Despite a decline in apparent demand in the United States, world demand for refined selenium rose slightly and continued to outstrip production. According to data compiled by the American Bureau of Metal Statistics (ABMS), inventories of refined selenium held by reporting companies declined by about 225 tons. However, at the prevailing rate of consumption, yearend inventories of selenium still constituted almost a 6-month supply.

According to ABMS shipment data for market economy countries, the United States was the largest recipient of selenium, followed by the United Kingdom, Japan, the Netherlands, Belgium, and China. Combined, these countries accounted for about 82% of shipments. However, in addition to these shipments, China was believed to consume about 125 tons per year of domestically produced selenium, making it the fourth largest world consumer.

According to ABMS shipment data, world demand for refined tellurium remained at about the same level as in 1988 despite the large decline in U.S. apparent consumption. Supply and demand were balanced and reported world inventories were essentially unchanged.

Capacity

In the past 5 years, annual world selenium production capacity increased by about 200 tons, while that for tellurium remained stable, or could have declined. In North America, selenium production and capacity increased, while that for tellurium decreased. In the United States, closure of AMAX Copper Inc.'s selenium and tellurium refinery in New Jersey was balanced by the opening of the new Phelps Dodge Corp. selenium refinery at El Paso, TX. In 1987, BP Minerals America Corp. reopened its Bingham Canyon operations and associated copper/selenium/precious metals refinery, which had been shuttered since 1985. In Canada, Noranda commissioned a new anode slimes treatment plant in 1988. Canadian production of tellurium declined when the tellurium-rich Horne mine closed in 1987.

In Asia, the Philippines began recovering selenium in 1984 at the new Philippine Associated Smelter and Refining Corp. (PASAR) copper smelter/refinery. Prior to this, Philippine concentrates exported to the United States had been a major source of selenium and tellurium. However, while PASAR recovered selenium, no production of tellurium from the PASAR smelter was reported. International Recoveries Inc. of Manila began producing tellurium dioxide in 1984, and secondary selenium, on a toll basis in 1987. In 1989 it commissioned an electrowinning circuit to produce up to 3 tons of tellurium metal per month. In Europe, Metallurgie Hoboken-Overpelt (MHO) completed expansion of its selenium refinery at its Hoboken operations during 1988. Capacity of the refinery, which processed slimes generated at the Olin refinery, increased from 260 tons per year to 360 tons per year.

CURRENT RESEARCH

The Fourth International Symposium on Uses of Selenium and Tellurium was held on May 8-10 in Banff, Alberta, Canada. More than 60 papers were presented covering environmental health and safety,

photoelectric and photovoltaic applications, catalysis, biology and nutrition, chemical technology, and agricultural applications.⁵

OUTLOOK

World production of refined selenium has fluctuated greatly over the past 10 years. However, the overall trend has been flat, with production over the 10 years averaging about 1,500 tons per year. Meanwhile, world mine and refinery production of

copper have increased by more than 10%. Factors leading to a disparity between copper production and refined selenium production include an increasing production of refined copper by electrowinning, which precludes selenium recovery, and shut-downs of mines having a high selenium content in their ores. Perhaps the most important factors leading to the disparity between copper and selenium production trends, have been the effects of selenium price and demand on the rate of recovery of selenium from slimes. During times of weak prices and stagnant demand, sele-

mium refineries, lacking the economic incentive to recover selenium, may stockpile crude selenium intermediates for future refining or may bypass selenium recovery circuits altogether.

The Bureau of Mines forecasts a significant increase in copper mine capacity for the next 5 years. However, as noted above, selenium production over a 10-year period has remained flat and has not followed the upward trend in copper production. If this trend in selenium production continues, and demand remains at the high level of the past 2 years, the current production deficit

¹Because of the implementation of the Harmonized Tariff System in Jan. 1989, import and export categories for 1989 are not necessarily comparable to those of previous years.

²Listed as "tellurium" under the Harmonized Tariff System, and grouped together with boron. However, imports of boron are thought to be very small relative to tellurium.

³Less than 1/2 unit.

for selenium will continue. This trend could be reversed if demand weakens, or if higher prices, brought about by declining stocks, stimulate increased recovery rates for both primary and secondary selenium.

Data on demand for and production of tellurium are incomplete. However, available data indicate that market economy country demand over the past 5 years has been comparatively stable, averaging about 220 tons per year. Demand peaked in the 1978-1979 period at about 400 tons per year, stimulated by a short-lived demand for tellurium catalysts by a North America producer of ethylene glycol.

World production of refined tellurium, according to ABMS data, has trended downward. Excess supply following the demand turndown depressed prices and

discouraged recovery of tellurium. The closing in 1985 of Asarco's Tacoma smelter, which had processed high-tellurium Philippine concentrates, significantly reduced the tellurium content of the company's anode slimes, and hence its tellurium recovery. Production of tellurium by Noranda in Canada has fallen to about 20% of the 1978 level, owing to a drop in the tellurium content of its ores. By 1986, the supply of tellurium had fallen short of the demand, and by the end of 1987 stocks of crude and refined tellurium were sufficiently low to precipitate a 350% price rise.

The near-term outlook is for the continued tight balance between the supply and demand for tellurium. The high price for tellurium was expected to moderate the future demand for tellurium in traditional metallurgical applications and stimulate the

substitution of alternative materials. If new thin-film technologies stimulate the demand for tellurium in electronic applications such as solar energy conversion or thermoelectric power generation, supply pressures could increase. Though no significant new tellurium capacity was expected, additional resources, such as the gold telluride ores found in Fiji and Colorado, are potential new sources of tellurium.

^eEstimated. ^PPreliminary. ^rRevised. W Withheld to avoid disclosing company proprietary data; not included in "Total."

¹Insofar as possible, data relate to refinery output only; thus, countries that produced selenium contained in copper ores, copper concentrates, blister copper and/or refinery residues, but did not recover refined selenium from these materials indigenously, were excluded to avoid double counting. Table includes data available through May 25, 1990.

²In addition to the countries listed, Australia, the Federal Republic of Germany, and the U.S.S.R. produced refined selenium, but output is not reported, and available information is inadequate for formulation of reliable estimates of output levels. Australia is known to produce selenium in intermediate metallurgical products and has facilities to produce elemental selenium. In addition to having facilities for processing imported anode slimes for the recovery of selenium and precious metals, the United Kingdom has facilities for processing selenium scrap.

³The 1985 refinery output is from all sources including imported materials and secondary sources; 1986-89 excludes secondary production.

⁴Reported figure.

⁵Data for fiscal year beginning Apr. 1 of year stated. In addition to refined selenium metal produced domestically as shown, Zambia is believed to have exported anode slimes from electrolytic copper production that have been estimated to additionally contain more than 30,000 kilograms per year of selenium.

TABLE 8

TELLURIUM: WORLD REFINERY PRODUCTION, BY COUNTRY¹ (Kilograms, contained tellurium)

United States	W	W	W	W	W

^eEstimated. ^PPreliminary. W Withheld to avoid disclosing company proprietary data.

¹Insofar as possible, data relate to refinery output only; thus, countries that produced tellurium contained in copper ores, copper concentrates, blister copper, and/or refinery residues, but did not recover refined tellurium, are excluded to avoid double counting. Table is not totaled because of the exclusion of data from major world producers, notably Belgium, the U.S.S.R., and the United States. Table includes data available through May 31, 1990.

²In addition to the countries listed, Australia, Belgium, the Federal Republic of Germany, and the U.S.S.R. are known to produce refined tellurium, but output is not reported, and available information is inadequate for formulation of reliable estimates of output levels. Moreover, the other major copper-refining nations such as Chile and Zambia may produce refined tellurium, but output in these nations is conjectural.

³For 1985, refinery output from all sources, including imports and secondary sources; for 1986 onward, primary recoverable output.

⁴Reported figure.

SILICON

By Joseph Gambogi

Mr. Gambogi, a physical scientist with more than 7 years of Government and industry experience, has been the commodity specialist for silicon since 1988. Domestic survey data and trade data were prepared by Ms. Robin Johnson, Mineral Data Assistant in the Branch of Data Collection and Coordination.

For most of 1989, demand for silicon products remained near the high levels reached in 1988. However, a reactivation of idle capacity, combined with new global capacity, resulted in an oversupply of silicon materials. Prices that had reached record highs in 1988 decreased significantly. Consequently, production cutbacks were scheduled by several domestic producers in the second half of 1989.

LEGISLATION AND GOVERNMENT PROGRAMS

Several proposals were introduced in the 101st Congress that would limit the amount of sulfur dioxide emissions from coal-based power utilities. The Bureau of Mines conducted a study to determine the possible effects of these proposals on the minerals industry. The study found that, if passed into law, significant cost increases could be incurred by certain utilities. These costs would in turn be passed along to their consumers, which included several silicon and ferrosilicon

producers. The study estimated the legislation proposed would increase the average cost of production from 2 to 4.5 cents per pound of contained silicon metal. At yearend, a resolution regarding this legislation had not been reached.¹

Under Title III provisions of the Defense Production Act, the Air Force System Command awarded two contracts totaling more than \$33 million to encourage development of commercial suppliers of metal matrix composites (MMC). The contracts were awarded to Advanced Composite Materials Corp., Greer, SC, and DWA Composite Specialties Corp., Chatsworth, CA. The Air Force indicated the goal of the program was to make MMC materials "market competitive."² Aluminum matrix composites with silicon carbide fiber reinforcement appeared to show the most promise for achieving this goal.

STRATEGIC CONSIDERATIONS

Silicon semiconductors played an es-

sential role in electronic devices for military and commercial applications. In 1989, the United States was one of the world's leaders in semiconductor device manufacture. However, portions of the domestic semiconductor market were dominated by imports. An area of significant concern was the domestic capability to produce infrared (IR) detector-grade silicon metal. IR detector-grade silicon was used by the Department of Defense for the manufacture of devices that guide highly advanced weapons. IR materials also served numerous functions as part of satellite surveillance systems. Nevertheless, these materials were obtained almost exclusively from foreign sources in 1989.³

PRODUCTION

Overall gross production and shipments of silicon containing products were comparable to those of 1988. Overall production increased 4% while shipments were nearly unchanged. However, production and shipments of

TABLE 1
PRODUCTION, SHIPMENTS, AND STOCKS OF SILVERY PIG IRON, FERROSILICON,
AND SILICON METAL IN THE UNITED STATES IN 1989

Miscellaneous silicon alloys (excluding silicomanganese)	32-65	—	15,111	90,561	77,309	22,293

^r Revised. W Withheld to avoid disclosing company proprietary data.

certain products changed significantly. The most significant change occurred in production and shipments of 75%-grade ferrosilicon. Shipments of this product rose 28% while production rose 56% compared to that of 1988. Producer stocks of silicon-containing material rose 32% overall. Estimated ferrous scrap consumption was 275,000 tons in 1989.

Globe Metallurgical Inc., Beverly, OH, purchased Materials & Methods Ltd., Reigate, England. Materials & Methods held several patented processes used to produce foundry ductile iron. Many of these processes used silicon ferroalloys, which Globe produced at its operations in the United States. This was Globe's first major acquisition since its management buyout in 1987. By mid-year, Globe terminated its 34-year-old relationship with its sales representatives, Pickands Mather & Co., to form an internal sales force. Late in 1989, Globe shut down one of its 13-megavolt-ampere (MV•A) ferrosilicon furnaces for repair.

Following a financial reorganization in 1988, Simetco Inc., Montgomery, AL, bought Quadracast Inc., and its Harrison Handling Division. Quadracast specialized in metals fabrication. Harrison built patented belt conveyors and other equipment used in the mining industry.

Silicon Metaltech Inc., Wenatchee, WA, expanded its operations in Rock

Island, WA, with the construction of a new chemical lab. The new facility allowed the company to perform detailed analyses of silicon metal. This type of analysis was essential for Silicon Metaltech to produce chemical-grade silicon metal.

Cominco American Resources Inc. rekindled an idle ferrosilicon furnace at its Glenbrook Ferronickel Operations where ferrosilicon was consumed in the ferronickel process. The company reported some of the furnace's 18,000 short tons per year (tpy) of capacity was intended for commercial sales. For most of the year, Cominco American Resources was a wholly owned subsidiary of Cominco Resources International Ltd. and USA Investments. However, Cominco International purchased the remaining Cominco American interest late in 1989.⁴

In September, American Alloys Inc. began production of silicon metal at its New Haven, WV, plant. The new furnace was reported to be capable of producing 6,000 tpy of contained metal. The furnace represented the first new addition to the company, which was formed in a management buyout of Foote Minerals Co. in 1987.⁵

In June, Elkem Metals Co. temporarily idled a ferrosilicon furnace at Ashtabula, OH, after a burnthrough in the furnace lining. The furnace was brought back on-line in October after maintenance repairs had been com-

pleted. Late in the year, Elkem Metals announced plans to shut down one of two furnaces at its Ashtabula, OH plant.

Several companies made plans late in 1989 for reducing output of silicon products during 1990. Among these companies, SKW Alloys Inc. planned to shut down one of two 35-MV•A ferrosilicon furnaces at its Calvert City, KY, plant. Meanwhile, Globe Metallurgical also planned to shut down individual furnaces for maintenance during 1990.

Monsanto Electronics Materials Co. (MEMC) was sold to Huels AG of the Federal Republic of Germany. MEMC was the last major domestic silicon wafer producer catering to independent chip makers. All other major producers made wafers for their own chip production.⁶

CONSUMPTION AND USES

Apparent consumption (demand) of silicon-containing ferroalloys and silicon metal decreased 5% compared with that of 1988. The continued strong demand reflected high production levels in the aluminum, iron and steel, and silicon-base chemical industries. Specifically, consumption of silicon metal decreased 11% while ferrosilicon applications decreased 2%. The aluminum industry used silicon metal in the production of wrought and cast products while ferrosilicon was used as a deoxidizing and alloying agent in the production of iron and steel products. Ferrosilicon and miscellaneous silicon alloys used in the production of iron and steel accounted for 70% of all the silicon materials consumed, based on silicon content.

Metallurgical-grade silicon metal produced by tonnage methods was used as the basic raw material in the manufacturing of many chemical products and intermediates such as silicones and silanes. Silanes were used in the production of high-purity silicon for semiconductor devices and solar cells (photovoltaic cells). The Bureau of Mines did not collect data on electronic grades of silicon, which were relatively low in quantity but high in unit value.

Union Carbide Corp. reorganized its silicone fluids, silicone surfactants, and silanes business into a new worldwide operating unit called Organo-Silicon

TABLE 2

PRODUCERS OF SILICON ALLOYS AND/OR SILICON METAL IN THE UNITED STATES IN 1989

Producer	Plant location	Product
American Alloys Inc.	New Haven, WV	FeSi and Si.
Applied Industrial Minerals Corp.	Bridgeport, AL	FeSi.
Cominco American Resources	Riddle, OR	Do.
Dow Corning Corp.	Springfield, OR	Si.

Consumers' stocks, Dec. 31	778	8,272	87	7,460	48	2,569	1,035	1,451

¹ Includes briquettes.

² Primarily magnesium-ferrosilicon but also includes other silicon alloys.

³ Does not include silicon carbide for abrasive or refractory uses.

⁴ Included with "Miscellaneous and unspecified."

⁵ Consists primarily of consumption of silicon metal for the production of silicones and silanes and estimated consumption for the production of fumed silica and other chemicals.

Products, Systems and Service Group. The announcement follows a 1988 decision not to form a joint venture with General Electric Co. due in part to objections by the Federal Trade Commission. The new group made plans to expand its silane operations in Sisterville, WV, as well as its silicone facility at Italiba, Brazil. Union Carbide was one of the major consumers of chemical-grade silicon metal in 1989.⁷

PRICES

Following record high prices in 1988, published prices for silicon containing materials decreased significantly in 1989. However, overall demand for these products was only slightly lower than in 1988. Several factors contributed to an oversupply of material forcing lower market prices. One of the most influential factors affecting prices was the recent reactivation of idle U.S. capacity. Other factors affecting prices were the development of new production capacity in South America and the escalation of low cost imports from China, South

America and the U.S.S.R. into the United States. Large stockpiles of Chinese material developed by Japanese consumers and traders in the second half of 1988 contributed to the fall in prices worldwide. The average published prices for silicon-base commodities are listed in the following table. All prices are posted in cents per pound of contained silicon.

Year	Si Met	50% FeSi	75% FeSi
1980	59.17	39.80	41.77
1981	61.04	41.54	40.01
1982	57.35	41.42	37.93
1983	53.77	37.12	36.67
1984	60.35	41.22	41.89
1985	58.77	37.52	35.71

1987	58.06	38.51	36.78
1988	68.67	52.08	56.82
1989	58.75	49.57	48.96

Source: Metals Week

FOREIGN TRADE

In 1989, several domestic producers

increased their sales efforts in the global market. Meanwhile, global demand remained relatively high. As a result, ferrosilicon exports increased significantly compared with those of 1988. The major markets for ferrosilicon exports included Canada, the Republic of Korea, and the United Kingdom. In contrast to ferrosilicon, silicon metal exports decreased by nearly one half. This depression was believed to be caused by a saturation of Chinese material within the Japanese market. Exports of silicon metal were shipped primarily to Mexico, the Netherlands, and Venezuela.

Under the Omnibus Trade and Competitiveness Act (Public Law 100-418, Subtitle B), tariff schedules were revised on January 1, 1989, to conform to the internationally established Harmonized Tariff System (HTS). Consequently, U.S. customs import and export categories for silicon-base alloys were revised. The law was designed to enhance the competitiveness of the Nation's industries and to improve the management of the U.S. trade strategy. The revisions significantly changed the tariff categories for silicon-base products as shown on the following table:

Item	Harmonized Tariff Schedule Number	Most Favored Nation (MFN) ¹	Non-MFN ¹
Ferrosilicon, 55%-80% Si:			
More than 3% Ca	7202.21.1000	1.1% ad val.	11.5% ad val.

¹ Tariff effective Jan. 1, 1989.

In accordance with the United States-Canadian Free Trade Agreement, U.S. duties on ferrosilicon products imported from Canada were removed on January 1, 1989. Also effective on January 1, duties on Canadian silicon metal imports were lowered. Duties on all grades of metal were scheduled to be eliminated by 1998.⁸ The new U.S. duty rates per kilogram of silicon metal originating in Canada were as follows:

Year ¹	Harmonized Tariff Code		
	2804.61.00	2804.61.10	2804.69.50
1989	2.9%	4.7%	8.1%
1990	2.2%	4.2%	7.2%
1991	1.4%	3.7%	6.3%
1992	.7%	3.1%	5.4%

1994	Free	2.1%	3.6%
1995	Free	1.5%	2.7%
1996	Free	1.0%	1.8%
1997	Free	.5%	.9%
1998	Free	Free	Free

¹ Rates of duty effective Jan. 1, 1989.

In April, the Office of the U.S. Trade Representative (USTR) released its 1988 Product Review of the Generalized System of Preference. The U.S. Ferroalloy Association had requested an end to duty-free imports of 99.00 to 99.99% silicon metal from Argentina and Yugoslavia. The USTR decided to continue Generalized System of Preference (GSP) status of these imports. However, effective July 1, 1989, the USTR removed GSP status of Brazilian

silicon metal less than 99.99% but not less than 99% silicon and ferrosilicon containing by weight more than 55% but less than 80% silicon and more than 3% calcium.⁹

Late in 1989, the Office of Foreign Availability, Bureau of Export Administration, Department of Commerce, began an investigation to assess the foreign availability of high purity polycrystalline rods and chunks. These materials were the basic raw materials for most semiconductor devices in 1989. Subsequently, the sale of these materials was regulated for national security reasons. A decision on this investigation was pending at yearend.¹⁰

WORLD REVIEW

Australia

Barrack Mines Ltd. successfully commissioned its silicon metal plant near Perth, Western Australia. When fully operational, the furnaces were reported to be capable of producing 36,400 tpy of silicon metal. However, the production output for 1990 was targeted at 27,600 short tons. Silicon metal from these furnaces was expected to meet the stringent purity requirements of the primary aluminum and chemical industries. Barrack was reported to have long term contracts with both Thyssen Handesunion AG, West Germany, and Dow Corning Corp., Midland, MI. The company also had announced plans for an additional two furnaces scheduled for start up in July 1991.¹¹

Brazil

Brazilian ferroalloy producers announced several expansions and expansion plans during 1989. However, because of poor market conditions in the second half of 1989, the completions of these plans were in question.¹²

Electrovale SA Industria e Comercio, a Brazilian-Japanese joint venture, began construction of a 31 MV•A furnace at its Nova Era Works, Minas Gerais state. The expansion was expected to double the output of 75%-grade ferrosilicon from 26,500 to 55,100 tpy.¹³

Late in the year, Cia. de Ferro Ligas da Bahia (Ferbasa) began a project to convert five 75%-grade ferrosilicon furnaces to produce silicomanganese. The company also planned to build four hydroelectric plants in Bahia. The first two plants were planned for completion in 1992.¹⁴

Cia. Ferroligas Minas Gerais (Minas Ligas) moved into silicon metal production for the first time in 1989. The company commissioned a 15 MV•A furnace at its Pirapora site. The new furnace was provided by Delp Engenharia Mecancia, Minas Ligas' parent company. Minas Ligas also planned to start up a second furnace in 1990. Because of escalating energy costs, Minas Ligas conducted feasibility studies into constructing its own hydroelectric plant at Retiro.¹⁵

Cia. Paulista de Ferro Ligas delayed its move into ferrosilicon production until late 1991. Two 18-MV•A furnaces were planned for installation at Cia Paulista's subsidiary, Electrosiderúrgica Brasileira SA (Sibra).¹⁶

Camargo Corrêa Metais started production at its second 18-MV•A silicon metal furnace at Tukurui, Para State in northern Brazil. The first 18-MV•A furnace was commissioned in 1988. A third and fourth furnace were near completion at yearend. The furnaces were manufactured by the Demag Corporation. Production from the furnaces was intended for export.

Italmagnésio SA Industria e Comércio made plans to double its existing capacity to produce 75%-grade ferrosilicon. The plan included the installation of 24-MV•A and 6-MV•A furnaces.¹⁷

Multisilicon, a new Brazilian company, announced a project aimed at producing 27,600-30,900 tpy of chemical and metallurgical grade silicon metal at Leopoldina, Minas Gerais.

Source: Bureau of the Census.

The project was scheduled for completion by 1991. Prior to construction, the company had obtained a 10-year sales contract with Dow Corning Corp., Midland, MI. Multisilicon intended to export the majority of its production. Initial plans called for two 18-MV•A furnaces.¹⁸

The Rima group was reported to have brought two silicon metal furnaces on-line in Minas Gerais state. Rima also began construction of a 50-MV•A hydroelectric plant at Rodeado. The electric plant was intended to help provide a small portion of the plant's enormous energy needs.¹⁹

Canada

SKW Canada Inc. shut down one of its furnaces for repair late in 1989. The furnace was not expected to return to full capacity for at least a 6-month period.

India

VBC Ferro Alloys Ltd. upgraded its ferrosilicon capacity from 11,000 to 16,500 tpy. Nav Bharat Ferroalloys Ltd. sought permission from the Indian Government for an additional 11,000 tpy of ferrosilicon capacity. Ispat Alloys Ltd. was in the process of installing a silicon metal furnace to increase its capacity to 22,000 tpy. In an effort to alleviate problems with electrical power cutbacks, several companies began projects to build captive power plants.²⁰

Iran

The Iran Ferro-Alloy Co. scheduled the opening of Iran's first ferrosilicon plant for early 1991. The new facility was being constructed in Azna within the western province of Luristan. The plant was expected to produce 27,600 tpy of ferrosilicon for domestic consumption. Technical support for the project was to be provided by Elkem Technology AS.²¹

Japan

Effective in August 1989, Japanese steelmaker NKK Corp. sold its interest in the ferrosilicon producer Yakushima Denko Co. Ltd. The sale was based on a decision by the company to rely on imports for ferrosilicon. The Brazilian ferroalloy producer Ferro Ligas Assofon SA, of which NKK held a 27% portion of ownership, was expected to

fulfil a large portion of the company's ferrosilicon needs.²²

Denal Silane Co. Ltd. completed a state-of-the-art monosilane plant at Omi. Denal was a joint venture between Denki Kagaku Kogyo KK and the L'air Liquide Group. The plant was reported to be the largest merchant producer of monosilane and was capable of producing monosilane at the parts per billion (ppb) purity level.²³

Norway

Elkem A/S reorganized its global management structure from geographic divisions to a product based organization. In order to give the company a firmer footing in the European aluminum industry and to boost its downstream involvement, Elkem increased its share in Alcoa Nederland BV from 25% to 50%. Late in 1989, Elkem announced it would maintain its worldwide ferrosilicon production level in the coming year. Elkem also announced plans to purchase the remaining interest in Bjølvfossen AS. During 1989, Bjølvfossen operated four ferrosilicon furnaces at its facility in Ålvik.²⁴

In December, Fesil KS announced plans to reduce its Norwegian ferrosilicon production by 11,000 tons to 16,500 tpy. The company planned to idle one of its furnaces at Ila og Lilleby Smelteverker and begin a furnace maintenance program at its Hafslund facility. The company delayed bringing ferrosilicon furnaces on-stream at its Mo I Rana facility.²⁵

Philippines

Mindanao Ferroalloys Co. (Minfaco) was formed as a joint venture between Maria Cristina Chemicals Industries (MCCI), Sangyong Co. Ltd., Pohang Iron and Steel Co. (Posco), and Dongil Chungong Co. Ltd. The new company planned to convert a 27-MV•A carbide furnace at MCCI's plant on the island of Mindanao to producing ferrosilicon. The estimated 14,300 tpy of new capacity was scheduled for startup in mid-1991. Production from this facility was intended for export to the Republic of South Korea.²⁶

Portugal

Brazilian Italmagnésio Group formed a new subsidiary in Portugal called Novos Fornas de Beira Alta Lda. (Forbel). In a 10-year rental agreement with So-

ciedade Portuguesa de Electrometallurgia SA, the new company restarted ferrosilicon furnaces previously operated by Cia Portuguesa de Fornos Eléctricos S.A.R.L. The operations were capable of producing 33,000 tpy of 75%-grade ferrosilicon. However, a 19-MV·A furnace included in this capacity was being dismantled and sent to Venezuela. Ital-magnésio SA Industria e Comercio, which had previously experienced antidumping problems in the European Community, hoped the new subsidiary would give the company a better sales position in the European market.²⁷

Venezuelan PT Investment Alloy acquired two 19-MV·A Demag silicon metal furnaces from Portugal's Metalurgia do Norte S.A.R.L. (Milnorte). The furnaces were being dismantled and sent to Venezuela for installation.²⁸

Venezuela

Work began on several major ferroalloy projects in 1989. All of the projects revolved around joint-venture agreements with the state development body Corporacion Venezolana de Guayana (CVG). The ventures planned to take advantage of Venezuela's abundant electricity available from CVG's Guri Dam near Puerto Ordaz.

Rima Electrometallurgical SA signed an agreement with CVG to set up a new silicon metal plant in Venezuela. The company reportedly was awaiting an import license from the Venezuelan Government for two new 13,200-tpy silicon metal furnaces. If approved, the furnaces were to be constructed by Rima Mecanica SA in Brazil.

Progress continued on the Guaysil project to produce chemical-grade silicon metal. The project was a Latin-American joint venture between the Rima Group, Cia Minera Autlan SA de CV, and Corporacion Venezolana de Guayana. In 1989, the project received an authorization from the Venezuelan Government for a debt swap arrangement with Venezuela's Morgan Guaranty Bank.

C.V.G. Ferrosilicio de Venezuela CA (Fesilven) started construction of a silicon metal furnace with a scheduled completion within 2 years. Fesilven also planned to install two 32-MV·A furnaces to produce 27,600 tpy of 75%-grade ferrosilicon and modernize two existing furnaces.

Central de Ferroaleaciones de Venezuela CA (Cefeca), which had plans for

no less than 11 new ferroalloy plants, began to purchase equipment for these operations. The Cefeca company, PT Investment Alloy, acquired two 19 MV•A Demag silicon metal furnaces from Metalurgia do Norte S.A.R.L. in Portugal. These furnaces were being dismantled and were planned for installation in 1991. An additional silicon metal furnace was acquired from Portugal's Cia. Portuguesa de Fornas Electricos. The plans called for a total of 76 MV•A of capacity, producing up to 52,900 tpy of silicon metal by 1993. The company also hoped to acquire two Nippon Denko Co. Ltd. furnaces with capacities of 22 and 33 MV•A for the production of 75%-grade ferrosilicon. These furnaces were scheduled to be brought on-line in 1994.²⁹

CURRENT RESEARCH

Engine Components Inc. introduced a silicon carbide coating process for aircraft piston engines designed to ex-

pedite ring seating, reduce oil consumption, and increase cylinder service life.³⁰

Silicon nitride ceramic valves were produced by the American Ceramic Engine Co., Bolingbrook, IL, for use in stockcar racing engines.³¹

The Duralcan Corp., San Diego, CA, successfully marketed its aluminum and silicon carbide metal matrix composite. The material was sold to Specialized Bicycle Corp. Specialized used the composite material to produce bicycle wheel rims that offered a 40%-higher specific stiffness than unreinforced rims. The company's San Diego pilot plant produced an estimated 100 tons per month in 1989. A 12,500-tpy plant at Jonquiere, Quebec, was under construction and scheduled for completion in 1990. In November, Duralcan cast the largest metal matrix composite (MMC) ingot ever produced. The ingot weighed 1,325 pounds and was composed of an aluminum and silicon carbide composite.

Lanxide Corp., Newark, DE, continued to develop several patented processes

that were used to produce ceramic and metal matrix composites. Many of the processes were based on directed metal oxidation and were used to grow metal matrix composites through an oxidation reaction between molten metal and an

adjacent gaseous oxidant. Several of the Lanxide products used silicon carbide reinforcements.³²

Whole-wafer integrated circuits came to fruition in 1989. Anamaric Ltd. Cambridge, United Kingdom, produced a 6-inch wafer with 202 1-megabyte (MB) dynamic random access memory chips. The success was achieved though the use of control logic to bypass defects on a wafer. The first product based on the wafer-scale integration was a 40-MB solid-state computer disk drive.³³

Ibis Technology Corp., Danvers, MA, used a new process called Separation by Implantation of Oxygen (SIMOX) to bury oxygen ions just below the surface of a standard silicon wafer. As a result of this process, circuits printed on the SIMOX chip ran 30% faster than an ordinary silicon chip. The SIMOX process implants a layer of silicon dioxide in the chip, which insulates the circuits from stray capacitances and currents triggered by radiation or high temperatures. The SIMOX process was originally developed by Harris Semiconductor, Melbourne, FL, for military and space applications. Ibis produced SIMOX wafers for commercial applications commercially.³⁴

In 1989, micromechanics emerged as a viable industry. Researchers used techniques used to produce computer chips to carve out minuscule devices only two-thirds the width of a human hair. Although these devices included mechanisms such as micromotors and microswitches, commercial success was achieved though microsensors. These sensors were the result of early research efforts by such research centers such as AT&T Bell Labs, Murray Hill, NJ; Stanford University, Stanford, CA; and Massachusetts Institute of Technology, Cambridge, MA. The largest producer of these sensors was Delco Electronics Corp, Kokomo, IN. Delco incorporated the sensors into controls and diagnostics for automobile engines and transmissions. Future applications for the sensors included antilock braking, dynamic suspension, crashbag activation, and tire pressure monitoring.³⁵

Dow Corning Corp., Midland, MI, proceeded with plans to develop a process using silica sand to produce silicon metal. After the completion of a \$1.1 million feasibility study, Dow made plans to construct a \$42 million research facility. The facility was to in-

clude a pilot plant to allow further study of the new process. A 25 MV•A furnace producing 30 million pounds-per-year of silicon metal was scheduled for 1994 contingent upon the success of the pilot plant study. If successful, the new process was expected to significantly reduce energy costs and virtually eliminate the need for consumable electrodes normally associated with silicon metal production.³⁶

Researchers at Sandia National Laboratories in New Mexico achieved a record solar to electric conversion efficiency ratio of 20.3% using a silicon-base photovoltaic concentrator module. The module consisted of 12 lenses that concentrate concentrated sunlight over several hundred times onto silicon solar cells. A commercial product using these cells was expected within three years.³⁷

OUTLOOK

Demand for silicon metal is driven by the aluminum and the chemical industries. Consumption by the aluminum industry, which uses silicon as an alloying agent, is expected to undergo slow growth over the next 5 years. The increased use of aluminum in automobiles, which reached a record high in 1989, will contribute to this growth. Additionally, a trend toward the use of higher silicon content in aluminum castings is expected to continue. The chemicals industry consumes silicon metal to produce a wide variety of compounds such as silanes, silicone resins, and lubricants. In the past, this industry has shown steady growth and is expected to continue this trend.

Ferrosilicon is consumed primarily by the iron and steel industry. The industry uses ferrosilicon for both deoxidation of molten metal and as an alloying agent. The American Iron and Steel Institute studied the consumption of steel by industrialized countries and predicted an average decline of 0.1% per year from 1985-95. Subsequently, ferrosilicon consumption is not expected to grow over the next 5 years.³⁸ However, several factors could influence consumption of ferrosilicon by the steel industry. These factors may include possible technological advances, environmental legislation, and trade agreements.

Production cutbacks were scheduled by many producers in the latter half of 1989. These cutbacks are expected to affect moderate price increases in the coming year. However, average prices are not expected to rise appreciably over the long term because of increases in worldwide capacity.

SILVER

By Robert G. Reese, Jr.

Mr. Reese, a physical scientist with the Branch of Nonferrous Metals, has covered silver for 8 years. Domestic survey data were prepared by Lisa Conley, Eraina Dixon, and Stephen Hays, Nonferrous Data Section. International data were prepared by Giovanni Jacarepaqua, International Data Section.

Domestic silver production increased for the third consecutive year, reaching its highest level since 1941. Higher byproduct silver production from copper, lead, and zinc mines and the opening of new mines were the primary reasons for the higher output. Most of these new mines, as has been the case for the past several years, were gold mines with byproduct silver production. Notable exceptions were the openings of two large lead, silver, and zinc mines in Alaska. World mine output of silver increased primarily in response to a more stable labor situation in Peru and to the increased U.S. production.

LEGISLATION AND GOVERNMENT PROGRAMS

The U.S. Department of the Treasury, as required by Public Law 100-440, the Treasury and Postal Service Appropriations Bill, sold a portion of its silver stocks. Public Law 100-440 authorized the disposal of approximately 233 metric tons of Treasury Department silver over a 3-year period. Sales of nearly 78 tons was to occur in each of fiscal years 1989-91, although the quantity of silver sold could be reduced to avoid severely disrupting the domestic silver market.

In early fiscal year 1989, officials at the Treasury Department developed criteria to determine whether a proposed sale would severely disrupt the domestic silver market. According to the criteria, a proposed sale should proceed, unless the silver price had declined in 15 of the 20 previous days, and the silver price had declined by 5% or more during that same 20-day period.

The Defense Logistics Agency (DLA), acting as sales agent for the Treasury Department, sold 78 tons of

silver as required for fiscal year 1989 in two sales. The first sale occurred on May 9 and the second on July 18. The silver was sold through an auction process, marking the Government's first use of auctions for silver disposal since late

1981 when 62 tons of National Defense Stockpile (NDS) silver was sold. From 1982 until the May 9 sale, Government disposals of excess silver had been accomplished through various coinage programs. Purities of the disposed

¹ Less than 1/2 unit.

² Defined as refinery production from primary materials plus refinery production from old scrap plus imports of bullion. Represents not only the quantity of silver required by the domestic fabricating industry, some of which may be placed in stocks, but also the quantity of silver demanded by U.S. investors.

³ Handy & Harman.

⁴ Mine Safety and Health Administration.

Treasury silver ranged from 40% to 99.9%.

For fiscal year 1990, DLA proposed selling the required 78 tons in four sales. The first sale occurred on October 31, and bids for slightly more than 19 tons were accepted.

Near mid-June, the first gold and silver coins commemorating the bicentennial of Congress were struck at the U.S. Capitol Building. The coins were authorized by Public Law 100-673, the Bicentennial of the United States Congress Commemorative Coin Act, and signed by the President on November 17, 1988. The ceremony marked the first time that official U.S. coins had been struck outside a U.S. Mint facility since 1792. Public Law 100-673 authorized the production of 1 million gold coins, 3 million silver coins, and 4 million copper clad coins. The silver coin was to contain 24 grams of silver, and the silver was to be obtained from the NDS. A surcharge added to each coin's price was to be used by the Capitol Preservation Commission to maintain and restore the capitol building.

PRODUCTION

Silver was produced from precious metal ores at 111 lode mines. Silver also was produced as a byproduct of the processing of copper, lead, and zinc ores at 51 lode mines. In 1989, 18 mines each produced more than 30 tons of silver; their aggregated production equaled 79% of total domestic production. Silver was also produced at 15 placer operations. U.S. silver production in 1989, 2,007 tons, was the largest quantity produced in any year since 1941 when 2,211 tons was produced.

Alaska

Commercial production began at the Greens Creek Mine during the first quarter of 1989. The underground mine, on Admiralty Island, used a 900-ton-per-day mill to produce gold, lead, silver, and zinc. Kennecott Corp. operated the mine. Other partners in the venture included CSX Energy Inc., Exalas Resources Corp., and Hecla Mining Co. Although Greens Creek did not achieve full production during the year, nearly 161 tons of silver was produced during the first 11 months of operation.¹

The first concentrates were produced at the new Red Dog Mine in late November. The mine, an open pit operation 192 kilometers north of the Arctic Circle, near the Chukchi Sea, produced lead and zinc concentrates containing byproduct silver. Owing to the mine's location, concentrates can only be shipped from the area during an approximate 100-day interval in the summer. As a result, a concentrate storage facility, capable of holding 9 months of production, was constructed near the port. The first concentrates were delivered to the storage facility in December. The mine was developed by Cominco Alaska Inc., a subsidiary of Cominco Ltd. Cominco Alaska leased the property from the NANA Regional Corp., one of 13 native corporations established by the Alaska Native Claims Settlement Act of 1971.

Idaho

Production began at the Champagne Mine, an open pit, heap-leach operation. The mine, near Arco, was owned by Bema Gold Corp. (85%) and Glamis Gold Ltd. (15%).

Mining and milling resumed at the Copper Cliffs Mine in June. The open pit mine, closed since 1981, produced copper concentrates containing byproduct silver. Copper Cliffs was operated by Alta Gold Co., a company formed in late November following the merger of Silver King Mines Inc. and Pacific Silver Corp. Known reserves at the mine were expected to be depleted in 1990.

A heap-leach facility was constructed at the Yellow Pine gold-silver mine in Valley County. During 1989, approximately 84,000 tons of ore was mined and stockpiled at Yellow Pine in preparation for the resumption of processing in 1990.

Michigan

Callahan Mining Corp. announced the indefinite closure of the Ropes gold-silver mine in late September. Ground control problems near the mine's main production shaft and low gold prices were cited as the reasons for the closure. The mine, located near Ishpeming, has had a history of ground control problems since its opening in late 1985. A number of methods for transporting ore to the surface were investigated during the remainder of

the year. Among the methods examined were trucking the ore directly from the mine, trucking the ore to the mine's 900-foot level and then using existing facilities to hoist the ore to the surface, and installation of a steel and concrete liner in a portion of the shaft. Company officials stated, however, that regardless of the method chosen to transport the ore, the mine would not reopen until the gold price recovered.

Metall Mining Corp. acquired the Copper Range Co. in May. The principal assets of Copper Range were the White Pine Mine, mill, and smelter. Copper Range was formed in 1985 when the employees and management of White Pine reached an agreement to purchase the facilities from Echo Bay Mines Ltd. White Pine, the State's largest silver producer, recovered silver as a byproduct of its copper operations.

Montana

In June, Pegasus Gold Inc. acquired Pangea Resources Ltd., an Australian mining company with interests in the United States. As a result of the acquisition, Pegasus became the owner of the Basin Creek Mine. Basin Creek was an open pit, heap-leach, gold-silver producer located near Helena.

In Silver Bow County, commercial production began at the Beal Mountain Mine during May. Beal Mountain was an open pit operation owned by Pegasus. Ore from the mine was crushed, agglomerated, and placed on impermeable pads for heap leaching. During 1989, the mine produced nearly 1.2 tons of gold and 0.25 tons of silver.²

ASARCO Inc. acquired a 49.9% interest in the Continental Mine in June. Asarco reportedly acquired the holding from Montana Resources Inc. as part of its strategy to change from being primarily a custom smelter and refiner to being a fully integrated producer. The Continental Mine was an open pit copper-molybdenum-silver producer located near Butte.

American Copper and Nickel Co., a subsidiary of Inco Ltd., officially began production at the underground Mineral Hill gold-silver mine in September. Mineral Hill, a 50-50 joint venture of American Copper and Nickel and Homestake Mining Co., was located in Park County, adjacent to Yellowstone National Park. Owing to the site's environmental sensitivity, the

companies went to unusual lengths to minimize the mine's visual and environmental impacts. Among the steps taken were complete containment of the mine and mill water systems, limiting surface excavations as much as possible, using only existing roads, and the initiation of special procedures for tailings disposal. The mine received the Greater Yellowstone Ecosystem Bald Eagle Working Group Award, recognizing its environmental commitment and efforts to ensure the well-being of bald eagles near its property. Ore from the mine was processed by a 400-ton-per-day mill located on-site.

Nevada

Mining operations at the Alligator Ridge Mine were suspended near mid-December, owing to the exhaustion of identified ore reserves. The mine, a joint venture of NERCO Minerals Co. (50%) and Kennecott Corp. (50%), processed ore using both heap-leach and carbon-in-leach facilities. Ore treatment and metal production were expected to continue into 1990.

Mining was halted at the Austin Mine in November. The decision was attributed in part to low ore grades and reserves. The mine was operated by WESTGOLD Inc., in partnership with FMC Gold Co. Reclamation of the site was begun and was expected to be completed by late 1990.

Two projects to enhance production capabilities were completed in June and September at the Big Springs and Jerritt Canyon Mines, respectively. The main components of both projects were the installation of ore roasting circuits at the mills. These new facilities operated independent of the older mill circuits and allowed treatment of refractory ores as well as ores previously considered sub-economic. At Jerritt Canyon, the new roasters were designed to treat about 3,200 tons of ore per day. Total ore throughput at Jerritt Canyon following installation of the roasters was estimated to be about 6,400 tons per day.

Mining was completed at the Borealis Mine. Echo Bay, the mine's owner, expected leaching operations to continue through 1990. Reclamation of the mine site was begun.

The first gold-silver doré bar was poured at the Bullfrog Mine in late July. The mine, located near Beatty,

was wholly owned by Bond International Gold Inc. Ore from the pit was processed through a modified carbon-in-leach circuit. Construction of the mine and mill was completed in less than a year.

In late October, U.S. Gold Corp. sold its 29.3% interest in the Dee Mine to its principal partners, Corona Corp. and Rayrock Yellowknife Resources Inc. After the sale, Corona and Rayrock each had a 44% interest in the mine with the remaining 12% privately held. Dee, an open pit operation in Elko County, used both milling and heap leaching to recover gold and byproduct silver.

The Golden Butte Mine, located about 80 kilometers north of Ely, began production in June. The mine, an open pit operation, recovered gold and a small quantity of silver using heap leaching. Golden Butte was operated by Alta Bay Venture, a joint venture of Alta Gold (60%) and Echo Bay (40%).

Heap leaching was completed at Alta Bay's Illipah Mine. Mining at the site had ended in 1988.

Milling operations began at the Marigold Mine in September. The new open pit mine used a 1,100-ton-per-day mill to produce gold and a small quantity of byproduct silver. Heap leaching was expected to begin during the first quarter of 1990. The mine was owned by Corona, Placer Dome U.S. Inc., Rayrock, and Santa Fe Pacific Mining Corp.

At the McCoy/Cove Mine, a new 6,800-ton-per-day mill began commercial operation in July. The new mill processed high-grade oxide ore from both the McCoy and Cove pits. Lower grade oxide ore continued to be heap leached. Ramps were driven into the sulfide ore beneath both pits, and underground mining began beneath the Cove pit in December. The sulfide ore produced underground was also processed by the new mill. Ground water problems reduced the expected underground mining rate to about 540 tons per day. As a result, in December Echo Bay, the mine's owner, initiated a program to increase the surface mining rate from 118,000 tons per day to 150,000 tons per day. An extensive core drilling program undertaken in 1989 resulted in a reduction of proven and probable reserves at McCoy and Cove by 11%, to about 390 tons and about 4,000 tons of

contained gold and silver, respectively.³ Contamination of earlier drill samples owing to the nature of the host rock, combined with the presence of ground water and the high-water flow rates associated with reverse circulation drilling were cited by Echo Bay as the reasons for the reserve revision.

Ore at the Preble Mine, an open pit operation in Humboldt County, was exhausted during the third quarter. Heap leaching was expected to continue until the second quarter of 1990. In the future, the facilities were expected to be used to process ore from the Kramer Hill deposit, about 20 kilometers southwest of Preble.

Pegasus commenced reclamation of the Relief Canyon Mine. Mining operations were completed, and the loading of ore on the pads for heap leaching ended in late 1989. Leaching operations and gold-silver recovery were expected to end in 1990.

A program begun in 1987 to increase the production capacity of the Round Mountain Mine was completed in 1989. The new plant consisted of a large gyratory primary crusher, an intermediate ore storage and reclaim system, secondary and tertiary cone crushers and screens, a conveyor system to transport the ore, and an automated stacking system for the leach pad. With the new facilities, Round Mountain was expected to be capable of processing 41,000 tons of ore per day.

In April, Amax Gold Inc. began commercial operations at its Wind Mountain Mine in Washoe County. The open pit, heap-leach operation reportedly produced about 1 ton of gold and more than 10 tons of silver from May through December.⁴ The mine used the Merrill-Crowe process to produce precious metal precipitates. The precipitates were subsequently processed to produce doré at Amax Gold's Sleeper Mine. Notable was the fact that the mine began production 84 days after the first concrete pour at the site.

Mining was completed at the Wood Gulch Mine, a small heap-leach operation owned by Homestake Mining Co. Leaching and precious metal recovery were expected to continue through 1990.

Other States

The Royal Mountain King Mine in Calaveras County, CA, began produc-

tion in late February. An open pit operation, the mine used a 2,300-ton-of-ore-per-day mill and produced gold and silver doré. The mine was developed by Meridian Minerals Co. and Mother Lode Gold Mines Consolidated.

Mining was halted at the Sixteen-to-One Mine in October. The mine, a joint venture of Royal Gold Inc. and Lucky Chance Mining Co., was located in Sierra County, CA. Sixteen-to-One was an underground operation that produced gold and byproduct silver. Royal Gold officials attributed the decision to temporarily suspend mining operations to the low gold price.

At the end of August, Nerco acquired Texasgulf Minerals & Metals Inc. Texasgulf and its joint-venture partner, Golden Cycle Gold Corp., used heap leaching to process previously mined material in the Cripple Creek Mining District near Victor, CO. After the acquisition, Texasgulf was renamed Pikes Peak Mining Co.

CONSUMPTION AND USES

Apparent U.S. demand for silver in 1989, calculated as refinery production from primary materials and from old scrap plus net imports of refined bullion, was 4,967 tons. Included in the apparent demand calculation was the amount of silver absorbed by investors, as well as the amount of silver required by the domestic fabricating industry.

The most important use of silver is in photographic materials. Silver is used in the manufacture of film, photographic paper, photocopying paper, X-ray film, photo-offset printing plates, and in some other minor light-sensitive products. Photographic materials are produced by depositing thin layers of silver salts, gelatin, and dyes onto a support material. Silver salts, although not extremely sensitive to light when first exposed to illumination, produce a greatly intensified image when subsequently treated with photographic chemical developers. The developer reduces a portion of each silver salt grain to metallic silver, depending on the intensity of the light to which the grain was exposed. The resulting gray to black metallic silver forms a negative image of the original object.

Silver is used in electrical and electronic products because of its high electrical and thermal conductivity and its resistance to corrosion. Silver has the highest thermal and electrical conductivity of any known substance. Silver, in general, can be characterized as strongly resistant to atmospheric and ordinary oxidation and exceptionally resistant to corrosion by weak acids. Although silver commonly reacts with sulfur-containing atmospheric gases to form a sulfide tarnish, the tarnish itself offers little electrical resistance and does not prevent the use of silver as an electrical contact material. Pure silver is generally used in low- and medium-current switching devices. In other applications where the device requires higher strength, more wear resistance, better resistance to arcing, or lower costs, silver is usually alloyed with another metal such as copper or palladium to produce the desired characteristics.

Batteries constitute another electrical use for silver. Silver batteries produce a high-energy output per unit size and weight, but are generally characterized by a short life and high per unit cost. Primarily because of the short life and high costs, the use of silver batteries has been confined to defense and space applications where battery weight, size, and reliability are major concerns. There is, however, a growing use for small silver-zinc button cells in such commercial applications as calculators and hearing aids.

The use of silver for decorative purposes can be divided into three main applications. Probably the oldest use of silver is its use in jewelry. Silver or a silver alloy, usually silver and copper, is flattened and shaped into objects that can be worn for personal adornment. Sterlingware, the second decorative use, consists of articles such as bowls and flatware that are often functional as well as decorative. Sterling silver is an alloy of silver (92.5%) and copper (7.5%). The third decorative use for silver is electroplated ware. Electroplated ware generally consists of the same types of objects produced as sterlingware, the difference being that electroplated ware is made by depositing a thin silver layer on a base metal object, whereas the sterlingware object is formed entirely of the silver-copper alloy. Because less silver is used in a piece of electroplated ware than is used in a

similar piece of sterlingware, the price of the plated piece is less than the price of a corresponding sterlingware piece.

The refrigeration and air-conditioning industry uses silver in the form of brazing alloys because of the ability of silver brazing alloys to wet various base metals at temperatures below their melting points. In general, silver brazing alloys do not dissolve or attack steel in normal usage, are ductile, maintain their strength over a wide range of temperatures, and will join a variety of materials. Silver is added to some solders to improve their flow properties, corrosion resistance, and wettability.

Silver is also used in mirrors, catalysts, medicinals, dental amalgams, bearings, coins, medallions, and a variety of commemorative objects. Silver is used in mirrors because of its high reflectivity in the visible portion of the spectrum. Silver catalysts are used in oxidation reactions such as the production of formaldehyde from methanol and the conversion of ethylene to ethylene oxide. Medicinal compounds include the soluble salts, such as the nitrates and citrates, and insoluble compounds such as the oxides, halides, and proteinates. In dentistry, silver is an important component of amalgam fillings.

STOCKS

Total accountable stocks at yearend 1989 increased by more than 1,700 tons over the previous year owing to a significant increase in Commodity Exchange Inc., (COMEX) held stocks. Analysts attributed the larger COMEX stocks to the movement of unreported bullion stocks to New York depositories from depositories and warehouses outside the State, in response to the abolition of New York's precious metals sales tax. As reported to the Bureau of Mines, refiner, fabricator, and dealer stocks remained essentially unchanged from the previous year.

The quantity of Government-held silver continued to decline. The U.S. Mint used NDS silver stocks for various coinage programs, and a portion of excess Treasury Department stocks were sold through Government-sponsored auctions in May and July.

PRICES

The domestic silver price as quoted by Handy & Harman remained in a relatively narrow range throughout 1989. The price began the year at \$6.07 per troy ounce and was \$5.18 at yearend. Throughout the year, there were no significant upward price movements; rather, the price gradually drifted lower toward \$5.00 per troy ounce. In mid-November, the price rallied briefly, reaching \$5.84 on November 22 before resuming a downward trend. Factors that analysts believed to have affected the silver price during the year included: the value of the U.S. dollar in terms of certain foreign currencies; expectations of no more than a moderate U.S. inflation rate; a lower demand for bullion by investors; and increased U.S. interest rates.

As with the domestic price, the London spot price was quoted within a relatively narrow range throughout the year. The U.S. dollar equivalent of the London spot price, as published in Metals Week, began 1989 at \$6.07 and ended the year at \$5.22. The high price for the year, \$6.21, occurred on January 24. The low price for the year, \$5.05, occurred on September 1 and again on October 11. The average for 1989 was \$5.51.

The amount of silver represented by the future contracts traded on the COMEX decreased in 1989 to 680,640 metric tons. At the Chicago Board of Trade (CBT), the quantity of silver corresponding to the futures trading volume decreased from 15,626 tons to 8,295 tons in 1989. Silver futures trading volume on the Mid-America Commodity Exchange (Mid-Am), at 422 tons, remained essentially unchanged from the previous year.

FOREIGN TRADE

U.S. silver exports increased in 1989 for the fifth consecutive year, probably owing in part to the lower domestic silver price and increased domestic production. The countries recording the largest increases in receipt of U.S. silver exports were Canada and Japan with increases of about 135 tons and 123 tons, respectively. In the case of both

Canada and Japan, most of the increased shipments were in the form of silver-bearing waste and scrap materials. The largest decrease in U.S. silver exports from the previous year was in shipments of waste and scrap materials to France—approximately 59 tons.

U.S. silver imports for consumption increased, probably owing in part to the stronger U.S. dollar in terms of foreign exchange rates. The countries with the largest increases of silver exports to the United States were Mexico, with an increase of more than 541 tons; Canada, with a 98 ton increase; and Uruguay, with a 61 ton increase. For all three countries, the increased exports were primarily refined bullion.

WORLD REVIEW

The data in table 13 were rated production capacity in mines as of December 31, 1989. Rated capacity was defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgement of the author, can be brought into production within a short period of time with minimum capital expenditure.

World mine production of silver increased slightly in 1989. Increased production of copper, lead, and zinc resulted in increased byproduct silver production. Other reasons for the higher production included a more stable labor situation with fewer strikes in Peru and the opening of a number of new gold mines, many of which produce byproduct silver. Although gold continued to be the primary metals exploration target during the year, the higher prices for copper, lead, and zinc encouraged exploration for these metals also. Most copper, gold, lead, or zinc deposits contain some silver. Oceania and countries bordering the Pacific Ocean continued to be the most active exploration areas.

Before 1989, Handy & Harman, in its annual review, estimated silver production and consumption for market economy countries only. However, in

response to the year's geopolitical developments, Handy & Harman began making world production and consumption estimates. In its 1989 review, Handy & Harman estimated world silver consumption at about 18,100 tons, an increase of more than 600 tons over the revised 1988 figure.⁵ Of the total, approximately 17,000 tons was used in industrial applications, a 333-ton increase over the 1988 level. The quantity of silver used for coinage increased from about 800 tons in 1988 to about 1,100 tons in 1989.

Canada

Mine production resumed at the Heath Steele lead-zinc-copper-silver underground mine in June. The Heath Steele Mine in New Brunswick had been inactive since 1984. Partners in the mine were Noranda Inc. (75%) and Brunswick Mining and Smelting Corp. Ltd. Operations at the new Stratmat Mine, adjacent to the Heath Steele Mine, began in July. Stratmat, consisting of both open pit and underground operations, produced lead, zinc, copper, and silver. Noranda and Brunswick Mining each had a 50% interest in the Stratmat Mine.

Near mid-December, shareholders of Dumagami Mines Ltd. voted to merge Dumagami with Agnico-Eagle Mines Ltd. Dumagami's principal asset was the LaRonde Mine, an underground gold-silver-copper operation located in Quebec. In 1989, during its first full year of operation, the LaRonde Mine produced 2.6 tons of gold and 4 tons of silver.⁶

Cominco Ltd. completed construction of its new lead smelter near Trail, British Columbia, near yearend. The new plant was expected to result in significantly lower sulphur, lead, and particulate emissions through the use of an oxygen smelting process. Although the first lead bullion was produced by the plant in late December, mechanical problems and metallurgical process difficulties prevented the plant from achieving normal operations by yearend. At its Trail facility, Cominco produced more than 350 tons of refined silver during 1989.⁷

At the Valley Mine in British Columbia, Highland Valley Copper Co. completed the renovation and expansion of its milling facilities. Two mills formerly owned by Highmont Mining Co. were

moved to a site adjacent to the Lornex mill, and an older nearby mill was closed. The new facility, called the Highland mill, can process more than 130,000 tons of ore per day. Near mid-October, a 2-year agreement was reached with the mine's workers, ending a 15-week strike.

An 8-year legal battle for ownership of the Williams Mine ended in August. The Supreme Court of Canada ruled that the mine, in the Hemlo District of Ontario, belonged to Corona Corp. The decision upheld earlier rulings that LAC Minerals Ltd., developer of the mine, had used confidential information supplied by Corona's predecessor company to acquire the property where the Williams Mine was later located. The mine, which recovers some byproduct silver, was Canada's largest gold producer. After the ruling, Corona split the mine's ownership with Teck Corp. in return for Teck's paying 50% of the related legal costs. Included in the legal costs was approximately C\$213 million to reimburse LAC for its expenditure to develop the mine.

In September, Noranda and Trelleborg AB acquired control of Falconbridge Ltd. Falconbridge, a Canadian copper, gold, nickel, silver, and zinc producer, was expected to increase Noranda's silver production by 40% in 1990. Following the acquisition, Noranda and Trelleborg each had a 50% interest in Falconbridge's assets, including 11 mines and 5 metallurgical plants.

Other Countries

In March, Battle Mountain Gold Co. acquired 33.3% of the stock of Inti Raymi S.A., a Bolivian gold-silver producer. In July, Battle Mountain acquired an option to increase its equity interest in Inti Raymi to 51%. Inti Raymi operated the Kori Kollo Mine, a heap-leach operation in Western Bolivia near Oruro. For 1989, Kori Kollo produced about 6 tons of silver.⁸

In November, the initial pour of gold-silver bullion was made at the Crixas Mine, an underground operation in the Brazilian State of Goiás. The mine was a joint venture of Mineração Morro Velho S.A. (50%) and two Brazilian subsidiaries of Inco Ltd. Included at the mine site was a 1,000-ton-per-day mill.

In November, Freeport McMoRan Inc. announced that it and three affiliates would restructure their operations

by selling what were regarded as non-strategic assets and businesses. Proceeds from the sale of these assets were to be used for debt reduction and the development of Freeport's two new mineral discoveries, one of which was the Grasberg copper-gold-silver deposit in Indonesia on the western half of the island of New Guinea. By yearend, Freeport had sold a number of its oil and gas assets and reportedly was seeking buyers for others.

Development work began at the Grasberg deposit with the prestripping of waste material. Ore from Grasberg was expected to be processed at the mill serving Freeport's other mines in the area. In February, Freeport began a program to increase the mill's processing rate to 32,000 tons of ore per day. In August, Freeport's board of directors approved expanding the mill's capacity to 52,000 tons of ore per day by 1992. In the fourth quarter, a fourth ball mill became operational, allowing the mill to process up to 32,000 tons of ore per day.

Control of Consolidated Gold Fields PLC was acquired by Hanson PLC, a British conglomerate, in early August. The acquisition ended a nearly year-long battle for Gold Fields, an international mining company with gold and silver operations in Australia, the Republic of South Africa, and the United States. Gold Fields became an acquisition target when Minorco S.A., a Bermuda-based investment company with ties to the Republic of South Africa, made a hostile bid for all of the Gold Field shares that it did not already own. Hanson's winning bid, made in July, valued Gold Fields at more than \$5.5 billion, making the acquisition the largest in British history. It was widely believed that Hanson would attempt to recover part of the purchase price by selling some of Gold Fields' assets. In mid-August it was announced that Hanson had sold a 30% stake in Gold Fields South Africa, a gold and byproduct silver producer. The sale reduced the original Gold Fields holding in the South African company to 8%.

CURRENT RESEARCH

Silver-related research and development was extensive in 1989. Numerous

reports on silver-related research were summarized in *New Silver Technology*, a publication published under the auspices of The Silver Institute.⁹

OUTLOOK

The recent increase in domestic silver production was due in part to significant operating cost reductions at many mines, which allow these operations to remain profitable at silver prices as low as those in 1989. Another factor in the higher domestic production is that silver is often recovered as a byproduct of other nonferrous metals. Extensive exploration and development during the past decade has resulted in the opening of a large number of new, low-cost gold mines, most of which produce some byproduct silver. More recently, the prices of such nonferrous metals as copper, lead, and zinc have increased, stimulating an increase in the production of these commodities. As is the case with gold mines, most of these other nonferrous mines also produce some byproduct silver. In either case, the byproduct silver is either concentrated when the ore is processed or recovered with the principal product. Because the additional cost of recovering the silver is relatively low, its production is not dependent on the demand for silver; rather, its production is dependent on the demand for and resultant production of the principal product. Therefore, assuming that domestic economic conditions remain similar to those of 1989 and that the price of commodities such as copper, gold, lead, and zinc do not decline significantly, it is expected that the domestic silver supply will remain near 2,000 tons per year during the 1990-92 period.

Worldwide, the silver supply is also expected to remain near the 1989 level of 14,500 tons. It is assumed that labor unrest in countries such as Peru does not increase significantly and that local population concern about mining operations, such as in Papua New Guinea, does not spread.

Future industrial demand for silver is harder to forecast owing to the lack of data. Some analysts believe that the domestic industry demand for silver is

growing at a rate of perhaps 5% per year. Other analysts believe that in 1989, U.S. industrial demand for silver declined. It is believed that during 1990-92, industrial silver demand will grow slightly, primarily because of its lower cost. Worldwide, demand for silver is expected to grow at a slightly higher rate than in the United States, primarily because political events such as those in Eastern Europe should open new markets for products containing silver.

BACKGROUND

Silver has played an important role in peoples' lives since ancient times. Early man used silver for ornaments and utensils and as a substance that could be bartered for other goods and services. This concept of the "value" of silver eventually led to its use as the standard in monetary systems, such as that of the Roman Empire, and as a means of paying for international trade. Silver continued to be the standard for most currencies until the discovery of major silver deposits in Mexico and Peru. As more silver deposits were discovered in the 18th and 19th centuries, countries gradually abandoned silver as the standard for their currencies in favor of a gold standard.

Expanding industrial use of silver eventually led to the elimination of silver in U.S. coinage. In the early 1960's, the U.S. Department of the Treasury became a major supplier of silver to industrial consumers. The Treasury, however, had insufficient stocks to meet both industrial demand and maintain an adequate supply of circulating silver coinage for a prolonged period. When the silver price reached \$1.29 per ounce, the value of the silver in a silver dollar equaled \$1 in currency. At silver prices greater than \$1.29, the silver in a silver dollar would have been worth more than \$1 in currency, and as a result, it could have been advantageous to melt silver dollars for their silver content, thereby decreasing the amount of circulating coinage. Similarly, if the silver price rose above \$1.38 per ounce, the silver in dimes, quarters, and half-dollars would have been worth more than the coin's face value. To avoid a possible melt-

down of the circulating coinage, the Treasury attempted to control the silver price through increased silver sales and increased minting operations from 1964-67. A reduced silver content half dollar, along with silverless dimes and quarters, were introduced in 1965 to help maintain the supply of circulating coinage, and in 1967, the Treasury announced that all silver coins were being withdrawn from circulation.

Silver occurs as native metal, but is usually found combined with sulfur. Until the 16th century, the ratio of silver to gold produced in Europe was about 10 to 1. Most of the silver was obtained from the lead sulfide ore galena. With the discovery and exploitation in the 16th and 17th centuries of silver deposits in Bolivia, Mexico, and Peru, silver production shifted from Europe to these countries. As production increased in Bolivia, Mexico, and Peru, the world ratio of silver to gold production increased because silver was relatively more abundant than gold in the New World. Following the 1859 discovery of the Comstock Lode in Nevada, the United States was the world's leading silver producer from 1871 to about 1900. Mexico was the leading producer from 1900 to 1968, yielding to Canada from 1968 to 1976. In 1976, Mexico regained the position of the world's leading silver producer, a position that it held through 1989.

Definitions, Grades, and Specifications

The purity of silver in bullion, coinage, jewelry, or other items is usually expressed by its "fineness," or parts per thousand. Pure silver or fine silver is 1,000 parts fine, or 100.0% silver. Sterling silver is 925 fine, or 925 parts (92.5%) silver and 75 parts (7.5%) copper. Domestic coin silver is an alloy that was used in minting coinage until 1964 and contained 900 parts silver and 100 parts copper. Commercial silver bullion ranges from a minimum of 999 to 999.9 fine. For any fineness of silver bullion, the principal impurities are gold or copper. Doré silver is unrefined silver bullion generally containing a variable percentage of gold as an impurity. Silver for the NDS is required to be 999 fine; free of slag, dirt, or other foreign material; and in bars weighing approximately 31 kilograms.

Products for Trade and Industry

Refined silver is available in the form of bars, grain, sheet, strip and foil, wire, rod and tubing, powder, and flake. Bars produced at refineries generally weigh about 31 kilograms and are about 30.5 centimeters long by 12.7 centimeters wide and 10.2 centimeters thick. Grain silver is produced by pouring molten silver into water, creating irregularly shaped silver particles less than 1.3 centimeters across. Silver sheet, strip and foil, are available in widths of up to almost 2.1 meters and as thin as 0.01 millimeters. Generally, the thinner the sheet or foil, the narrower it is in width. Silver rod and wire can range from 5 centimeters in diameter to 0.1 millimeter in diameter. Openings in silver tubing can range from capillary size through 15 centimeters in diameter. Silver powders are generally powder-size (0.5 to 2 micrometers) spherical particles, although coarser sized particles can be produced.

Geology-Resources

About two-thirds of the world silver reserves and resources are contained in copper, lead, and zinc deposits. Ores in which silver or gold are the main components account for the remaining one-third of total world reserves and resources. U.S. silver resources are estimated to be about 190,000 tons.¹⁰ Total world silver resources are estimated to be about 780,000 tons.

The chief silver minerals found in U.S. reserves are native silver (Ag), argentite (Ag₂S), cerargyrite (AgCl), polybasite (Ag₁₆Sb₂S₁₁), proussite (Ag₃AsS₃), pyrrargyrite (Ag₃SbS₃), stephanite (Ag₃SbS₄) and tetrahedrite [Cu₃(Sb,As)S₃]. Other ore minerals of silver are the tellurides, stromeyerite, and pearceite.

U.S. silver reserves are usually found associated with intermediate felsic rocks such as andesites and rhyolites, in veins ranging from a few inches to 8 feet in width. Ores from which silver is produced as a byproduct are usually found in copper porphyries, massive sulfide deposits, or in copper-lead-zinc vein deposits. Currently, the United States is experiencing extensive exploration for precious metal deposits, most of which is being conducted in the Rocky Mountain States. It is likely that if major new reserves are discovered, the deposits will be located in this region.

Technology

Mining.—Silver is mined using well-established open pit and underground methods. Open pit mining consists of removing overburden, drilling and blasting the exposed ore, loading the broken ore, and hauling the ore to the processing plant. Overburden removal is done with draglines or bulldozers, depending on the depth of the ore body. The broken ore is loaded by either power shovels or front-end loaders, and the ore is shipped to the processing plant by truck, train, conveyor belt, or some combination of these transport modes, depending on the distance to the plant.

Underground mining of silver is generally done using one of several stope mining methods. Stope mining consists of the development of a series of horizontal workings, or stopes, into the ore body from a shaft or tunnel. The stopes are located above each other and are vertically separated by as much as 200 feet of ore. The ore between the stopes is removed through the use of explosives.

Beneficiation.—Current treatment of silver-containing base metal ores is almost entirely by a flotation process. The concentrates contain the silver along with the copper, lead, and zinc. The silver is recovered from intermediate products resulting from smelting the concentrates. In predominately lead ores, silver is carried down with the lead in smelting and separated from it by the addition of zinc to the molten silver-lead mixture. The mixture is allowed to cool, and the virtually insoluble silver-zinc alloy separates from the molten lead and rises to the surface where it is skimmed. In addition to the silver, this first crust contains lead and any gold contained in the original ore. The zinc is distilled in a retort for reuse. The retort residue is roasted to recover the gold and silver as doré metal and the lead as litharge.

In predominantly copper ores, the silver is carried down with the copper in smelting. In the electrolytic refining of copper, the silver accumulates in the anode slime, from which it is recovered as silver bullion by smelting.

Gold and silver ores are generally treated by cyanidation. The ores are crushed by grinding in rod or ball mills and then leached with a dilute cyanide

solution. Zinc dust is used to precipitate the gold and silver from the cyanide solution. The precipitate is melted in a furnace to produce a doré metal.

Silver bullion is generally refined using an electrolytic process. In the process, electricity is applied to a standard electrolytic cell in which the impure silver bullion is used as the anode, silver nitrate and nitric acid is used as the electrolyte, and either pure silver strips or graphite are used as the cathode. Passage of an electrical current results in dissolution of silver in the anode and its subsequent deposition as silver crystals on the cathode. The silver crystals are collected, melted, and cast into bullion bars.

Economic Factors

Costs of mining silver ores vary greatly with depth, ground control problems, ventilation, width of vein, continuity of ore bodies, location, presence of byproduct metals, and the availability of electricity, water, labor, and equipment. Low-grade deposits can often be mined profitably if sufficient quantities of other metals are contained in the ore. Accurate information on capital costs is difficult to obtain, not only because of variability in the factors enumerated above, but because of differences in accounting methods and definitions used by the mining industry. In general, some mines appear capable of producing silver at a cost of less than \$160,000 per ton while other mines require a silver price in excess of \$260,000 per ton to be profitable. Underground mining is, in general, more expensive than surface mining.

U.S. silver-producing companies are permitted a depletion allowance of 15% for domestic operations and 14% for foreign operations. There are no tariffs on the importation of silver ores, concentrates, doré scrap, or refined bullion. Tariffs on semimanufactured silver can be as high as 27.5% ad valorem for countries receiving most-favored-nation classification and can be as high as 110% ad valorem for imports from those countries classified as non-most-favored nation, depending on the item.

Operating Factors

Silver mining is, in general, no more hazardous than other mining, but be-

cause of the depths reached in the Coeur d'Alene district, rock bursts are relatively common. Temperatures are uncomfortable at these depths, and air conditioning must be used in ventilation systems. Gains in productivity are difficult to achieve because the possibilities for mechanization are limited by the relatively narrow veins mined. In recent years, companies have attempted to increase productivity through modification of labor agreements to allow more flexibility in work assignments and compensation and by improved mining plans.

Although silver is not a toxic substance in other than very large doses, a standard has been established for worker exposure to airborne silver. The Occupational Safety and Health Administration currently requires that worker exposure to either silver metal or soluble silver compounds be less than 0.01 milligram per cubic meter of ambient air.

Nearly all silver-bearing ores are processed after grinding by flotation or cyanidation. Pollution of downstream waters by fine solids from flotation plants is a problem that requires adequate ponding and retention of tailings. Disposal or stabilization of the accumulated tailings can be a problem at some mines. It can be partially solved in those deep mines where ground support is needed by pumping the tailings back into the mine. In cyanidation operations, extreme care must be exercised to avoid contamination of the groundwater, nearby water courses, or surrounding areas through losses of leach solution. As a result, the solution collection system for returning the leachant to the storage tanks and the system for monitoring water in the surrounding area must be adequate to prevent pollution.

Achieving adequate air pollution (sulfur dioxide) control and disposing of slag and other wastes (iron and silica) are the problems encountered in smelting silver ores. Refining presents little environmental concern because the bulk of noxious impurities are removed during the smelting step; however, spent solutions from electrolytic refining present a disposal problem because of toxic materials in the solutions.

1989	37,031,057	226	117,836,833	564

¹ Revised.

² May include small quantities recovered by leaching with thiourea, by bioextraction, and by proprietary processes.

³ Including autoclaves.

⁴ May include small quantities recovered by gravity methods.

⁵ May include tailings and waste ore dumps.

¹ Revised. W Withheld to avoid disclosing company proprietary data; included in "Total."

² Includes old tailings and some nonsilver-bearing ores not separable, in amounts ranging from 0.04% to 0.12% of the totals for the years listed. Excludes fluorspar, molybdenum, and tungsten ores from which silver was recovered as a byproduct and excludes ores leached for recovery of copper.

³ Data may not add to totals shown because of independent rounding.

⁴ Less than 1/2 unit.

⁵ Includes some placer production to avoid disclosing company proprietary data.

¹ Recoverable content of ores and concentrates produced unless otherwise specified. Table includes data available through June 20, 1990.

² In addition to the countries listed, Botswana produces silver and Austria and Thailand may produce silver, but information is inadequate to make reliable estimates of output levels.

³ Reported figure.

⁴ Of total production, the following quantities, in metric tons, are identified as placer silver (the balance being silver content of other ores and concentrates): 1985—14 (estimated); 1986—20 (estimated); 1987—20 (estimated); 1988—22 (estimated); and 1989—22 (estimated).

⁵ Smelter and/or refinery production.

⁶ Less than 1/2 unit.

⁷ Includes production from imported ores.

SLAG—IRON AND STEEL

By Judith F. Owens

Ms. Owens, a physical scientist with 3 years Bureau of Mines experience, has been the commodity specialist for iron and steel slag since 1988.

Notable events in the iron and steel slag industry during 1989 included the acquisition of one of the Nation's largest slag companies and a major international concrete conference on natural pozzolans in which slag played an integral role. The Federal Environmental Protection Agency (EPA) continued to assess iron and steel slags as potential Bevill exclusion candidates under the Resource Conservation and Recovery Act (RCRA). The Bevill exclusion temporarily exempts certain high-volume, low-hazard wastes from hazardous waste regulation.

Research during the year pertaining to slag utilization included studies such as slag in the manufacture of asphaltic concrete, road base pavements, glass, concrete, mine backfill, and ceramics.

Domestically, consumption of both iron and steel slag combined showed a moderate increase when compared with that of 1988, with continuing imports of granulated blast furnace slag entering into the west coast of the United States. Steel slag consumption increased significantly for the second consecutive year in a row, with substantial gains in the marketing of steel slag as the aggregate in asphaltic concrete.

DOMESTIC DATA COVERAGE

Sales, use, and transportation data for iron and steel slag are developed by the Bureau of Mines from a voluntary survey of U.S. processors. Of the 86 operations canvassed, 86 responded, representing 100% of the total sales or use quantity data shown in table 1. Value data had to be estimated for several operations using reports from prior years adjusted by industry trends.

LEGISLATION AND GOVERNMENT PROGRAMS

On September 25, 1989, the EPA conditionally proposed the retention of iron and steel slags under the exemption afforded by the Bevill exclusion of RCRA, pending further evaluation of hazard data.¹

The Bevill exclusion, section 3001(b)(3)(A)(ii) of RCRA, exempts from hazardous (subtitle C) regulation high-volume, low-hazard wastes generated from the extraction and beneficiation of ores and minerals, pending the evaluation of EPA

studies on these wastestreams as mandated under RCRA section 8002. The EPA had been under a court-imposed deadline to narrow the scope and definition of the Bevill exclusion. The general criteria for the Bevill exemption were as follows:

1. Nonliquid mineral processing wastes were generated at an average annual rate greater than 45,000 metric tons per year per facility during any year between 1983 and 1988.
2. Wastes had to pass both a mobility test (Method 1312) and toxicity test (i.e., Method 1310), and the pH of the mineral processing wastestream could not have been less than 1.0 or greater than 13.5.

The specific iron and steel slags retained under the Bevill exemption are iron blast furnace, basic oxygen furnace, and open-hearth furnace. Electric arc furnace slags did not qualify for the exemption because the percentage of nonminerals (scrap) used in the charge of the furnace was greater than 50%.

It was expected that these iron and steel slags would be permanently retained under the Bevill exclusion of RCRA once the EPA finalized the list of wastes by mid-January 1990. If so retained, they would then be

TABLE 1
Iron and steel slags sold or used¹ in the United States

subject to a study for Congress, which would be issued by about late July 1990. A final regulatory determination on all Bevill exempted wastestreams, i.e., whether subtitle C or the nonhazardous subtitle D regulation was warranted, was anticipated by late January 1991.

The Bureau of Mines continued to support the position of the domestic iron and steel slag industry by publicly submitting comments to the EPA that basically stated that those slags that were processed and sold as commercial products were not, and should not be, regulated as solid wastes.

PRODUCTION

The Standard Slag Co., one of the Nation's top slag processors based in Youngstown, OH, was sold in September 1989 with six other affiliates for an undisclosed sum to the Lafarge Corp. based in Reston, VA.² Included in the sale were the Duquesne Slag Products Co., Pittsburgh, PA, and the St. Louis Slag Products Co., Granite City, IL. Also acquired from the Standard Slag Holding Co. were Standard Aggregates Inc., Cleveland Builders Supply Co., Standard Materials Inc., and the Portsmouth Trucking Co. Lafarge, a major producer of aggregates and construction materials in North America, bought these companies to expand its Construction Materials Group in the United States. This acquisition represents a growing U.S. trend toward vertical integration by some cement, concrete, and aggregate companies to lock up sufficient minerals reserves for the future.

Edward C. Levy Co., Detroit, MI, another of the country's top slag processors, entered into a joint venture with Queensland Cement Ltd. and Cleary Brothers to form Australian Mill Services Pty.³ Australian Mill Services will process and market the slag from Broken Hill Properties (BHP) Port Kembla complex; included are air-cooled, expanded, and granulated slag.

International Mill Service Inc., a wholly owned subsidiary of EnviroSource Inc. headquartered in Stamford, CT, acquired the Waylite Corp., Bethlehem, PA, in January 1989. Waylite processed blast furnace slag into both air-cooled and lightweight (expanded) aggregate and primarily marketed the slag as cement and cement-based products throughout the Northeastern United States.

Domestic production of iron and steel slag, which is not reported to the Bureau of Mines, apparently remained essentially unchanged from that of 1988 according to U.S. iron and steel production figures of the American Iron and Steel Institute. However, sales and uses of iron and steel slag, when combined, increased 6% when compared with the level of the previous year.

Production and consumption of iron slag in this chapter refer only to those slags that are generated in a blast furnace. Depending on how the molten slag is cooled and solidified, three different types of blast furnace slags can be produced. In the United States, those types are as follows: air cooled, expanded, and granulated. Steel slag in this country, however, is not processed in any special manner and, for all practical purposes, is essentially air cooled. The different types of steel slag are solely dependent on the furnaces that generate them, which are open hearth, basic oxygen, or electric arc.

CONSUMPTION AND USES

Historically, iron and steel slags have effectively replaced natural aggregates such as crushed stone and sand and gravel in many end uses, owing to slag's relatively lower cost, proven superior performance in many applications, and/or shortages of natural aggregates in certain regions.

Sales of slag products generally reflect demand from the construction industry. According to the U.S. Department of Commerce, total new construction in 1989 remained essentially unchanged from that of 1988.⁴ Private nonresidential construction also remained at the level of the prior year, whereas new road and bridge construction decreased 5%.

Air-cooled blast furnace slag continues to be the predominant form of iron slag processed in the United States, accounting for more than 89% of the blast furnace slag sales in 1989. The most significant increases from 1988 in end uses for air-cooled slag were as the aggregate in asphaltic concrete and for use in roofing, either built-up or in shingles. The increases were 61% and 31%, respectively.

Granulated and expanded blast furnace slag accounted for the remainder of the iron slag sold or used in the United States in 1989. Consumption of combined expanded and granulated slag increased slightly from that of 1988 to 1,706,000 tons valued

at \$29,143,000. Grand totals and specific end-use information for both the expanded and granulated slag had to be withheld to not disclose individual company proprietary information. Granulated slag was predominantly used in the manufacture of cement, and expanded slag was utilized in the manufacture of lightweight concrete blocks. Total end uses for 1989 were as follows:

	Expanded slag	Granulated slag
Cement manufacture		X
Lightweight concrete aggregate	X	
Road base		X
Soil conditioning		X

Steel slag consumption increased 29% over that of 1988. The most significant increase in end-use consumption for steel slag was as the aggregate in asphaltic concrete.

TRANSPORTATION

Historically, high transportation cost is one of the major factors affecting the delivered price of construction aggregates such as crushed stone and sand and gravel. Because slag is a relatively high-volume, low-value commodity, nearly all of it is marketed locally. Most slag is shipped by truck because hundreds of customers are widespread geographically and generally require a more flexible and rapid delivery system than is offered by rail or barge.

Of all the iron and steel slag products sold in 1989, 87% traveled by truck with an average marketing range of 27 miles; 3% traveled by waterway with an average range of 245 miles; and 5% traveled by rail with an average range of 210 miles. The remaining 5% was used at the plant where it was processed.

PRICES

The average price, f.o.b. plant, for all blast furnace slag sold decreased slightly from that of 1988 to \$6.18 per ton. The price of air-cooled blast furnace slag remained essentially unchanged from the level of the previous year at \$4.83 per ton. Granulated and expanded slag price information was withheld to avoid disclosing

company proprietary data. The unit value for steel slag increased 3% from that of 1988 to \$3.26 per ton.

FOREIGN TRADE

Statistics developed by the U.S. Department of Commerce, Bureau of the Census, indicated that 109,854 tons of granulated blast furnace slag valued at \$4,533,227 was imported into the country during 1989. The breakdown was as follows: 40,014 tons from Japan, valued at \$336,719; 23,149 tons from Switzerland, valued at \$240,660; and 46,691 tons from Canada, valued at \$3,955,848. It should be noted that the Canadian imports may be, in fact, expanded or pelletized slag. Verification by the Census Bureau of the type and actual value of the Canadian imports was not completed by the time of publication. The Japanese imports entered into the country through the port of Los Angeles, CA, and the Switzerland imports reportedly entered through Cleveland, OH. Canadian imports reportedly entered into the country primarily through Detroit, MI, Cleveland, OH, and Baltimore, MD.

WORLD REVIEW

Australia

A joint project between the University of Newcastle, New South Wales, and industry was undertaken to construct and test road pavement sections incorporating iron and steel slags.⁵ The main objective of the study was to monitor and determine whether steel mill slags could be suitable as road base materials. The companies involved in the study were BHP Rod and Bar Products Div., Newcastle, BHP Slab and Plate Products Div., Port Kembla, and Boral Resources, Sydney. The test sections were made from various blends and mixtures of the following materials: air-cooled blast furnace slag; granulated blast furnace slag; basic oxygen furnace steel slag; fly ash; and a high-quality natural aggregate, dacite. Control samples were made with the natural aggregate. The test sections were constructed on a road that was subject to heavy industrial traffic on the approaches to a weigh bridge at BHP's Newcastle Works. The performance of the test sections was monitored both in the field and laboratory. Pavement stiffness, assessment of deformation, and surface skid

resistance were among the factors studied. Researchers concluded in part that the use of iron and steel slags as a road pavement base performed as well as or even better than the test sections constructed with the natural aggregate. The one blend that performed outstandingly well as a bound base material contained air-cooled blast furnace slag, basic oxygen furnace slag, granulated slag, and fly ash in the following proportions: 50:20:20:10.

A joint venture between Queensland Cement Ltd., Cleary Bros., and the Edward C. Levy Co. of Detroit, MI, was formed in 1989 to process and market blast furnace and basic oxygen furnace slag from BHP's Port Kembla complex. The consortium was awarded a long-term contract. The blast furnace slag will be processed into three different types: air-cooled, expanded, and granulated. Queensland Cement's wholly owned subsidiary, North Australia Cement Ltd., will produce a portland blast furnace slag cement at its Townsville plant from the granulated blast furnace slag.

Canada

Mining companies in the Sudbury Basin region of Ontario have been interested in a low-cost viable alternative to portland cement as the binding agent for cementing mine backfill. Research on ground granulated blast-furnace slag as a potential binder in the backfill was undertaken by the Canadian Centre for Mineral and Energy Technology of the Energy, Mines and Resources of Canada.⁶ The main objective of the study was to determine the compressive strength of mine backfills constructed with slag in both a laboratory and a field test. A slag granulating system was constructed at Algoma Steel Corp.'s Sault Ste. Marie plant. Forty-six metric tons of granulated slag was produced and shipped for grinding down to the appropriate fineness. Samples were then constructed with varying proportions of granulated slag and portland cement Type 10 (Canadian Standards Association) as the binders and tailings from four different mines as the aggregate. Control samples were made with 100% portland cement. Laboratory test results found that when the slag was used, the compressive strength of the mine backfill was either comparable with or even greater than the compressive strength of the control sample. A field test was designed to test the physical properties of the cemented mine backfill. The performance in the field of the mixtures incorporating slag was considered satisfactory.

Egypt

Researchers at Zagazig University, Zagazig, Egypt, studied the hydration effects of hydrothermally hardened granulated blast-furnace-slag-alite pastes in the presence of quartz.⁷ Granulated slag is widely used as a raw material source for the manufacture of cement because of its relatively low price and savings in fuel energy. The relationships between the hydration characteristics of various slag-alite-quartz mixtures and the compressive strength of the final hardened products were determined experimentally. Investigations of the hydration kinetics, such as the free lime content, were also studied. Researchers concluded that the addition of quartz to the slag-alite-quartz mixture increased the strength of the final product. They also discovered that the higher the alite content, the higher the compressive strength.

Germany, Federal Republic of

Traditionally, ground granulated blast furnace slags have been used as an integral component in cement. Steel slag historically has not been used in such a confined application because of its inherent capability to expand owing to its relatively high free lime content. Recently, however, researchers have undertaken a closer examination of the possibility that steel slag could be used in the manufacture of cement. One such study was undertaken by researchers at the University of Dortmund, Dortmund, Federal Republic of Germany.⁸ Researchers observed the hydration of five different basic oxygen furnace (bof) steel slag pastes. They were interested in determining the effect different activators would have on hydration and if a correlation between the mineralogical and chemical composition of the different steel slags and the rate of hydration existed. Methods used in the analysis included thermogravimetric, loss on ignition, and powder X-ray diffraction. Mortar specimens were also constructed utilizing various blends and proportions of granulated blast furnace slag, steel slag, and portland cement clinker. The goal was to study the performance characteristics, such as the strength and porosity, of the various cement blends. Methods employed in the analysis of the mortar specimens included mercury porosimetry. The study concluded in part that the steel slags hydrated in the presence of water were comparable to portland cement rather than granulated slag. In the beginning, sodium

hydroxide acted as an accelerator, and the sodium was not incorporated in the slag hydrate phases. The results of the analysis of steel slag as a cement binder revealed that the high free lime content did not result in unsoundness when blended with either portland cement or blast furnace slag. No clear correlation between the different bof slags' chemical and mineralogical components and mortar strength diminution was found. Based on the analysis of the porosity and compressive strength of the mortars made with blast furnace slag, bof slag, and portland cement, the researchers concluded that the cement would be acceptable for practical use on specific occasions according to German standards.

Japan

Researchers at NKK Corp.'s Steel Research Center, Kawasaki City, Japan, have developed a low-cost amenity ceramic based on granulated blast furnace slag.⁹ The material has strong growth potential in the construction industry as a low-cost replacement for wood and artificial wood products in buildings. The material is considered a wet ceramic because the composite mixture can be molded and dried without the need for expensive sintering. A typical composition of the material is: 85% to 95% ground granulated blast-furnace slag mixed with water and alkali, 5% to 10% polymer binding, and 3% to 5% glass fibers. Some of the amenity ceramic's properties are as follows: specific gravity of 0.5; fire resistant; does not physically change in response to water or dry air; easily cut and colored; and is hygroscopic.

Figures released by Japan's Steel Slag Association revealed that the production of blast furnace slag in 1989 was 25,215,000 tons, of which 60%, or 15,129,000 tons, was utilized in the production of cement.¹⁰ Steel slag production during the year was 12,448,000 tons, of which only 31%, or 3,858,000 tons, was utilized in road construction.

NKK, in conjunction with another Japanese company, Okutana Kogyo, began marketing a ground solidifying material based on slag.¹¹ The material is prepared by mixing soil with powdered slag which in turn stabilizes the ground for construction work to be undertaken in such difficult areas as harbors and rivers.

Taiwan

The National Chen University, Taiwan, conducted research on the suitability of

blast furnace slag as the major raw material in the production of glass containers.¹² Batches were prepared with 40% to 50% slag by weight, powdered quartz sand (SiO_2), and varying amounts of reagent-grade chemicals such as lithium oxide, zirconium oxide, and sodium sulfate. The slag glasses produced were amber to yellow-green in color. Experimental results demonstrated that the slag glasses were very effective in absorbing ultraviolet (UV) radiation owing to the presence of both ferrous and ferric ions. The researchers concluded that containers made from slag glass would be suitable for liquids that require protection from UV rays, such as beer, wine, and citrus-flavored drinks.

United Kingdom

The Building Research Establishment in England published the results of a 24-year special investigation on the effect of blast furnace slag aggregate in concrete on the embedded steel reinforcing bars.¹³ In 1962, chloride-free concrete prisms were constructed using ordinary portland cement, a sulfate-resisting portland cement, and four types of commercially available air-cooled blast furnace slag products. Control samples were also constructed utilizing a Thames Valley River gravel aggregate. The steel reinforcement was of a commercially bright mild steel stock. The concrete prisms were then placed outside in an industrial environment for 24 years and were removed in 1986 and destructively examined. The reinforced steel bars revealed no cracking nor indication of corrosion and were judged to be in nearly perfect condition. No observed differences between the steel bars embedded in the slag aggregate concrete and those embedded in the natural aggregate concrete were found. The researchers concluded that the concrete made with the slag aggregate had provided almost complete protection for the reinforcing steel in chloride-free conditions, and the performance was comparable with the dense concretes made with natural aggregate.

The Building Research Establishment also published the results in 1989 of a 22-year study on the durability of slag aggregate concretes stored in sulfate solutions.¹⁴ Six different air-cooled blast furnace slags were examined. All but one complied with British Standards 1047. Numerous concrete cubes were made with slag as the coarse aggregate, river sand as the fine aggregate, and either ordinary portland cement or sulfate-resisting portland cement (SRPC) as the cementing

medium. Control samples were constructed similar to those above but with river gravel substituted as the coarse aggregate. The concrete cubes were then immersed in four different aggressive sulfate solutions for more than 20 years. The solutions consisted of strong and weak solutions of magnesium sulfate and sodium sulfate. Some of the conclusions reached after 22 years included the following: those blast furnace slag aggregate concretes complying with British Standards 1047 performed satisfactorily in terms of sulfate resistance; performance of the slag aggregate concretes in corrosive sulfate solutions was broadly similar to that of the natural aggregate concretes; slag aggregate concretes made with SRPC in strong sulfate solutions deteriorated at a rate similar to the gravel aggregate concretes; slag aggregate concretes in SRPC performed as well as the natural aggregate concretes in weak sodium sulfate, but were marginally worse in weak magnesium sulfate.

CURRENT RESEARCH

A third major international conference entitled "Fly Ash, Silica Fume, Slag and Natural Pozzolans in Concrete," was held in Trondheim, Norway, June 18-23, 1989.¹⁵ The conference was sponsored by the American Concrete Institute, Detroit, MI; the Canadian Centre for Mineral and Energy Technology of the Energy, Mines and Resources of Canada; the Norwegian Institute of Technology; and several other organizations in Canada and Norway. More than 11 sessions were held on slag, specifically granulated blast furnace slag. Topics included durability, curing, activation, characterization and reactions, mechanical properties, waste containment, and various other topics.

Steel slag usage has steadily increased worldwide, particularly in the application of asphalt surface mixtures. Research conducted as part of an investigation for the Indiana Department of Transportation (INDOT) attempted to further evaluate steel slag's suitability as an aggregate in bituminous pavement surface layers.¹⁶ The findings were presented at the January 1990 annual meeting of the Transportation Research Board in Washington, DC. The study was conducted on samples made from various combinations of steel slag and natural sand aggregates. The research, in addition to a comprehensive literature search, included field and laboratory testing. Six different combinations of varying

proportions of steel slag as the coarse aggregate, natural sand as the fine aggregate, and an AC-20 asphalt cement were made. Between 1979-81, these steel slag asphalt mixtures were used to construct thick surface layers for several Indiana roadways. A pavement performance history of these test sections was compiled and included the results of skid resistance measurements, visual inspections, and even pavement surface temperatures. Marshall mix design procedures such as unit weight, percent air voids, flow values, and Marshall stability were conducted in the laboratory. Indirect tensile tests and the effects of freezing and thawing cycles were also studied as part of the investigation. Some of the conclusions reached were as follows: pavement surfaces that used steel slag aggregate in the asphalt surface mixtures may provide good skid resistance; steel slag in the asphalt paving mixtures displayed exceptionally high stability, which may also be rut resistant; and the use of natural sand as the fine aggregate in combination with the steel slag as the coarse aggregate provided among other attributes good stability for the mixture.

OUTLOOK

Production of iron and steel slags is directly related to the production of iron

and steel. Consumption of slag is solely dependent on supply and demand. In certain regions in the United States, demand for slag products exceeds supply. For iron and steel production and outlook, please refer to the Bureau of Mines Minerals Yearbook chapter on Iron and Steel.

In the United States, there has been only a slight variation in the markets for iron slag occurring over the past 100 years, and there is very little indication that this will change in the future. However, there will be a gradual change over the next 5 to 10 years in the type of iron slag produced in this country. Some iron slag that is currently processed as air cooled will be replaced by the granulated type. It is expected that the capacity for granulated slag in the United States will effectively double in the future.

Steel slag has not yet achieved the full market potential that iron-blast-furnace slag has in this country, in part, owing to steel slag's capability to expand upon the hydration of its calcium and magnesium oxides. However, the market for steel slag should continue to grow in the future, particularly if research continues to demonstrate its market potential.

SODA ASH

By Dennis S. Kostick

Mr. Kostick, a physical scientist with 11 years Bureau of Mines experience, has been the commodity specialist for soda ash since 1979. Domestic survey data were prepared by Carleen Militello, mineral data assistant; and international data tables were prepared by William Zajac, Chief, International Data Section.

The U.S. soda ash industry operated at 97% of rated capacity to produce a record 9.9 million short tons. The increase in production was because of the strength of export sales, which also was a record, and moderate growth in certain domestic markets, such as in soaps and detergents and pulp and paper. Although consumption in these two domestic markets was higher than in the previous year, total domestic consumption declined. Most of the decrease was attributed to certain sectors that switched back to using caustic soda when prices and availability became favorable by midyear.

The high operating rate of the domestic soda ash industry prompted an increase in the offlist price of the material as supplies became tight. Several consumers, concerned about future

availability, negotiated new contracts at higher prices. The strong world demand for soda ash also made U.S. exports grow 18% over the previous year. The environmental and political events in the world, which began to occur in 1989, should provide excellent opportunities for U.S. soda ash in the future.

DOMESTIC DATA COVERAGE

Domestic production data for soda ash are developed by the Bureau of Mines from monthly, quarterly, and annual voluntary surveys of U.S. operations. Of the six soda ash operations to which a survey request was sent, all responded, representing 100% of the total production data shown in table 1.

¹ Includes natural and synthetic for 1985 and 1986; natural only thereafter. Soda liquors and mine waters converted to soda ash equivalent in 1987 and thereafter; 69,963 tons in 1987, 80,871 tons in 1988, and 104,749 tons in 1989.

² Export data for 1985-1988 were adjusted by the Bureau of Mines to reconcile data discrepancies among the Bureau of the Census, the American Natural Soda Ash Corp, and Statistics Canada.

ISSUES

Environmental concerns of emissions of chlorine-based compounds, such as those used in chlorofluorocarbons (CFC's) and in paper bleaching, have reduced chlorine demand and production of coproduct caustic soda since 1988. As a result, caustic soda prices increased while supplies became tight. Certain chemical consumers, such as the pulp and paper, chemical, and alumina industries, began switching to less expensive soda ash. However, after mid-1989, many customers reverted to caustic soda as prices and availability became balanced. Because of the discovery of trace amounts of carcinogenic dioxin (2,3,7,8-TCDD) and furan (2,3,7,8-TCDF) from paper bleaching, many paper mills stayed with soda ash.

The international awareness of environmental problems is growing, and the effects of chlorinated compounds are under investigation. If the demand for chlorine, which cannot be easily stored, continues to decline while the demand for caustic soda remains strong, soda ash demand may soar. One soda ash producer announced plans to make caustic soda directly from trona rather than the traditional route of using salt as the feedstock. Some chlorine and caustic soda manufacturers reportedly are also evaluating the possibilities of producing caustic soda directly. The future outlook for this scenario depends on the production economics of making caustic soda from trona and the transportation costs from Green River, WY, to caustic soda markets.

Another environmental issue that has growing national importance is recycling. Glass containers, the preferred packaging medium for many years, have undergone years of strong competition from plastic materials, especially in the beverage container sector. Public con-

cern regarding the problems of nonbiodegradable landfill waste accumulation have prompted more glass recycling. Various plastics do not degrade easily, and few are easily recyclable. Glass has the advantage in terms of recyclability. Unfortunately, more recycling will require less soda ash used in new batch mixtures.

Other important issues confronting the growth of U.S. soda ash are the political events in China and Eastern Europe, both regions which have tremendous potential for increased soda ash consumption. The export opportunities are favorable, pending a peaceful resolution to the political and economic problems.

PRODUCTION

Domestic production of natural soda ash from California and Wyoming reached a record 9.9 million tons; that quantity had been expected, based on production forecasts in the Bureau of Mines 1985 Mineral Facts and Problems. About 105,000 tons of soda ash equivalent from soda liquors and mine waters were included in the total and used primarily for neutralizing powerplant process water. The liquors represent a growing market for soda ash producers and

provide additional revenue.

FMC Wyoming Corp. resumed its longwall mining operation at its Green River, WY, trona mine after being idle for several years. It reportedly was the only noncoal longwall activity in the United States.¹ The new longwall shearing unit, which was built in the Federal Republic of Germany, incorporated changes obtained from FMC's previous experiences with longwall technology. The new unit has greater horsepower to cut the tough trona ore, thereby increasing mine output and feed to the refinery. The company anticipates the longwall's high extraction rate will offset production losses from its suspension of soda ash solution mining operations. Some solution mining will occur, but only to feed sodium carbonate solutions to the new sodium cyanide facility.²

Tenneco Minerals Co. finished the first of two projects in March that added 75,000 tons of incremental nameplate capacity, raising total capacity to 1.15 million tons. The second phase will add another 100,000 tons in 1990.³

Cominco American Inc.'s subsidiary, Lake Minerals Corp., and Vulcan Materials Co. conducted a feasibility study to construct and operate a 500,000-ton-per-year soda ash facility at Owens Lake, CA. The engineering, environmental, and marketing study

was expected to take 6 months to complete. The project was slated to come on-stream in 1991, pending the outcome of the study.⁴

NaTec Ltd., a partnership among CRS Serrine, Industrial Resources Inc., and Church & Dwight Co., successfully completed a full-scale demonstration of its dry nahcolite (natural sodium bicarbonate) injection technology for reducing SO₂ and NO_x emissions from coal-fired power utilities. The test was conducted at a 575-megawatt facility in Texas.⁵ NaTec also was chosen to provide equipment, technical service, and solution-mined sodium bicarbonate to Western Slope Refining Co. at its Fruita, CO, power facility.⁶

CONSUMPTION AND USES

Based on reported industry sales, the manufacture of glass represented about 51% of domestic soda ash consumption, with the container sector comprising 30% of this end use; flat, 14%; fiber, 4%; and specialty, 3%. The other end uses include chemicals (primarily sodium bicarbonate, sodium chromates, sodium phosphates, and sodium silicates), 22%; soap and detergents, 12%; distributors, 6%; fluegas desulfurization and miscellaneous, 3%

¹ A joint venture between General Chemical Corp. and Australian Consolidated Industries International, which owns 49% of the soda ash operation.

² Joint venture between Rhone-Poulenc Basic Chemicals Co., formerly Stauffer Chemical Co., and Union Pacific Resources Co.

³ Owned by Texasgulf Inc. of Societe Nationale Elf Aquitaine. Acquired permits to operate at 1.3 million tons of capacity.

NOTE: Nameplate capacities may differ from total shown in table 9 for rated capacity.

each; pulp and paper, 2%; and water treatment, 1%.

Domestic demand for soda ash remained strong during the first half of 1989, following the trend that started in late 1988. The rise in demand was primarily caused by the substitution of high-priced caustic soda for less expensive soda ash by chemical consumers in the pulp and paper, chemical, and alumina industries. The crossover reduced soda ash availability, which increased the market price of soda ash by about \$10 per ton over the previous year. Although many consumers came back to caustic soda by yearend, soda ash for pulp and paper manufacture continued to show increased sales due to the environmental concerns raised by the studies that found minute quantities of dioxins and furans in various bleached-paper products that used chlorine-based bleaches.

Although the quantity of glass containers manufactured increased in 1989, less soda ash was used because of the increased use of cullet. Sales to the flat-glass sector rose, mainly due to use in industrial building construction, which consumes about 57% of all flat glass made. Automotive glass represented 25%, and the remainder went to specialty flat-glass products.

The third largest use of soda ash directly is as a builder to emulsify oil stains, reduce the redeposition of dirt during washing and rinsing, provide alkalinity for cleaning, and soften laundry water. In addition, soda ash is a

component of sodium tripolyphosphate (STPP), another major builder in detergent formulations. Because phosphatic detergents contribute to the environmental problems of eutrophication, many regions of the nation have adopted phosphate limitations or bans. About 33% of the U.S. population resides in the areas that have adopted restrictions. In response to the environmental issue, detergent manufacturers began reformulating their detergents by switching from STPP to tetrasodium pyrophosphate, which has the same building power as STPP but requires less to be used, thereby reducing the amount of phosphate released into the environment. These reformulations also require more soda ash as a direct addition. From 1988 to 1989, soda ash sales to the soap and detergent industry rose approximately 9% because of these changes. This was encouraging because liquid detergents, which do not contain any soda ash, commanded 40% of the household laundry detergent market. Liquid detergents were only 15% in 1978.

STOCKS

Yearend stocks of dense soda ash in plant silos, warehouses, terminals, and on teamtracks amounted to 243,131 tons. Producers indicate that a potential supply problem could exist when inventories fall below 200,000 tons. Most consumers of soda ash do not

have storage facilities to accommodate large quantities of soda ash and must rely on suppliers to provide the material on a timely basis.

PRICES

An announcement was made on April 15 by General Chemical Corp., and later by Tenneco Minerals Co., to raise the list price of soda ash by \$12 per ton, the offlist price by \$15 per ton, and bagged price by \$17 per ton. However, the increases were not unanimously supported by all the producers and the effort to raise the list price was abandoned by June. The strong domestic demand caused by the substitution of high-priced caustic soda for the less-expensive soda ash during the first half of 1989, and the rise in export sales caused soda ash supplies to become very tight. In anticipation of possible supply shortages, several high-volume soda ash contracts were renegotiated for higher prices than in the previous year. The result was that the annual soda ash value increased to \$77.07 per ton, for bulk, dense natural soda ash, f.o.b. Green River, WY, and Searles Valley, CA.

FOREIGN TRADE

U.S. soda ash exports have increased each year since 1976, growing more than 325% between 1976 and 1989, when exports reached a record high of 2.9 million tons, or about 29% of production. Exports to 46 countries, on a regional basis, were: Asia, 51%; South America, 20%; North America, 15%; Africa, 7%; Oceania, 3%; Europe, 2%; and the Caribbean and Central America, 1% each. Exports to the Middle East were negligible.

Section 1205 of the Omnibus Trade and Competitiveness Act of 1988 required the United States to adopt an international nomenclature and metric units for reporting trade information. On January 1, 1990, the Harmonized Commodity Description and Coding System (HS) replaced the Tariff Schedule of the United States, Annotated, for import data and Schedule B for exports. The new code numbers for

⁶ Estimated. NA Not available; included in "Other."

¹ Natural and synthetic except where noted.

² Natural soda ash only in 1980 and 1987-89; natural and synthetic from yearend 1981-1986.

³ Also known as apparent consumption (production + imports - exports + / - stock changes) and is equal to Total U.S. primary demand.

⁴ Estimated consumption for 1980-1986 was based on industry sources; reported consumption 1987 and thereafter were from quantitative and qualitative quarterly surveys of producers' sales. Other end use categories were incorporated in the survey.

⁵ Includes soda ash used in petroleum and metal refining, leather tanning, enamels, etc.

⁶ Represents the amount of discrepancy between "Total U.S. consumption" (obtained from estimated and reported consumption surveys) and "Total U.S. primary demand," which is the calculated quantity of soda ash available for consumption. The discrepancy is because of the fluctuating balance of inventory in transit from plants to domestic or export destinations.

⁷ Values are the combined total revenue of California and Wyoming natural soda ash sold at list-prices, spot-prices, discount, long-term contracts, and for export, divided by the quantity of soda ash sold, bulk, f.o.b. plant. The value may or may not be synonymous with the posted list prices of the commodity.

soda ash are listed in the appropriate trade tables in this report.

Officials of the antidumping directorate of the European Community Commission (ECC) made a surprise visit to the corporate offices and plants of six West European synthetic soda ash producers to obtain information about alleged anticompetitive practices in the European Community (EC) market.⁷ The companies were Solvay et Cie. of Belgium, Akzo N.V. of the Netherlands, Imperial Chemical Industries PLC of England, Rhône-Poulenc S.A. of France, and Chemische Fabrik Kalk and Matthes and Weber G.m.b.H. of the Federal Republic of Germany. The combined output of these producers represented about 20% of world soda ash production. The Commission had reason to believe that all six producers conspired to prevent competi-

tion in the EC soda ash market by blocking U.S. imports in the early 1980's, when antidumping duties were levied. The current duty is 67.5 European Currency Units (ECUs), about \$67.13 per short ton. ECC investigators also investigated U.S. producers at yearend and indicated that a decision would be forthcoming in early 1990. European soda ash consumers would prefer to have an alternate source of soda ash, namely the United States. With two Wyoming soda ash plants co-owned by French companies, the U.S. soda ash industry is hopeful that the investigation will result in reduced or eliminated duties, which would increase U.S. export sales to Europe.

TABLE 6
U.S. EXPORTS OF SODA ASH

(Thousand short tons and thousand dollars)

Year	Disodium carbonate ¹	
	Quantity	Value ²
1985 ³	1,747	173,937
1986 ³	2,049	241,238
1987 ³	2,224	253,200
1988 ³	2,467	286,945
1989	2,919	365,469

¹ Beginning in 1989, export data were reclassified under the Harmonized Commodity Description and Coding System (HS Code No. 2836200000). Prior years were classified under Schedule B No. 4208400.

² Free alongside ship (f.a.s.) value at U.S. ports.

³ Adjusted by the Bureau of Mines to account for discrepancies in data.

Source: Bureau of the Census, as adjusted by the Bureau of Mines.

For the previous several years, international tariffs on imports of soda ash from the United States have blocked U.S. efforts to increase export sales. In 1989, however, an easement of these

trade barriers began with the announcement that Taiwan was reducing the import tariff from 12.5% to 10%, which equals a \$5.90 per short ton savings for Taiwanese consumers. Reducing the tariff could result in greater overseas trade as well as better trading relationships.⁸

WORLD REVIEW

Industry Structure

The developed nations are generally the largest consumers of soda ash. Although the production and consumption quantities vary among the countries, the end-use patterns are basically the same (e.g. glass, chemicals, and detergents are the major sectors). Although the United States is the largest soda ash-producing country in the world, foreign ownership in the U.S. soda ash industry is presently 30% of nameplate capacity.

Eleven countries have the capability to produce more than 1 million tons annually. The major ones include, in descending order, the United States, the U.S.S.R., China, the Federal Republic of Germany, France, Bulgaria, and India. Most of these countries have large populations, which require consumer products made with soda ash. The developing nations tend to have greater soda ash demand and higher rates of growth.

Capacity

World soda ash production capacity is about 38.3 million tons, divided among 35 countries. Approximately 72% of world capacity is synthetic soda ash, 28% natural. The United States represents 27% of world capacity, and 94% of the total natural capacity.

The largest soda ash company in the world, excluding State-owned facilities, is Solvay et Cie. of Belgium. It operates nine plants in seven countries and has a combined annual capacity of more than 4 million tons. FMC Wyoming Corp. of the United States is the second largest with 2.85 million tons of capacity.

The data in table 9 are rated capacities for mines and refineries as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operat-

ing rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Natural soda ash mine capacity assumes two daily mine shifts and one daily maintenance shift per 5-day work week. Considerations were made for operations that mine underground trona, surface sodium salts, and sodium car-

bonate-bearing brines. Natural and synthetic soda ash refining capacities are based on 360 working days per year with scheduled short-term maintenance periods once or twice per year, depending on the physical characteristics of the plant.

The U.S. soda ash industry rated capacity was derived by averaging each producer's third and fourth highest months of output during the past year. These months were used because the first and second highest months were not realistic for sustained production rates. The range between each producer's third and fourth highest months

were close and probably more indicative of what each plant can effectively sustain on a monthly basis, given favorable market conditions. The calculated averages were aggregated and annualized. Individual rated capacities may or may not be synonymous with plant nameplate capacities.

Australia

ICI Australia Operations Pty. Ltd. sold its Osborne synthetic soda ash plant, salt fields, quarry, a bulk terminal, and bagging facilities to Penrice Pty. for \$35 million.⁹

^e Estimated. ^p Preliminary. ^r Revised.

¹ Table includes data available through Apr. 27, 1990. Synthetic unless otherwise specified.

² Production for sale only; excludes output consumed by producers.

³ Reported figure.

⁴ Natural only.

⁵ Includes natural and synthetic. In 1988 and 1989, Mexico allegedly produced an estimated 180,000 metric tons per year of natural soda ash.

⁶ Excludes potash for 1985-87.

⁷ Includes natural and synthetic for 1985-86, natural only thereafter.

Botswana

In June, financing of the Sua Pan soda ash project was finalized in an agreement among Soda Ash Botswana Ltd., three South African shareholders, and a consortium of South African banks. The agreement includes commercial loans at the 17.5% South African prime rate and lower interest rate export credits. The principal engineering contractors have been chosen with completion scheduled for mid-1991.¹⁰

Mexico

Vitro S.A. of Monterrey, the largest glass and raw material for glass manufacturing company in Mexico, acquired for \$265 million Anchor Glass Container Corp. and Latchford Glass Co. in the United States.¹¹ The buyout involved more than 20 glass container plants. The acquisition made Vitro the largest glass container manufacturer in the United States and probably the largest single consumer of soda ash in North America.

OUTLOOK

Although world demand for soda ash has grown about 2.4% per year since the early 1970's, the environmental, energy, and economic issues of the 1980's reduced the international growth rate of soda ash to slightly more than 1% per annum. Developed nations, where soda ash consumption is mature and growth rates are proportional to population changes, are more concerned about environmental quality, energy efficiency, recycling, and consumer preferences, all of which have an adverse affect on soda ash usage. These issues will be of greater importance in the 1990's. Lesser developed countries still have a greater demand for soda ash, but often have less hard currency to purchase all their requirements.

The U.S. annual growth rate for domestic consumption since the 1973 energy crisis, which changed the operating factors between competing natural and synthetic soda ash industries, to the present has been less than 1%. The forecast of 1.2% made in the 1985 Mineral Facts and Problems did not fully anticipate the inroads made by plastic bottles, cullet, and liquid deter-

gents. Although U.S. production was close to what was forecast by 1990, the export market grew greater than anticipated, mainly through the efforts of the industry's export association.

Exports

The outlook for soda ash is excellent. Export opportunities are favorable, particularly to new regions such as the Middle East and Western and Eastern Europe. If the ruling in the EC anti-dumping investigation is favorable to the United States, additional U.S. soda ash may be exported to Western Europe in the near future. The changes in the political situation in the U.S.S.R. and the East European countries may also lead to more U.S. exports to meet the growing demand for consumer products in those areas. The limiting factor, however, may be the lack of available hard currency and the internal manufacturing capabilities of the industries that use soda ash.

The environmental problems in Eastern Europe are critical. Inefficient and polluting synthetic soda ash plants may be targeted for shutdown in order to resolve some of the pollution problems. These problems are similar to those that adversely affected several U.S. synthetic facilities in the late 1970's and finally led to their closures. Any changes in East Europe's soda ash production capacity could signal opportunities for the U.S. soda ash industry.

The future of U.S. exports to China is uncertain. China has been debottlenecking several synthetic soda ash plants and constructing new ones but production cannot keep pace with demand. China was forced to reduce its soda ash consumption by limiting imports because of economic problems. Although Bulgaria had supplied some of China's requirements, future shipments could be curtailed in order to satisfy the East European countries' needs, thereby reducing Bulgaria's level of exports. This could allow the United States the opportunity to continue to export to China, pending the availability of U.S. product. Despite these obstacles, total U.S. exports could grow by several hundreds of thousands of tons in the next several years.

Glass

Although glass is the largest end use of soda ash, domestic consumption in

² Estimated. NA Not available, although production is known to occur.¹ From natural sources of trona and sodium carbonate-bearing brines and from the manufacture by the Solvay, ammonium chloride, and caustic carbonation processes.² Includes soda ash obtained as a byproduct of aluminum processing from nepheline-bearing ore at at least four locations.

the glass container sector is declining because of the increasing use of cullet; the national interest in recycling; and the continuing competition with polyethylene terephthalate (PET) plastic containers.

The glass container shipments were higher in 1989 than in previous years, mainly because ethylene feedstock shortages for plastic resin caused prices of plastics to increase, thereby increasing glass usage. This situation is temporary. However, the public's perception that glass is completely recyclable compared with plastics will raise the quantity of cullet now being consumed. This trend will probably be short-lived as plastic manufacturers develop biodegradable materials, such as polyhydroxybutyrate-hydroxyvalerate (PHBV), which completely decompose into inert compounds. Aside from the problems with plastics' recyclability, the public also is concerned about the dioxin emissions from incineration of polyvinyl chloride (PVC) bottles.

Municipal landfills are a growing national problem. Glass reportedly accounts for 8.4% of disposable household waste. The U.S. Environmental Protection Agency has a goal of reducing the nation's waste by 25% by 1992. It is probable that new taxes will be placed on items manufactured at the source of production to encourage greater use of recycled products. Rebates would be given for every ton of recycled material utilized. It is also likely that domestic glass container manufacturers will strive to add more cullet in new batch mixtures, which will reduce the amount of soda ash consumption, in order to use most of the collected glass.

The glass container industry is

changing. Two facilities closed in 1989 and Vitro S.A. of Mexico bought Anchor Glass Container Corp. and Latchford Glass Co. There reportedly are plans to close more plants, thereby reducing domestic capacity and improving industry operating rates. As plants operated at higher rates, production costs decreased. Soda ash sales for glass containers should remain at the same levels despite the closures.

Soda ash for flat glass and fiber glass is expected to decline in the automotive industries. Consumption will probably be the same in the building construction sector. Strong demand is not anticipated until the mid-1990's.

Soap and Detergents

The world consumes about 10 million tons of laundry detergents annually, which are composed of many active and inert chemical ingredients. Household liquid detergents and phosphate-free detergents are considered environmentally safe products. More soda ash has been added as a phosphate-replacement builder in various detergent formulations in order to meet regional phosphate discharge requirements.

The environmental movement in Europe has also prompted foreign detergent manufacturers to consider changing formulations to reduce phosphate content. In the Federal Republic of Germany, consumption of phosphates in detergents dropped from 276,000 tons in 1975 to 80,000 tons in 1987.

Consumer preferences may ultimately decide the preferred detergent and format (i.e. liquid versus powdered, unit dose packets versus bulk). Depending on the choice, the growth of future soda ash sales is uncertain, despite the current level of sales.

Pulp and Paper

The U.S. pulp industry is growing at about 2.75% per year. Amid this prosperous outlook, changes are taking place to alter the pulp and paper-making processes. Pulp mills are striving to address the environmental issues regarding dioxins and furans, improve productivity, reduce costs, and improve paper quality. One solution is alkaline paper-sizing, which produces alkaline-based paper rather than acid-based. The conversion is not being implemented as fast as the environmental issue is mounting. Other alternatives include substituting certain pulping chemicals.

Dioxins, created from chlorine molecules introduced in the paper bleaching process, have been detected in bleached paper products as reported in a study of the 104 kraft-pulp mills in the United States. To avert the public's reaction to the issue, the industry began investigating substituting chlorine-based chemicals for nonchlorine pulping and bleaching agents, such as oxygen and hydrogen peroxide. About 1.8 million tons of chlorine are used in pulp bleaching annually. Industry sources estimate a 25% to 30% reduction in chlorine consumption by 1995. If this forecast is accurate, coproduct caustic soda, which is used to delignify wood pulp, could be in short supply. This situation could result in additional quantities of soda ash being used instead of caustic soda, although it would take 1.3 tons of soda ash to have the same chemical effect of 1.0 ton of caustic soda. FMC Wyoming Corp. and Tenneco Minerals Co. have announced plans to produce caustic soda from their Green River, WY, soda ash operations. Although the majority of the output is for captive needs, the opportunity will demonstrate the economic feasibility of producing caustic soda from nonsalt feedstocks. Soda ash consumption in the pulp and paper sector could increase during the next few years depending on the strength of chlorine demand; however, assertive strategic planning by one or more chlorine-caustic soda producers to produce their own caustic soda from trona could alter this outlook.

Flue Gas Desulfurization

With changes to the Clean Air Act, the nation's powerplants will be required to reduce emissions of sulfur and nitrogen

compounds produced from burning fossil fuels. Although most high-sulfur coal is used in eastern powerplants where inexpensive calcium-based compounds are located, sodium-based sulfur dioxide removal agents, such as trona and nahcolite, have opportunities for commercial development in the West.

In 1989, nearly 0.5 million tons of soda ash was used for reducing harmful stackgas emissions in the West and Midwest. Transportation costs will reduce the competitiveness of sodium minerals in the East in the future; however, the concern regarding water quality and quantity will be major issues in the Western United States in the 1990's. Several wet-scrubbing utility plants, which use tremendous amounts of water, are evaluating the economics of replacing traditional wet-scrubbing systems using lime with dry-injection technologies using calcium- and sodium-based agents. The addition of some sodium minerals removes additional sulfur and a substantial amount of the nitrogen materials. Eastern powerplants will probably use low-sulfur coal rather than use trona or nahcolite resources found in the West. As Western powerplants retrofit older facilities with dry-injection scrubbing equipment to conserve water, demand for soda ash will increase.

BACKGROUND

Soda ash is the eleventh largest inorganic chemical in terms of production of all inorganic and organic chemicals, excluding petrochemical feedstocks. In 1989, soda ash represented about 2.4% of the total \$32 billion nonfuel mineral industry that was surveyed by the Bureau of Mines. The average U.S. citizen consumes about 40,000 pounds of new minerals in the form of consumer goods each year. Based on the 1989 U.S. population of nearly 248 million, the 1989 per capita consumption of soda ash was 58 pounds, compared with copper, 20 pounds; aluminum, 45 pounds; salt, 345 pounds; cement, 742 pounds; and iron and steel, 863 pounds. An infant born in 1988 would require 4,344 pounds of soda ash in a lifetime, based on an average life expectancy of 74.9 years.

Natural soda ash was probably first obtained as evaporite incrustations along

the edges of alkaline lakes in Lower Egypt. It was used around 3500 B.C. to make ornamental glassware, as evidenced by many of the early Egyptian glass artifacts. The Egyptians also mixed lime and soda ash to make caustic soda. The caustic soda was combined with silicate minerals obtained from the Sinai desert. This made a soluble silica that was added to aluminum-rich Nile River silt, producing a silica-aluminate cement mortar with superior bonding properties. Soda ash was also used in the mummification process. Natural soda ash was placed on the deceased to dry out the body, which was then wrapped in cloth for 70 days.

In the Old Testament, soda ash was referred to as neter; it has also been known as natrium, kali, trona, and natron. Until the 18th century, soda ash was obtained mainly by burning seaweeds and marine plants, leaching the soluble material from the ashes, and evaporating the solutions to dryness. About 13 tons of ash yielded 1 ton of sodium carbonate and 30 pounds of iodine as a byproduct. The final material was very impure but could be used in the manufacture of glass and soap and detergents. Pliny, a Roman historian, listed soda ash in the manufacture of glass, as a medicine for colic pains and skin eruptions, and for making bread, in the first century A.D.

In 1791, Nicolas Leblanc, a French chemist, developed a process for making soda ash from "salt cake" (from salt and sulfuric acid), coal, and limestone. The French Revolution interfered with its development; his patent and factory were confiscated, and he received only token compensation. Napoleon returned the factory to Leblanc who, unable to raise enough capital to reopen it, committed suicide in 1806. More than 30 years passed before the process first became successful in Liverpool, England. The process was not used successfully in the United States except during a short period from July 1884 to January 1885 at Laramie, WY.

Ernest and Alfred Solvay developed an improved method for making soda ash from salt, coke, and limestone, with ammonia as a catalyst in the early 1860's. That process was first used in the United States in 1884 at Syracuse, NY, in a plant that continued to produce soda ash until 1986. It was the first of about 17 synthetic Solvay plants

that were in operation by 1939 in the United States and, ironically, the last one to close. The Solvay process gained in popularity over the years and is now the basic method used throughout the world for making synthetic soda ash.

The site of the first commercial production of natural soda ash in the United States was from two deposits known as the Soda Lakes near the present town of Fallon, NV. Asa L. Kenyon acquired title to Little Soda Lake in 1855 and sold it to Higgins and Duffy in 1868, when the first 300 tons of natural soda ash was produced. Production at adjacent Big Soda Lake began in 1875 and reached its peak in 1887. The brines became diluted when the lake levels rose in 1907 because regional dam construction affected the local water table.

Searles Lake in California was originally mined for borax as early as 1874. Soda ash production began in 1926 by the West End Chemical Co. American Potash Corp., formerly the American Trona Corp., was the second company to produce soda ash in 1931.

Definitions, Grades, and Specifications

The following terms are used in the soda ash industry:

Ammonia-Soda Process.—Also known as the Solvay process and lime-soda process.

Dense Soda Ash.—Has a bulk density of 60 to 66 pounds per cubic foot. It is produced by hydrating light soda ash followed by dehydration through calcination to produce denser crystals. In Eastern Europe, dense ash is made by compressing light ash between rollers to increase the density, followed by screening.

Light Soda Ash.—Has a bulk density of 32 to 39 pounds per cubic foot. It is produced by calcining the sodium sesquicarbonate precipitate recovered from the carbonation towers or vacuum crystallizers.

Natural Soda Ash.—Soda ash produced from trona ore, sodium carbonate-bearing brines, or surface mineralization.

Soda Ash.—Synonymous with sodium carbonate. It is a general term that

FIGURE 2
HISTORICAL CHRONOLOGY OF U.S. SODA ASH ACTIVITIES

can apply to soda ash produced from natural sources or from various chemical processes.

Sodium Sesquicarbonate.—Can refer to the name for the chemical composition of trona, or the chemical process that produces a light to intermediate grade of soda ash having an average bulk density of 50 pounds per cubic foot.

Synthetic Soda Ash.—Term for soda ash produced from one of several chemical processes, such as the Solvay process.

Trona.—The principal ore from which soda ash is made. It is composed of sodium carbonate, sodium bicarbonate, and water. The monoclinic crystals are prismatic to tabular with colors ranging from translucent (spar variety) to shades of brown, which vary depending on the amounts of contained organic matter. Trona has a specific gravity of 2.17 with a hardness of 2.5 to 3, on the Mohs' scale. About 1.8 tons of trona are required to produce 1 ton of soda ash.

The terms "soda ash" and "sodium carbonate" are used interchangeably. The material manufactured from Wyoming trona normally contains more than 99.8% sodium carbonate, and the sodium chloride content ranges between 0.01% to 0.02%. The amount of iron is less than 10 parts per million. Searles Lake brines are processed to yield a product of similar high quality with salt and sodium sulfate as the principal trace impurities. The average material produced by a Solvay soda ash plant is about equal to the natural product in sodium carbonate content, but often contains a larger quantity of salt. Dense soda ash, because of its greater bulk density, may command a higher price than the light variety, and is preferred for glass manufacture because the light soda ash leads to frothing in the glass melt. Light soda ash is preferred by many chemical and detergent industries because it dissolves more readily. Sodium sesquicarbonate has an intermediate bulk density and is used in some detergents and bath salts.

Typical official specifications for soda ash include American National Standard K60, 11-1956 (R1969) "Standard Specifications for Soda Ash," which appears as the American

Society for Testing and Materials (ASTM) Designation D458-74 (Reapproved 1979); and British Standard (BS) 3674: 1963 "Specification for Sodium Carbonate (Technical Grades)." The British Standard specifies, among other requirements, not less than 57.25% Na_2O and not more than 0.005% Fe_2O_3 ; the ASTM, a minimum of 99.16% Na_2CO_3 . Both standards specify methods of testing.

Industry Structure

The U.S. soda ash industry is comprised of six companies, five in Wyoming and one in California. All produce natural soda ash only either from sodium carbonate-rich brines or from underground mining of trona ore. Foreign investment in U.S. soda ash operations has risen from 10% of capacity in 1981, when Société Nationale Elf Aquitaine of France bought Texasgulf Chemical Co., to 30% in 1989. Three of the six U.S. companies have either Australian or French partners.

Geology-Resources

The definitions of resources, reserves, and reserve base are published in U.S. Geological Survey Circular 831, "Principles of a Resource/Reserve Classification for Minerals." Briefly, "resources" describe the quantity of ore present, regardless of grade or ease of extraction. The "reserves" are the portion of the resource, which is economic to mine using the current technology and value of the commodity.

There are more than 60 identified natural sodium carbonate deposits in the world, the largest of which is the trona deposit in southwest Wyoming. Although several of these deposits have been quantified, most are economically insignificant or too remote to be commercially developed. Table 10 lists the countries with known soda ash deposits. All soda ash deposits can be classified in one of five modes of occurrences. In decreasing order of economic importance they are: buried, surface or subsurface brines, crystalline shoreline or bottom crusts, shallow lake bottom crystals, and surface efflorescences.

The trona found in the Green River Formation in southwest Wyoming is an excellent example of a buried trona deposit. The Wilkins Peak Member contains 42 beds of trona, 25 of which have a thickness of 3 feet or more.

Eleven of these exceed 6 feet in thickness and cover an area of more than 1,200 square miles. The trona beds were deposited about 50 million years ago in the early to middle Eocene epoch in an ancient freshwater lake, named "Lake Gosiute" by Clarence King in 1878. The sodium and carbonate constituents of trona owe their respective origins to the leaching of the extensive pyroxene-andesite volcanic ash layers and the seasonal influxes of carbonate-rich sediments into the local depositional basin. In addition, subterranean thermal springs contributed a significant quantity of dissolved alkaline carbonates as well as sodium, calcium, silica, and bicarbonate ions. Trona can precipitate only in the presence of abundant carbon dioxide, which probably was supplied from the atmosphere and/or the biogenic decay of Eocene plant and aquatic remains. For 4 million years, Lake Gosiute went through many stages of filling and evaporation, thereby depositing over 42 beds of trona on the lake bottom along with repetitive beds of marlstone, limestone, oil shale, and sandstone-mudstone. The decrease of the inflow to the lake was probably in response to climatic changes that resulted in the final evaporation of the waters. The former Lake Gosiute is the present Green River Basin.

Assuming 1.8 tons of trona yields approximately 1 ton of soda ash, about 52 billion tons of identified soda ash resources could be obtained from the 62 billion tons of bedded trona and the 52 billion tons of interbedded or intermixed trona and halite that are in beds greater than 4 feet thick. Approximately 37 billion tons of reserve base soda ash could be obtained from the 40 billion tons of halite-free trona and the 27 billion tons of interbedded or intermixed trona and halite in beds more than 6 feet thick. Although about 16 million tons of trona are presently being mined there annually, Wyoming could supply all domestic requirements for more than 3,100 years at the 1989 demand level. As technology improves in the future, mining of the subeconomic grades of ore would further extend the life of the trona deposit to over 5,100 years. With Wyoming reserves estimated at 22 billion tons, the United States, through this one deposit, could provide the supply needed to meet the

current annual world soda ash demand levels for about 630 years.

The U.S. Government established a Known Sodium Leasing Area (KSLA) in Wyoming within the perimeter of the trona depositional basin. The trona located within the KSLA is subject to Federal and State leasing regulations and private lease agreements. Although most of the leasable trona averages 93% sodium sesquicarbonate, several areas contain lower grade trona because of local depositional contamination along the lake margins, thereby reducing the reserve estimates of that particular area.

A series of Pleistocene playa lakes rich in evaporite minerals found in California comprise the second largest reserves of sodium carbonate in the United States. Subsurface sodium carbonate-bearing brines and crystalline material comprise the resource at Searles Lake, which is a nearly dry playa 9 miles long by 7 miles wide with an area of about 40 square miles. Surface sodium-bearing crystalline minerals predominate at Owens Lake, which was first mined in 1885 by the Inyo Development Co. Both deposits have combined reserves of about 900 million tons.

Two potential sources of soda ash—nahcolite (natural sodium bicarbonate) and dawsonite (sodium-aluminum-carbonate)—are associated with oil shale in the Piceance Creek basin in north-west Colorado. Identified resources of 32 billion tons of nahcolite and 19 billion tons of dawsonite, equivalent to 20 billion tons and 7 billion tons, respectively, of sodium carbonate resources, would be available as a by-product of oil shale processing or as single mineral extraction. These deposits were formed in middle Eocene time with the nahcolite occurring as aggregates (62%), disseminated crystals (24%), and impure beds (14%).

The only other commercial natural soda ash deposit in the Western Hemisphere, excluding those in the United States, occurs at Lake Texcoco, near Mexico City, Mexico. Two caliche layers at a depth of 150 feet act as a filter and reservoir for the sodium carbonate-rich brine resource. With an average concentration of about 7% sodium carbonate, the resource contains about 200 million tons of available soda ash.

The Rift Valley of eastern Africa has several alkaline lakes resembling those of California. Only Lake Magadi in

Kenya is presently in production. The soda ash reserves of these lakes are renewed annually from natural active volcanic sources. Other African countries that may become future suppliers of soda ash are Chad, Ethiopia, Niger, the Republic of South Africa, Tanzania, and Uganda. Botswana is developing its Sua Pan salt and soda ash deposit and final completion of the project is scheduled for 1991. Elsewhere, deposits of natural soda ash occur in Bolivia, Brazil, Canada, India, Pakistan, the U.S.S.R., and Venezuela. Plans are underway to develop deposits in China at Xilin Gol and in the Wulan Buh desert area. A trona deposit in Turkey near Beypazari is also under consideration for development.

Technology

Soda ash from Wyoming trona is mined, crushed, dried, dissolved, filtered, recrystallized, and redried. In California, soda ash from sodium carbonate-bearing brines is solution mined, carbonated, filtered, dried, decomposed, bleached, and recrystallized to dense soda ash.

Mining.—Commercial mining of Wyoming trona began in 1950. Between 1950 and 1989, more than 230 million tons of trona (equal to about 128 million tons of soda ash) have been mined. Only about 0.6% of the 40 billion tons of halite-free trona reserve base has been used since mining began.

Underground mining of Wyoming trona is similar to coal mining, except that trona is a harder mineral than coal. The five present Wyoming soda ash producers use room-and-pillar, longwall, shortwall, and solution mining techniques individually or in combination. The room-and-pillar method has an ore extraction efficiency rate of about 45% (55% of ore remains as pillars for structural integrity), the longwall and shortwall methods each have efficiency rates of about 75%, and solution mining has an efficiency rate of about 30%. These rates are important when calculating the amount of reserves that are minable. Based on the types of mining techniques, the author used a 60% average extraction efficiency rate to calculate reserves; the remaining 40% stays in-place as pillars for structural integrity and is unavailable for present extraction. The ore is

undercut, drilled, blasted, mucked, crushed, and transported to the surface by well-established methods and various state-of-the-art mining equipment. The conventional blasting method using prilled ammonium nitrate and fuel oil (ANFO) is a standard and reliable method. Continuous mining uses vehi-

TABLE 10

WORLD NATURAL SODA ASH RESERVES AND RESERVE BASE

World total ⁷	26,600	43,700

NA Not available.

¹The reserve base includes demonstrated resources that are currently economic (reserves), marginally economic (marginal reserves), and some of those that are currently subeconomic (subeconomic resources).

²Includes Owens Lake and Searles Lake.

³Represents only the quantity recoverable based on an average rate of 60% extraction efficiency from room-and-pillar, longwall, and shortwall methods of underground mining. This extraction rate does not apply to brines or surface evaporite lake beds. When solution mining of trona and nahcolite is commercially used, a 30% extraction efficiency rate is expected.

⁴The sodium carbonate content of nahcolite reserves and reserve base are 0.8 billion tons and 1.26 billion tons, respectively. The sodium carbonate content of dawsonite reserves and reserve base are 1.82 billion tons, and 3.0 billion, tons respectively.

⁵Annual leaching of volcanic rocks replenishes the resources at Lake Magadi.

⁶Proven reserves in Inner Mongolia, 100 million tons; Tongbai, Henan, 132 million tons.

⁷Data may not add to total shown because of independent rounding.

Note.—There are at least 62 identified natural sodium carbonate deposits in the world, some of which have been quantified. The countries and number of deposits include Australia (1), Bolivia (2), Botswana (1), Brazil (1), Canada (3), Chad (9), China (9), Egypt (1), Ethiopia (1), India (2), Kenya (3), Mexico (1), Namibia (1), Niger (1), Pakistan (1), the Republic of South Africa (1), Tanzania (5), Turkey (1), Uganda (1), the U.S.S.R. (4), the United States (20), and Venezuela (1).

TABLE 11
SODIUM CARBONATE-BEARING MINERALS

Mineral	Composition	Percent Na_2CO_3 ¹
Themonatrite (monohydrate)	$\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$	85.5
Trona (sesquicarbonate)	$\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$	70.4
Nahcolite (sodium bicarbonate)	NaHCO_3	63.1
Bradleyite	$\text{Na}_2\text{PO}_4 \cdot \text{MgCO}_3$	47.1
Pirssonite	$\text{Na}_2\text{CO}_3 \cdot \text{CaCO}_3 \cdot \text{H}_2\text{O}$	43.8

¹ Includes bicarbonate converted to carbonate.

cles equipped with a rotating cylindrical cutter. Continuous miners are used by T.g. Soda Ash Inc., in its shortwall technique. The longwall technique was used by General Chemical Corp. (formerly Allied Chemical Co.), and is now used by FMC Wyoming Corp. Adopted from coal mining use, the longwall method uses a special track-mounted shearer that moves in front of a hydraulic-operated roof support system.

FMC has pioneered the use of solution mining to dissolve and recover deeply buried trona. Using an array of injection and recovery wells, a solvent, dilute sodium hydroxide, is introduced under pressure to dissolve the underlying trona. This technique has had moderate success since its first commercial debut in 1985.

To reduce mining costs and maintain their competitiveness in the world, many Wyoming soda ash companies implement continuous belt and mobile track conveyor systems to transport trona underground more efficiently. This new haulage system has replaced ore-carrying shuttle cars, reduced the mine workforce, and increased the quantity of ore mined per shift. Companies have also been considering eliminating conventional mining but retaining other mining methods, sometime in the foreseeable future, in order to further reduce labor, safety, and other operating costs.

Subterranean brines between 50 and 350 feet below the surface at Searles

Lake in California are extracted using an array of injection and recovery wells drilled down to specific depths where mineral concentrations favor maximum extraction. The Argus plant of Kerr-McGee Chemical Corp. uses sodium carbonate-rich brines found in the Mixed Layer zone, 220 feet to 310 feet below the surface. Solar concentration ponds are used to aerate and concentrate the brine to improve processing efficiency.

Beneficiation.—Crushed trona is calcined in a rotary kiln at 325° to 400° F to dissociate the ore by the monohydrate process, which produces only dense soda ash with carbon dioxide and water as byproducts. The calcined material is combined with water to dissolve the soda ash and to allow separating and discarding of the insoluble material such as shale and shortite by settling and/or filtration. The waste material is piped in a slurry to containment basins, also known as tailing ponds. The resulting clear liquid is concentrated as necessary by triple-effect evaporators or mechanical vapor recompression crystallizers, and the dissolved soda ash precipitates as crystals of sodium carbonate monohydrate, $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$. The crystallization temperature is about 212° F, which is below the transition temperature of monohydrate to anhydrous soda ash. Other dissolved impurities, such as sodium chloride or sodium sulfate, re-

main in solution. The crystals and liquor are separated by centrifugation. The sodium carbonate monohydrate crystals are calcined a second time at 300° F to remove water of crystallization. The resultant finished product is cooled, screened, and shipped by rail or truck in bags or bulk.

An alternate method of soda ash production from trona is the sesquicarbonate process. Crushed trona is first dissolved and filtered to remove insoluble impurities. The liquor is evaporated in vacuum crystallizers and the sodium sesquicarbonate precipitate is cooled to 100° F and centrifuged to produce a pure product, which has uses as such. The sesquicarbonate can be further calcined at 400° F to produce anhydrous soda ash of light to intermediate density.

The complex brines of the lower level of Searles Lake are first treated with carbon dioxide gas in carbonation towers to convert the sodium carbonate in solution to sodium bicarbonate, which will precipitate under these conditions. The sodium bicarbonate is separated from the remainder of the brine by settling and filtration and is then calcined to convert the product back to soda ash. The decarbonated brine is cooled to recover borax and Glauber's salt. A second dissolving, precipitating with carbon dioxide, filtering, and calcining the light soda ash to dense, refines the product to better than 99% sodium carbonate.

At Owens Lake in California, crude soda ash has been mined and processed by Lake Minerals Corp., by simply digging perimeter channels allowing the interstitial fluids to drain. The surface was tilted to promote evaporation to reduce moisture content, followed by harvesting with front-end loaders.

At Lake Magadi, Kenya, crude trona is dredged from surface crusts, crushed, washed, and calcined to convert the sodium sesquicarbonate to soda ash. At Lake Texcoco in Mexico, underground brines are recovered and sent to a surface spiral concentrator to promote the solar concentration of the sodium carbonate in solution. On the Kola Peninsula in the U.S.S.R., soda ash is recovered from processing nepheline-bearing rocks. Nepheline, a sodium-potassium-aluminum silicate is calcined in rotary kilns to yield alumina, potash, and soda ash. The alumina content of the rocks is about

one-half bauxite but the mining and processing produces byproduct soda ash. The Petukhi and Tanatar (Mikhaylovskiy) natural soda ash lakes in Altay Kray of West Siberia provide some source of natural product.

Synthetic soda ash using the Solvay process uses salt and limestone as raw materials. A purified sodium chloride brine is saturated with ammonia and carbon dioxide gas to produce ammonium bicarbonate, which reacts with the salt to form sodium bicarbonate and ammonium chloride. The sodium bicarbonate is calcined at 350° to 425° F to light soda ash, and the gases produced are recycled back to the liquid phase. The liquid containing ammonium chloride is reacted with milk of lime to recover the ammonia and to produce byproduct calcium chloride. Limestone and coke are required to make the milk of lime. Dense soda ash is produced by hydrating light ash to produce larger sodium carbonate monohydrate crystals. The crystals are dehydrated in dryers to change the bulk density. To produce 1.0 ton of synthetic soda ash requires about 2.8 tons of steam, 1.7 tons of salt, 1.4 tons of limestone, 0.6 ton of coal for the boilers, and about 0.2 ton of coal for the dryers. Disposition of effluent streams containing high concentrations of calcium chloride and sodium chloride is a major problem for all Solvay soda ash plants. The Solvay process discharges about 1.7 tons of waste products.

Other chemical processes can produce synthetic soda ash. The Japanese ammonium chloride coproduction process, a variation of the Solvay process, converts all the sodium content of the salt into soda ash, whereas the Solvay process converts only about 70% of the sodium. The Japanese process also produces byproduct ammonium chloride that can be used as a fertilizer for growing rice in wetlands. The New Asahi process was also developed in Japan and uses less energy than the traditional Solvay process. An electrolysis-free process to produce vinyl chloride monomer with coproduct soda ash was developed in the Netherlands but is not in commercial operation. The method yields soda ash instead of caustic soda, and uses steam and carbon dioxide instead of electricity. The energy consumption is reported to be one-half that of the Solvay process.

Recycling.—There is no recycling of soda ash by producers; however, many glass-container manufacturers are using cullet glass, thereby reducing soda ash consumption.

Byproducts and Coproducts

Borax, potassium chloride, sodium chloride, and sodium sulfate are produced as coproducts with soda ash by Kerr-McGee in California. In Wyoming, only value-added products, such as sodium bicarbonate, sodium hydroxide, sodium sesquicarbonate, and sodium tripolyphosphate are produced from trona ore. Soda ash-bearing purge liquors and waste streams, normally considered waste byproducts, have been sold to powerplants for fluegas desulfurization because of their sodium carbonate content.

Sodium hydroxide (caustic soda) can be substituted for soda ash in some applications, but usually only at a higher cost and when available. About 1.3 tons of soda ash must be used to have the same chemical effect as 1.0 ton of caustic soda. Soda ash is usually shipped in dry, bulk form whereas caustic soda is transported as a liquid in various-sized closed containers.

An alternate source of soda ash is nahcolite, natural-occurring sodium bicarbonate found in a vast deposit in Colorado. The nahcolite could be converted to soda ash by calcination.

Economic Factors

Prices.—The list prices of natural and synthetic soda ash historically were identical until the mid-1970's when higher energy costs and costs to implement the controls imposed by antipollution legislation caused the synthetic soda ash price to increase compared with that of the natural material. New natural soda ash producers came on-stream in 1976 and 1982 and contributed to slight changes in price-value trends. Changes in the domestic demand pattern also influences average annual values, especially after 1980, when domestic demand declined.

The list prices quoted in trade journals or by producers differ from the annual average values reported to and by the Bureau of Mines. The values are the combined total revenue of California and Wyoming natural soda ash sold at list-prices, spot-prices, discount,

TABLE 12
TIME-VALUE RELATIONSHIPS
FOR SODA ASH

Year	Average annual value (dollars per ton)	
	Natural soda ash	
	Actual value ¹	Based on constant 1989 dollars ²
1970	21.03	63.24
1971	21.21	60.33
1972	22.28	60.52
1973	25.36	64.71
1974	33.87	79.22
1975	42.20	89.88
1976	49.70	99.48
1977	54.19	101.70
1978	54.51	95.35
1979	64.55	103.72
1980	89.85	132.42
1981	91.19	122.52
1982	88.35	111.59
1983	76.95	93.54
1984	67.00	78.57
1985	67.82	77.24
1986	65.29	72.46
1987	66.78	71.84
1988	66.96	69.72
1989	77.07	77.07

¹ Values are the combined total revenue of California and Wyoming natural soda ash sold at list-prices, spot-prices, discount, long-term contracts, and for export, divided by the quantity of bulk soda ash sold, f.o.b. plant. The average annual value may not necessarily correspond to posted list prices for soda ash.

² From final 1989 implicit price deflators for Gross National Product, by the Council of Economic Advisors. Based on 1982 = 100.

long-term contracts, and for export, divided by the quantity of soda ash sold on a bulk f.o.b. plant basis. This value may or may not necessarily correspond to the posted list prices.

Tariffs.—The United States has a 1.2% ad valorem tariff on imports of soda ash from countries having most-favored-nation (MFN) status. There is an 8.5% ad valorem tariff on imports from non-MFN sources.

Many nations levy import tariffs or antidumping duties of varying percentages on U.S. soda ash. In Western Europe, an antidumping duty of 67.5 European Currency Units (about \$67.13 per ton) is imposed on any U.S. soda ash sold on the continent.

Taxes.—The total effective tax rate on the Wyoming trona industry is

about 12.64% and comes from two major taxes. The trona severance tax of 5.5% is a State excise tax on minerals as they are removed from the ground, and is applied as a percentage of assessed valuation. The collected taxes are disbursed to the Permanent Wyoming Mineral Trust Fund (2.0%), the General Fund (2.0%), and the Capital Facilities Revenue Account (1.5%). The property, or ad valorem, tax is about 7.14% of the assessed value of trona produced from the mines. The ad valorem taxes on trona are higher than any other Wyoming minerals, including oil, gas, and coal. Other ad valorem taxes are placed on the assessed value of real property (buildings and equipment), and State sales and use taxes on equipment and facilities.

Royalties.—Soda ash mined on Federal lands is subject to the Mineral Leasing Act of 1920, which provides royalty payments to the United States Government. The Federal royalty is 5% of the quantity or gross value of the output of the product at the point of shipment to market. Each Federal lease also has other costs, such as bonds, acreage rental fees, sodium prospecting permit application fees, and permit bonds.

In Wyoming, the soda ash deposit within the Known Sodium Leasing Area is under the jurisdiction of the U.S. Government (administered by the Bureau of Land Management), the State, and the Union Pacific Railroad, which was given alternate 1-square-mile sections north and south of the railway that was constructed in the 1860's. Of the nearly 915,000 total acres of sodium mineral estate, the Federal ownership is 55.7%; Union Pacific owns 38.1%, and the State, 6.2%. Sixteen lessees hold 53 active and inactive Federal leases, having a total of 75,783 acres. In order to prevent a possible land monopoly, no lessee may hold more than 15,360 acres of Federal land but may lease more private or State land. The State royalty rate is tied to the Federal rate of 5%; however, the private royalty rate varies. One-half of all Federal royalties collected by the Minerals Management Service is disbursed back to Wyoming for various State and local programs.

In California, the Federal Government maintains 33 sodium mineral

leases having 26,799 acres. The major lessee is Kerr-McGee Chemical Corp., which produces soda ash, sodium sulfate, and salt on its sodium leases on Searles Lake.

Depletion Provisions.—The mineral depletion allowance granted to the mining industry through legislation passed by the U.S. Government has been an important inducement for companies willing to accept the risk and high cost of mining development. The concept of depletion allowances for minerals is similar to the depreciation of other assets. Although cost depletion and percentage depletion are two methods used to compute depletion deductions, most companies prefer to use the latter. About 100 mineral categories are entitled to percentage depletion. The rates range between 5% and 22% of the gross income from the mineral property, depending on the mineral and location (foreign or domestic), and are subject to a limitation of 50% of the net income from the property. The significance of percentage depletion is that the deduction is based on the quantity of the first marketable product (soda ash and not trona) and not necessarily on the amount invested. The mineral depletion allowance for soda ash is 14% for U.S. companies mining from domestic or foreign sources.

Operating Factors

Operating factors are different for mining companies than for manufacturing facilities engaged in producing natural soda ash and synthetic soda ash, respectively. The shift in U.S. soda ash production from synthetic to natural has been caused by higher costs attributed to the greater energy and labor requirements of the Solvay process and to environmental regulations. Within the natural soda ash industry, the operating factors vary for producing the commodity from brines and from trona ore.

Environmental Requirements.—U.S. natural soda ash facilities do not have difficult problems disposing of effluents. Residual insoluble material is piped to surface tailing ponds, and allowed to settle. Some soda ash in solution that is not economically recoverable from processing is discharged and is converted to sodium decahydrate in the ponds and precipitates on the

bottom of ponds to become an additional source of soda ash if needed. For example, FMC has been dredging some of its sodium decahydrate, which has been accumulating since 1950. Some pond water is recirculated into the mines and used as drilling and cutting coolant. Because of changes in environmental legislation in Wyoming, Tenneco Minerals has begun discharging its waste material into abandoned sections of its underground mine, thereby using less surface area on the surface for tailing ponds. The expense of underground discharge is partially offset with the reduction in costs of constructing and maintaining surface tailing ponds.

The alkaline surface ponds, with a potential of hydrogen (pH) up to 10.5, have posed some problems for migratory fowl that land on the ponds. The alkaline solutions strip the insulative natural oils from the fowls' feathers, thereby increasing the vulnerability of the birds to death from hypothermia. Also, birds have drowned because of the weight of sodium decahydrate that crystallizes on them when the temperature falls below 40° F. All trona producers have established a rehabilitation program to recover and release contaminated birds and to minimize the mortality and morbidity rate.

Land surrounding trona operations in Wyoming is relatively undeveloped, and the influx of large numbers of workers has caused great strain on the local facilities for housing, schools, shopping, and entertainment. Soda ash companies have provided financial assistance to aid local governments in handling any overloads caused by the migration of their employees and families into the community. The companies have given financial aid to employees purchasing homes in the surrounding communities, and other fringe benefits, such as low-cost transportation to and from work.

Toxicity.—Although soda ash is not considered a highly toxic substance, contact with the eyes may be injurious and prolonged contact with the skin may cause irritation, especially to those who have allergic reactions to alkaline materials. It has also been found to be corrosive to the stomach lining if ingested. It has an acute oral lethal dose (LD50) of 2.8 grams per kilogram (when tested on a rat) and a primary

skin irritation index (PSII) of 2.54 (when tested on a rabbit). Simultaneous exposure to soda ash and lime dusts should be minimized because in the presence of moisture, as from perspiration, the two materials combine to form caustic soda, which is very harmful. Soda ash is not flammable, and the dust is not explosive.

Employment.—According to the Wyoming Office of the State Inspector of Mines, the Wyoming soda ash industry in 1980 employed 3,931 people, of which 1,817 were underground workers, to produce 12.9 million tons of trona. In 1989, 2,939 people were employed, of which 1,199 underground workers produced 16.2 million tons of ore. From 1980 through 1989, the underground workforce was reduced about 34%, while the quantity of trona increased 26%. This represented a 90% increase in the amount of ore mined per worker per year; 7,100 tons in 1980 and 13,511 in 1989.

Energy Requirements.—Natural soda ash plants consume considerably less energy per unit of product produced than do synthetic soda ash facilities. As the cost of energy has increased since the 1973 energy crisis, the differential in production costs between natural and synthetic soda ash has become greater. This is one of the major reasons that U.S. natural soda ash has maintained its competitiveness in the world market.

An early Bureau of Mines energy study, using 1973 data, indicated that 15.8 million British thermal units (Btu) was required to produce 1 ton of synthetic soda ash, whereas the energy requirement to produce the same quantity from trona was 7.2 million Btu. The domestic soda ash industry has reduced its energy requirements significantly since 1973, by replacing gas-fired dryers with steam-tube units and installing mechanical vapor recompression units to replace triple-effect evaporators. The industry has also converted to coal exclusively or combined with other fuel sources. Plants operated by T.g. and Tenneco, and the Argus plant operated by Kerr-McGee use coal only. As a result of these energy saving measures, the Wyoming soda ash in-

dustry lowered its energy requirement to a range of from 4.5 to 6 million Btu, depending on the individual producer. An estimated one-half of the energy consumed in natural soda ash refining using triple-effect evaporators is for evaporating; one-third is for calcining, and the remainder, for drying.

These energy requirements exclude the amount of energy needed to ship soda ash to foreign markets. Although it has been estimated that it would take about 2.9 million Btu of additional energy to transport soda ash by rail and by ship to Western Europe, natural soda ash production nevertheless requires less energy than the Solvay process or any other synthetic technique.

Transportation.—The western geographic locations of the domestic natural soda ash industry often pose problems because of the great shipping distance to most foreign customers. Even within the United States, the majority of domestic consumption is in the Midwest and east of the Mississippi River. Overland and ocean transportation rates become important factors in the delivered price of soda ash and must be considered seriously in negotiations with foreign consumers who often have alternate supply sources. Bulk freight rates can usually be reduced by shipping in larger volumes, such as in 7,500-ton units.

The railroad is the dominant mode of transportation for the shipment of soda ash. In Wyoming, the Union Pacific Railroad provides the main service to the industry. All bulk soda ash that is railed is carried in covered hopper cars, each handling about 98 tons. Although the railroad companies make their cars available, most soda ash companies have their own sizable fleet.

Beginning in 1985, soda ash was shipped in large quantities by truck. Bonneville Transloaders Inc. trucked soda ash from Green River to the Burlington Northern Railroad's line at Shoshone. Of the nearly 9 million tons of soda ash produced in Wyoming, Bonneville trucks about 850,000 tons out of Green River. Other trucking companies have started similar operations with the Southern Pacific (shipping over 250,000 tons per year) and

Denver & Rio Grande Railroads to compete with Union Pacific.

The railroads have been involved in establishing soda ash bulk loading terminals at ports to handle large volumes of material for export. Kansas City Southern Railroad's terminal at Port Arthur, TX, has a railcar unloading capacity of about 1,000 tons per hour. Material is conveyed to a ship loader spout for transfer to bulk cargo ocean vessels. Port Arthur was the third largest port of the 24 ports that shipped soda ash in 1989, most of which was shipped to South America. Longview, WA, which is in the Portland, OR, customs district, has a bulk loading terminal that transferred the most soda ash, 47%, in 1989.

SODIUM SULFATE

By Dennis S. Kostick

Mr. Kostick, a physical scientist with 11 years Bureau of Mines experience, has been the commodity specialist for sodium sulfate since 1979. Domestic survey data were prepared by Carleen Militello, mineral data assistant; and international data tables were prepared by William Zajac, Chief, International Data Section.

The U.S. sodium sulfate industry rebounded slightly in 1989 as demand increased in the detergent and pulp and paper sectors. After years of stagnant growth, domestic producers were encouraged at the positive trend but were aware the trend may be short lived because of environmental changes occurring throughout the Nation, which may affect domestic consumption. Additional imports from neighboring countries contributed to domestic supplies of sodium sulfate in response to a decline in U.S. production capacity. Although the United States continued to be one of the largest producers of natural and synthetic sodium sulfate, world production has grown only 1% per year since 1985.

ISSUES

The pulp and paper industry, which consumes about 28% of domestic sodium sulfate supplies, has been under investigation for discharging carcinogenic wastewater effluents into the environment. Although dioxin investigations have been conducted since 1983, 104 bleached pulp mills were studied in April 1988 by the U.S. Environmental Protection Agency to determine the cumulative risk of a certain dioxin (2,3,7,8 tetrachlorodibenzo-p-dioxin, or TCDD) and a furan (2,3,7,8-TCDF) released by the processes. Dioxins are toxic synthetic compounds that have been identified as carcinogenic to some animals but their effect on humans is controversial. The issue is whether or not the quantity of dioxin that has migrated from milk carton stock into milk and from other paper products, such as paper towels, coffee filters, disposable diapers and sanitary paper products, is harmful. If pulp

mills convert from chlorine-base bleaching chemicals to oxygen-base chemicals that are environmentally safe, less sodium sulfate will be used in the pulping process. This change in processing technology will have an adverse effect on future sodium sulfate consumption.¹

PRODUCTION

Domestic production of sodium sulfate decreased about 5% in 1989 primarily because of the closure of Avtex Fibers Inc., a rayon manufacturer in Front Royal, VA, that recovered byproduct sodium sulfate. Avtex was the second largest synthetic sodium sulfate producer in the United States with an annual production capacity of 85,000 tons. The company encountered economic and environmental problems at its facility beginning in late 1988. Because the facility manufactured special carbonized rayon fabric for the

U.S. Department of Defense and for the National Aeronautics and Space Administration, the Federal Government and private contractors intervened with sufficient funding to temporarily avert the closure. By September 1989, problems with carbon disulfide and polychlorinated biphenyl (PCB) emissions forced State and Federal regulatory agencies to demand a cessation of contaminated water discharges.² In November, the company abandoned its efforts to counter the mounting criticism of its operations and permanently closed the facility. In order to prevent possible supply disruptions, several sodium sulfate consumers relied upon imports to meet their anticipated supply needs.

Ozark-Mahoning Co., the Nation's second largest natural sodium sulfate producer, was included in the sale of its parent organization, Pennwalt Corp., to Atochem S.A. Atochem is the chemical sector of Société Nationale Elf Aquitaine of France. The reorganization of Atochem's U.S. chemical enterprises

¹ Ozark's Brownfield plant, owned by Atochem North America (formerly Pennwalt), was placed on standby in Sept. 1987; 70,000 tons of capacity is not included in total industry capacity.

² Closed in Nov. 1989. Facility had a capacity of 85,000 tons per year; not included in total.

was scheduled to be effective January 1, 1990, and to be called Atochem North America, Inc.³

The United States was the largest producer of natural and synthetic sodium sulfate, representing about 15% of the world total, followed by Spain and the U.S.S.R. with 13% each; Mexico, 10%; and Canada, 7%. These five countries accounted for approximately 58% of the world's output of total sodium sulfate, based on obtainable production data.

CONSUMPTION AND USES

U.S. consumption of sodium sulfate rose about 6% after several years of stagnation. Although production declined, imports of anhydrous sodium sulfate, primarily from Canada and

⁵ Data may not add to totals shown because of independent rounding.

Mexico, increased in order to meet domestic demand requirements.

Approximately 60% of the total sodium sulfate consumed in the United States is for use as a filler in powdered laundry detergents. Because phosphatic detergents contribute to the environmental problems of eutrophication, many areas in the country have adopted phosphate bans or limitations. These areas represent about 33% of the U.S. population. In response to the environmental issue, detergent manufacturers began reformulating their detergents by switching from sodium tripolyphosphate (STPP) to tetrasodium pyrophosphate, which has the same building power as STPP but requires less to be used, thereby reducing the amount of phosphate released into the environment.⁴ These reformulations used more sodium sulfate as filler, which was beneficial to the sodium sulfate industry.

Sodium sulfate consumption also in-

creased in the Kraft pulping industry because of the rise in demand for paper products and the high prices of caustic soda, which is an alternative to sodium sulfate when prices and availability are favorable. Kraft pulping represented about 83% of the domestic pulp market in 1989. Public awareness about the environmental issue of nondegradable plastic packaging made many people prefer brown paper grocery bags (produced by the Kraft process), which degrade in landfills much more readily than plastic bags. Kraft pulping represents about 28% of the total demand for sodium sulfate.

STOCKS

Yearend inventories of natural sodium sulfate stored by the three pro-

ducers were 26,285 tons. The material stockpiled was anhydrous sodium sulfate and Glauber's salt. Synthetic sodium sulfate was marketed mainly through major chemical distributors, which have separate storage facilities from the producers.

PRICES

The increase in domestic consumption and tightness in supply caused the prices of bulk and bagged sodium sulfate to also increase. The average value rose from \$78.81 per ton in 1988 to \$83.05 per ton in 1989 for bulk sodium sulfate, f.o.b. mine or plant. Increased bagging costs raised the price of 100 pound bags to \$7. Prices in the East are \$113 to \$114 per ton; \$90 to \$100 in the Gulf; and \$117 per ton in the West. Salt cake prices are about \$62 per ton.⁵

FIGURE 1

U.S. SUPPLY-DEMAND OF SODIUM SULFATE

FIGURE 2

PRODUCTION OF NATURAL AND SYNTHETIC SODIUM SULFATE

FOREIGN TRADE

Canada and Mexico represented about 84% and 13%, respectively, of the total U.S. imports of sodium sulfate, and the United Kingdom imported 4% of the total. Although the United States has a net import reliance of about 13%, most imports are less expensive than products from domestic sources, especially when overland shipping costs are considered.

U.S. exports of 68,000 tons were less in 1989 than in the previous year. About 54% of the total quantity was shipped to Australia; New Zealand received 12%; Thailand, 10%; Indonesia, 9%; and Colombia, 7%. Most was in the form of low-purity salt cake.

WORLD REVIEW

Industry Structure

Approximately 47% of the world sodium sulfate industry is from natural sources; the remainder is represented by synthetic sodium sulfate recovered from various chemical and manufacturing processes. Although the Bureau of Mines collects data from 29 sodium sulfate-producing countries, other countries are known or assumed to have produced synthetic sodium sulfate but production statistics are not reported and available information is inadequate to make reliable estimates of output.

Capacity

The data in table 9 are rated capacities for mines and refineries as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Mine capacity for natural sodium sulfate is derived from available company data on ore throughput to the refinery.

The ore refers to mined crystalline sodium sulfate, harvested precipitate, or sodium sulfate-bearing brines. Refinery capacity for natural sodium sulfate pertains to the total amount of anhydrous sodium sulfate that the plant is capable of processing from the ore. Synthetic (also known as byproduct) sodium sulfate-refining capacity is dependent on the production capabilities of the primary industry and the sodium sulfate recovery rates. The footnotes in table 9 list the various primary industries associated with synthetic sodium sulfate.

Canada

The owner of Saskatchewan Minerals, Kam-Kotia Mines Ltd., terminated its relationship with its U.S. distributor. Low prices and the strength of the Canadian dollar were cited as reasons for the decision.

Mexico

Industrias Penoles S.A. de C.V., Mexico's largest producer of natural sodium sulfate, negotiated with Nepras of Tulsa, OK, which will act as import agent for the Mexican firm. Imports from Mexico may increase to displace the amount of supplies lost due to the closure of Avtex in 1989.

OUTLOOK

Production and consumption of sodium sulfate have decreased about 42% since 1970. This represents an annual rate of decline of about 2.7% per year. These declines are attributed to changes in the recovery operations of consuming industries mandated by environmental legislation requiring reductions in sulfate emissions. Although production has been relatively flat since about 1982, domestic consumption of sodium sulfate is rising slightly but is not expected to grow appreciably in the next several years. Less expensive imports from neighboring countries will continue to serve a part of the needs of the domestic detergent and pulp and paper industries.

Detergents

Sodium sulfate consumption is related to the changes in detergent formulation by the various manufacturers. The increased use of sodium sulfate as

^e Estimated. ^P Preliminary. ^r Revised.¹ Table includes data available through Apr. 18, 1990.² In addition to the countries listed, China, Norway, Poland, Romania, and Switzerland are known or are assumed to have produced synthetic sodium sulfate, and other unlisted countries may have produced this commodity, but production figures are not reported, and general information is not adequate for the formulation of reliable estimates of output levels.³ Reported figure.⁴ Natural mine output, excluding byproduct output from the nitrate industry, which is reported separately under "Synthetic" in this table.⁵ Byproduct sodium sulfate is known to be recovered but reliable data are not available; not included under "Synthetic."⁶ Series reflects output reported by Industrias Penoles S.A. de C.V., Mexico's principal producer, plus an additional 30,000 metric tons (estimated) by a smaller producer.⁷ Less than 1/2 unit.⁸ Conjectural estimates based on 1968 information on natural sodium sulfate and general economic conditions.⁹ Byproduct of nitrate industry.¹⁰ Quantities of synthetic sodium sulfate credited to Spain are reported in official sources in such a way as to indicate that they are in addition to the quantities reported as mined (listed under "Natural" in this table), but some duplication may exist.¹¹ Derived approximate figures; data presented are the difference between reported total sodium sulfate production (natural and synthetic not differentiated) and reported natural sodium sulfate sold by producers (reported under "Natural" in this table).

a filler appears to have peaked in 1989. Major detergent producers apparently were reformulating to make concentrated detergent products rather than the traditional large boxes filled with bulk detergents containing up to 20% sodium sulfate as filler. Although a new powdered detergent plant was under construction in Cartersville, GA, the future outlook for increased sales of sodium sulfate in detergents is not optimistic. In addition, liquid laundry detergents, which do not contain any sodium sulfate, make up about 40% of the home laundry market. Because of the loss of 85,000 tons of production capacity in 1989, domestic supplies of natural and synthetic sodium sulfate are not sufficient to meet demand requirements; therefore, imports of anhydrous sodium sulfate for detergent use will continue in the future unless new domestic production capacity is brought on-stream or brought back into operation, such as Ozark's Brownfield plant.

Pulp and Paper

Because of environmental concerns regarding sulfur emissions, many Kraft pulpers are installing pollution control equipment to reduce sulfur losses in the pulping process. This may adversely affect the demand for sodium sulfate in the near future. The use of sodium chlorate and hydrogen peroxide as a pulp bleaching chemical may further lessen the demand for sodium sulfate because the process yields byproduct sodium sulfate in the pulp liquor.⁶ These losses in sodium sulfate consumption may be partially offset with possible gains in sodium sulfate sales if caustic soda prices continue to increase, as many industry analysts forecast.

BACKGROUND

Natural sodium sulfate reportedly was known to have been used as a medicine as early as the 16th century. It was first accurately described in 1658 by Johann Rudolf Glauber, a German chemist whose name is still associated with the hydrated crystal, Glauber's salt ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$), and the anhydrous mixed sulfate, Glauberite ($\text{Na}_2\text{SO}_4 \cdot \text{CaSO}_4$).

Glauber and other researchers prepared sodium sulfate by reacting common salt with sulfuric acid. The invention of the Kraft process for making pulp and paper in 1880 provided the first major industrial market for sodium sulfate.

Definitions, Grades, and Specifications

The following terms are used in the sodium sulfate industry:

Anhydrous Sodium Sulfate.—Refined sodium sulfate or the mineral thenardite (Na_2SO_4). Named for the French chemist, Louis Jacques Thenard, thenardite is a colorless to white mineral with a specific gravity of 2.67 and a hardness of 2.5 to 3. Because of its whiteness and purity, it is used in detergents, pharmaceuticals, dyestuffs, glass, and ceramic glazes. Commercial grade material has a bulk density of about 77 pounds per cubic foot.

Glauber's Salt.—Same as the mineral mirabilite (Latin "sal mirabile" or "wonderful salt"), sodium sulfate decahydrate ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$). The mineral contains 55.9% water of crystallization and forms opaque to colorless needlelike crystals.

High Purity.—Refers to anhydrous sodium sulfate with a purity of 99% or greater. Usually sold to detergent, glass, and textile industries.

Low Purity.—Some processes occasionally produce sodium sulfate that does not meet certain physical or color specifications required by certain consumers despite being a chemically pure product. This grade of sodium sulfate is generally sold to sectors that are not as concerned about whiteness or particle size, such as the pulp and paper industry, at reduced prices.

Salt Cake.—Normally refers to impure sodium sulfate containing 90% to 99% Na_2SO_4 . Because of its impurity or possible discoloration, it usually is sold only to the pulp and paper industry.

Sodium sulfate made from natural brine usually contains less than 0.5% total impurities, but that produced as a byproduct of other manufacturing may contain much larger quantities. The material meeting U.S. Pharmacopeia (U.S.P.) specifications and that in-

^c Estimated. NA Not available, although production and recovery are known to occur.

¹ Includes capacity at operating plants as well as at plants on standby basis. Production capacities of sodium sulfate are based on processing of solid minerals or sodium sulfate-bearing brines. Synthetic (byproduct) sodium sulfate capacities can fluctuate depending on the production capabilities of the primary industry (e.g., ascorbic acid, boric acid, cellulose, chromium chemicals, lithium carbonate, pharmaceuticals, rayon, resorcinol, and silica pigments) and the sulfate recovery rates.

² Does not include Ozark's Brownfield, TX, idle facility.

³ The Tessenderloo hydrochloric acid plant reportedly has 1 million tons of byproduct sodium sulfate capacity, most of which is diverted to potassium sulfate production. About 300,000 tons of sodium sulfate routinely can be recovered.

tended for glassmaking must contain at least 99% sodium sulfate. In addition, glassmakers' grade must be low in iron and heavy metals. Technical grades of sodium sulfate may have from 2% to 6% impurities. Purchases of detergent or rayon-grade sodium sulfate are based primarily on whiteness. Its salt content may be between 1.5% and 2.0%, and its iron content between 60 and 100 parts per million.

Industry Structure

Naturally derived sodium sulfate produced by three companies operating a total of three plants in California, Texas, and Utah supplied about one-half of the total output of domestic sodium sulfate. Because of the location of these plants, most natural sodium sulfate is marketed in the West and southern Gulf areas. Byproduct material was supplied by 15 companies operating 16 plants in the Midwest and Mid-Atlantic regions. Total rated production capacity in 1989 was 922,000 tons, and the industry operated at 84% of this capacity.

Geology-Resources

Sodium is the sixth most abundant element in the Earth's crust. Sodium sulfate-bearing mineral deposits are geologically young, mainly of post-glacial age. Sodium sulfate is widespread in occurrence and is a common component of seawater and many saline or alkaline lakes. Economic reserves of natural sodium sulfate are estimated at 3.6 billion tons worldwide. With world production of natural sodium sulfate averaging nearly 3 million tons per year, supplies are sufficient to meet anticipated demand for several centuries. The quantity of synthetic sodium sulfate is dependent on the longevity of the industry recovering byproduct sulfate.

Origin.—Surface depressions or lakes that have no outlets and are fed by spring waters flowing over volcanic rocks containing sulfide minerals often yield soluble sulfide salts that are oxidized by contact with the air to produce sulfates. Some minerals over which the spring water may flow contain the sulfates directly, such as bentonite or gypsum. When an inland lake of this type evaporates and becomes highly concentrated in salts, one of the first salts to precipitate

would be mirabilite, also known as Glauber's salt, which is a hydrous form of sodium sulfate that has very poor solubility at low temperatures. During seasonal temperature variations, the sulfate will precipitate preferentially to the lake bottom.

Thenardite and mirabilite are the only sodium sulfate minerals that are commercially important. Many economic deposits of sodium sulfate are in the form of crystalline beds of mirabilite such as those found in Canada and the U.S.S.R., which has the world's largest sodium sulfate resource in the Kara-Bogaz-Gol Gulf. Because mirabilite converts to thenardite when exposed to air, the outer surface may develop a thenardite crust. Some buried sedimentary formations contain very large deposits of thenardite and glauberite, such as the deposit in Villarrubia de Santiago in Spain.

Sodium sulfate also can be found dissolved in underground brines in California, Texas, and other parts of the world. The sulfate is usually converted to mirabilite when extracted from the brine by mechanical refrigeration techniques.

Technology

The technology to mine and process natural sodium sulfate involves mechanical refrigeration or natural chilling to induce crystallization followed by dissolution, filtration, evaporation, and drying. Recovery of byproduct sodium sulfate from various chemical processes involves various techniques.

TABLE 10
WORLD NATURAL SODIUM

¹Salt cake is anhydrous sodium sulfate with a purity lower than 98%.

Texas are the simplest of the domestic brine deposits. Mechanical refrigeration is used to extract Glauber's salt crystals from the brine. The Great Salt Lake in Utah also contains valuable quantities of sodium sulfate. Brine from the most concentrated northwest segment of the lake is pumped into solar evaporation ponds on the eastern shore of the lake where sodium chloride first precipitates as the water evaporates. Sodium sulfate crystals precipitate in a fairly pure state when winter weather cools the brine to 30° to 40° F. The crystals are picked up by large earth-moving machinery and stored outdoors until further processing to anhydrous sodium sulfate can take place.

Beneficiation.—At Searles Lake, the brine is first cooled at about 60° F to precipitate borax crystals, which are removed from the system for subsequent further processing for sale. A second cooling to about 40° F precipitates the sodium sulfate in the form of Glauber's salt. These crystals are separated from the rest of the brine on a rotating drum filter. They are then redissolved in fresh water in a vacuum evaporator. After the second separation and drying, the crystals are about 98.2% sodium sulfate. Additional treatment can obtain a 99.3% purity. Major impurities remaining are sodium chloride, sodium carbonate, and boron.

In Texas, after the crystals are processed in rotary drum vacuum filters and washed, they are melted and dehydrated using mechanical vapor recompression evaporators, which are more energy efficient than triple effect evaporators or submerged gas burners. Final classifying, centrifuging, drying in rotary kilns, and screening converts the Glauber's salt to marketable anhydrous sodium sulfate of 99.7% purity.

Purification and dehydration procedures at the facility on the Great Salt Lake are similar to those of other sodium sulfate plants. The final product results in a purity between 99.5% to 99.7%.

Sodium sulfate is also produced as a byproduct of the production of ascorbic acid, boric acid, cellulose, chromium chemicals, lithium carbonate, rayon, resorcinol, and silica pigments. The Mannheim and Hargreaves furnace processes also produce byproduct sodium sulfate. In the Mannheim fur-

nace, salt and sulfuric acid are reacted to form hydrogen chloride (HCl) and sodium sulfate. The Hargreaves furnace produces HCl and sodium sulfate by the reaction of sulfur dioxide, sodium chloride, air, and water. The Mannheim process is the major method used in Europe, but its use in the United States has decreased considerably since less expensive methods to produce HCl became available.

Recycling.—Because of environmental concerns regarding sulfur emissions from pulp and paper mills, many Kraft pulpers were installing pollution abatement equipment to reduce sulfur losses in the pulping process. This will result in more sodium sulfate being recycled and less used in batch makeup solutions.

Byproducts and Coproducts

The brines of Searles Lake in California contain sodium sulfate as well as coproduct borax, potassium chloride, sodium chloride, and soda ash. The Great Salt Lake in Utah is a source of magnesium compounds, potassium sulfate, sodium chloride, as well as sodium sulfate. The brines in Texas do not yield any secondary products.

Manufacturers of ascorbic acid, boric acid, cellulose, chromium chemicals, lithium carbonate, rayon, resorcinol, and silica pigments produce sodium sulfate as a byproduct of the process. The sodium sulfate is considered a waste product but has marketability.

Economic Factors

Prices.—Producers of natural sodium sulfate tend to market and sell their own product, but synthetic producers use major chemical distributors. The principal product made and sold by the synthetic sodium sulfate producer is the primary economic factor. Because the sodium sulfate is a waste product, it will be sold at whatever price in order to dispose of it. This practice tends to set the rates at which the natural product can be sold.

The list prices quoted in trade journals or by producers of all grades of sodium sulfate differ from the annual average values reported by the Bureau of Mines. The value represents the combined amount of total revenue of domestic natural sodium sulfate sold at list prices, spot prices, long-term con-

tracts, discounts, and export divided by the aggregated quantity of sodium sulfate sold. The published value does not necessarily correspond to the posted list price.

Tariffs.—Import tariffs serve to protect the interests of domestic producers for particular products. For sodium sulfate, a 32.5 cents per ton tariff is imposed on imported anhydrous sodium sulfate from countries having most favored nation (MFN) status and \$2.95 per ton from those with non-MFN status. There are no import tariffs on imported salt cake, regardless of the country of origin.

Royalties.—Sodium sulfate mined on Federal lands is subject to the Mineral Leasing Act of 1920, which provides for royalty payments to the United States

¹ Based on the average valuation by producers of their annual total production and reported sales. The values incorporate the price differences charged by producers for the same finished product sold in bulk at the plant.

² From final 1989 implicit price deflators for gross national product, by the Council of Economic Advisors. Based on 1982 = 100.

Government. The royalty is 5% of the quantity or gross value of the output of the product at the point of shipment to market. Each Federal lease also has other costs, such as bonds, acreage rental fees, sodium prospecting permit application fees, and permit bonds. The Searles Lake sodium sulfate deposit is the only resource that has any Federal leases. Because of the variety of the brine constituents, the operator has a commingling agreement with the U.S. Government to compute royalties.

Depletion Provisions.—Legislation passed by the U.S. Government provides an allowance for the depletion of natural resources, notably timber and minerals. The depletion allowance is an important inducement for companies willing to accept the risk and high cost of mining development. The concept of depletion allowances for minerals is similar to the depreciation of other assets. Although cost depletion and percentage depletion are two methods used to compute depletion deductions, most companies prefer to use the latter. About 100 mineral categories are entitled to percentage depletion. The rates range between 5% and 22% of the gross income from the mineral property, depending on the mineral and location (foreign or domestic), and are subject to a limitation of 50% of the net income of the property. The mineral depletion allowance for natural sodium sulfate is 14% for U.S. companies mining from domestic or foreign sources.

Operating Factors

Operating factors are different for mining companies producing natural sodium sulfate compared with manufacturing facilities recovering byproduct sodium sulfate. The quantity of synthetic sodium sulfate recovered is directly associated with the production capabilities of the primary industry (e.g., rayon, lithium carbonate, etc.) and the sulfate recovery rates.

Environmental Requirements.—Land usage may become a problem when sodium sulfate is obtained by solar evaporation, as in the case of the Great Salt Lake brines. Large areas of relatively flat land are required to allow for adequate concentration and evaporation. When land values are high, the capital required

for land acquisition may increase operating costs. Disposal of the waste liquors from which sodium sulfate was extracted may develop into a major ground water discharge problem in some areas. Reinjection of spent solutions into underground source strata is expensive but often is the only acceptable method of disposal.

Because sodium sulfate is water-soluble, most releases of sodium sulfate to the environment affect water quality rather than air or land quality. These releases are mainly from Kraft pulp mills, which typically discharge between 11 to 33 million pounds of sodium sulfate per year per site. The resulting drinking water concentrations have been estimated as high as 38.8 milligrams per liter, which is significantly below the maximum concentration level of 250 milligram per liter set by the National Secondary Drinking Water Standard.

Problems associated with chemical effluents discharged from manufacturing plants that recover sodium sulfate have also caused environmental concerns not attributed to sodium sulfate. The second largest byproduct sodium sulfate facility in the United States at Front Royal, VA, owned by Avtex Fibers Inc., was closed in late 1989 by Federal and State regulatory agencies because of contaminated water discharges containing carbon disulfide and polychlorinated biphenyls (PCB's). These toxic chemicals were produced from rayon manufacture, not sodium sulfate recovery.

Toxicity.—Sodium sulfate was deleted in early 1989 from the list of toxic chemicals under section 313 of Title III of the Superfund Amendments and Reauthorization Act of 1986. The U.S. Environmental Protection Agency determined that there was no evidence that sodium sulfate caused, or could reasonably be anticipated to cause, adverse human health or environmental effects as specified in the act.⁷

Employment.—According to the Bureau of Labor Statistics and industry sources, approximately 300 persons are employed in mining and processing natural sodium sulfate in the United States. No data are available on the number of personnel employed in recovering byproduct sodium sulfate.

Energy Requirements.—The energy requirements to mine natural sodium sulfate are minimal compared with the amount of energy required to process it. An early Bureau of Mines energy survey reported that 4.5 million British thermal units (Btu's) were required to produce 1 ton of natural sodium sulfate. With the interest in conserving energy, some technical improvements, such as the installation of mechanical vapor recompression crystallizers, have reduced the overall energy requirement to slightly less than 2 million Btu's per ton of sulfate produced.

Transportation.—All natural sodium sulfate is shipped in bulk or in bags by rail or truck. The method of transportation depends on the location of the customer, quantity purchased, and difference in freight rates. Due to the location of the natural producers in the West and Southwest, very little natural sodium sulfate is shipped to the East because transportation rates reduce the competitiveness between the two types of sodium sulfate. Consumers in the Midwest and East tend to rely on synthetic sodium sulfate produced in various Midwest and Southern locations.

CRUSHED STONE

By Valentin V. Tepordei

Mr. Tepordei, a geological engineer with more than 20 years industry experience, has been the crushed stone commodity specialist with the Bureau of Mines since 1981. Domestic survey data were prepared by the crushed and broken stone survey staff of the Branch of Data Collection and Coordination.

A total of 1.2 billion short tons of crushed stone was produced in the United States in 1989, a 2.8% decrease compared with the estimated 1988 total. This tonnage represents the third consecutive year of production over 1.2 billion tons, indicating a continuation of the strong demand for construction aggregates. About three-quarters of the crushed stone production continued to be limestone and dolomite, followed by granite, traprock, sandstone and quartzite, miscellaneous stone, marble, shell, calcareous marl, volcanic cinder and scoria, and slate, in order of volume.

Foreign trade of crushed stone remained relatively minor. Exports increased 7.1% to 3.9 million tons, while value decreased 23.2% to \$23.3 million. Imports of crushed stone, including calcium carbonate, increased 20.9% to 4.4 million tons, while the value increased 119.6% to \$36.9 million. Domestic apparent consumption of crushed stone was 1.2 billion tons.

The new regulatory requirements being proposed by the Occupational Safety and Health Administration (OSHA) constitute major areas of concern for the crushed stone industry. They include the revised asbestos standards governing occupational exposure to nonasbestiform varieties of actinolite, tremolite, and anthophyllite minerals, and the final promulgation of the permissible exposure limit for crystalline silica, measured as respirable silica.

DOMESTIC DATA COVERAGE

Domestic production data for crushed stone are developed by the Bureau of Mines from voluntary surveys of U.S. producers. Full surveys of crushed stone producers are conducted for odd-numbered years only. For even-numbered years, a preliminary survey that collects production information on a sample basis is used to generate only annual estimates for each State. In addition,

a new quarterly sample survey for crushed stone and sand and gravel was implemented by the Bureau of Mines in 1989 that provides for the first-time production estimates by quarters for each State, and the nine geographic regions. The results of this survey are published each quarter in a separate publication, the Quarterly Mineral Industry Survey. Both sample surveys canvass most of the large companies in each State, accounting for up to 80% of the State's total tonnage.

Of the 4,862 crushed stone operations surveyed, 3,416 were active. Of these, 2,901 or 84.9% reported to the Bureau of Mines survey, and their total production represented 92.8% of the total U.S. crushed stone output. The nonrespondents' production was estimated using adjusted production reports and/or employment data of prior years. Of the 2,901 reporting operations, 839 did not report a breakdown by end use. Their production represented 27.5% of the U.S. total and is included in table 13 under "Unspecified uses, actual." The estimated production of 515 operations represented 7.2% of the U.S. total. A total of 1,446 quarries was either idle or presumed to have closed down because no information was available to estimate their production.

LEGISLATION AND GOVERNMENT PROGRAMS

On January 13, 1989, OSHA announced the final promulgation of exposure limits for 400 air contaminants, establishing a permissible exposure limit (PEL) of 0.1 milligram per cubic meter for crystalline silica, measured as respirable silica.¹ Despite this ruling, some statements in the preamble indicate that OSHA may reconsider in the future the need to lower the standard, based on "emerging developments in this area."

On August 29, 1989, the Mine Safety and Health Administration (MSHA), published a new proposed rule that revises MSHA's existing standards for air quality and chemical substances at coal and metal-nonmetal mines. The proposed rule contains permissible exposure limits for substances that may pose health hazards at these operations. In addition, the proposed rule contains revised requirements for exposure monitoring, carcinogens, and respiratory protection programs. The original deadline for receiving comments about the proposed ruling was November 27, 1989, and was extended later to March 2, 1990.²

²Excludes precipitated calcium carbonate.

On July 21, 1989, OSHA announced another extension through November 30, 1990, of the stay for the new provisions of its revised asbestos standards governing occupational exposure to nonasbestiform varieties of actinolite, tremolite, and anthophyllite (AT&A) minerals. The revised asbestos exposure standards were originally published by OSHA on June 20, 1986. The former asbestos standard remains in effect for the extent of the stay. Based on OSHA's Hazard Communication Standard, a product is considered carcinogenic if it contains 0.1% or more of an OSHA-designated carcinogen. The inclusion of nonasbestiform AT&A minerals in the asbestos exposure standards effectively designates large areas of the United States as containing carcinogenic minerals. The revised OSHA regulations for airborne asbestos standards, if implemented, are expected to have a significant impact on the aggregates and the construction industries that could include increased mining and construction costs and disruption of the supply of aggregates in most areas.

In 1989, MSHA established a new program to combat illegal mining. The program will be enforced through an Illegal Mining Task Force, as well as MSHA officials at the local level. MSHA considers a mining site illegal when the operator fails to register the site with the agency.

ISSUES

On June 20, 1986, OSHA published a final rule titled "Occupational Exposure to Asbestos, Tremolite, Anthophyllite, and Actinolite; Final Rules." The regulation, which was amended in September 1988, established exposure limits for asbestos and nonasbestiform varieties of the amphibole minerals AT&A. Under OSHA regulation, all products containing a specified concentration of these minerals must be labeled as having a constituent that is a carcinogen. In an effort to assist OSHA in its decision regarding implementation of the final asbestos standard, the Bureau of Mines completed in August 1989 a study entitled "Analysis of the Cost Effectiveness of the OSHA Regulation of Nonasbestiform Amphiboles with Respect to Selected Sectors of the Domestic Minerals Industry."³ The Bureau's analysis questions "whether OSHA has conclusively demonstrated a health risk associated with AT&A and, consequently, that these minerals should be

regulated at all, given that no discernible net benefits will result." The study has also "identified a basic inconsistency between OSHA's definition of asbestos and its asbestos standard" and found that "the regulation will result in economic impacts on several mineral industry sectors."

"The economic impact of the OSHA regulation is expected to be greatest on the aggregates industry. Because of product liability considerations, it is expected that preliminary deposit evaluation and deposit sampling of some kind would have to be done at about 1,325 quarries, or one-fourth of the crushed stone quarries in the United States. It is estimated that about 780 quarries, or 15 percent of U.S. quarries, would need to conduct detailed testing. The annualized cost of preliminary deposit evaluation and deposit sampling of the 1,325 quarries is estimated at \$22 million." Significantly, the Bureau analysis concludes that "the remaining 345 of the 780 quarries would be financially unable to afford the cost of the required detailed testing because of their small size. These quarries, which produced an estimated 16.6 million tons in 1987 valued at \$72.5 million, f.o.b. plant, could be forced to close.

Sales losses in the aggregates industry are possible and would be contingent on the availability and cost of material that is essentially free of AT&A and the liability concerns associated with using products containing AT&A." In the concluding section of the study, "it is recommended that OSHA not regulate AT&A as asbestos unless medical data conclusively show that these minerals present a health risk which would be reduced through regulations"; that "OSHA should revise its asbestos and fiber definitions, to make the two terms consistent from a mineralogical standpoint"; and that "OSHA should specifically address the economic impact of its proposed regulation on the minerals industry and weigh these costs against possible benefits."

PRODUCTION

Of the total 1.2 billion tons of crushed stone produced in the United States, 856 million tons or 71% was limestone and dolomite, 168 million tons or 14% was granite, and 99 million tons or 8% was traprock. The remaining 7% was shared, in descending order of quantity, by sandstone and quartzite, miscellaneous stone,

marble, shell, calcareous marl, volcanic cinder and scoria, and slate.

A comparison of the four major geographic regions indicates that, in 1989, the South continued to lead the Nation in the production of crushed stone with 577 million tons, or 47.5%, of the total, followed by the Midwest with 324 million tons or 26.7%, and the Northeast with 185 million tons or 15.2%.

Approximately 74% of the total U.S. crushed stone output was produced in two major geographic regions, the South and the Midwest. Of the nine geographic regions, the South Atlantic led the Nation in the production of crushed stone with 316 millions tons or 26% of the U.S. total. Next was the East North Central region with 212 or 17.4% of the total, followed by the Middle Atlantic with 154 million tons or 12.7%.

A comparison of the estimated 1988 and reported 1989 production data by regions indicates that the output of crushed stone decreased in all regions except the East North Central, East South Central, and the Pacific. The largest decreases were recorded in New England, -17.3%, the Mountain, -15.1%, and the Middle Atlantic, -6.2%, while the increases were significantly smaller and occurred in the Pacific, 3.2%, East South Central, 1.4%, and East North Central, 0.8%.

Crushed stone was produced in every State except Delaware and North Dakota. The 10 leading States in the production of crushed stone, in decreasing order of volume, were Pennsylvania, Florida, Texas, Virginia, Illinois, California, Tennessee, Missouri, North Carolina, and Georgia. Their combined production represented 52.8% of the national total.

Changes in ownership, acquisitions by foreign or domestic companies, and mergers continued in the crushed stone industry in 1989. In January 1989, Lone Star Industries Inc. of Greenwich, CT, completed the sale of its remaining 40% interest in Tarmac-Lone Star joint venture to Tarmac America of Herndon, VA, a division of Tarmac PLC of Wolverhampton, United Kingdom. The original joint venture was established in 1986. The latest transaction included remaining interest in aggregates, cement, concrete, and concrete products operations in North Carolina, South Carolina, and Virginia.

Pioneer Concrete of America of Bedford, TX, a subsidiary of Pioneer International Ltd. of St. Peters, Australia, acquired Fletcher Granite Co. Inc. of Chelmsford,

FIGURE 1
**PRODUCTION OF CRUSHED STONE IN THE UNITED STATES
IN 1989, BY GEOGRAPHIC REGION**

MA. Fletcher operates six granite quarries in Maine, Massachusetts, and New Hampshire.

American Limestone Co. of Knoxville, TN, a wholly owned subsidiary of ASARCO Incorporated of New York, NY, acquired Porter Brown Limestone Co. and Robco Materials Co. of Springfield, TN, and Acme Stone Inc. of Abingdon, VA. Porter Brown operates two limestone quarries near Nashville, TN, while Acme Stone operates a limestone quarry near Knoxville, TN.

First Chicago Corp. of Chicago, IL, acquired Georgia Marble Co. of Atlanta, GA, a major producer of high-grade calcium carbonate with operations in Alabama, Georgia, and South Carolina. Georgia Marble Aggregates Corp. of Atlanta, GA, previously a division of Georgia Marble Co., was acquired by Blue Circle Holdings Inc. of Marietta, GA, the U.S. subsidiary of Blue Circle Industries PLC of London, United Kingdom. Georgia Marble Aggregates operates seven crushed stone quarries near Atlanta, GA.

Redland PLC of Gorbey, United Kingdom, acquired through its subsidiary, Western-Mobile Inc. of Denver, CO, Flatiron Sand & Gravel Co. of Boulder, CO. The transaction included the assets of Flatiron Sand & Gravel, Flatiron Paving,

²Data may not add to totals shown because of independent rounding.

Flatiron Premix Concrete, and Plains Aggregate Co. Redland also owns in the United States Genstar Stone Products Co. of Hunt Valley, MD, and Redland Worth Corp. of San Antonio, TX.

ARC America Corp. of Newport Beach, CA, a subsidiary of ARC Ltd. of Bristol, United Kingdom, and one of the major crushed stone and sand and gravel producers in the United States, was acquired by Hanson Trust PLC of London, United Kingdom. The change in ownership followed the acquisition by Hanson PLC of the Consolidated Gold Fields PLC, of London, United Kingdom, the parent company of ARC Ltd. At the end of 1989, Hansen PLC was in the process of selling all ARC America operations to Colonial Sugar Refineries (CSR) Ltd. of Sydney, Australia, a major sugar and building-material producer. The transaction includes American Aggregates Co. of Greenville, OH, Associated Sand and Gravel Co. of Everett, WA, and WMK Co. of Las Vegas, NV. CSR already owns Rinker Materials Corp. of West Palm Beach, FL.

Martin Marietta Corp. of Bethesda, MD, acquired eight limestone quarries in central Kansas and northern Iowa from Hallet Materials Corp. of Des Moines, IA.

George Wimpey PLC of London, United Kingdom, acquired Broyhill and Associates Inc. of Annville, PA, and its two rail-linked limestone quarries in Hanover and Annville, PA, that supply Baltimore-Washington and Delaware markets.

Vulcan Materials Co. of Birmingham, AL, acquired Dolcito Quarry Co. of Tarrant, AL, and Central Rock Minerals Inc. of Lexington, KY. Dolcito quarry is one of the oldest continuously operating crushed stone quarries in the southeast. Vulcan also announced the signing of a letter of intent to purchase Reed Crushed Stone Co. of Paducah, KY, and two subsidiary companies, Reed Terminal Co. and BRT Transfer Terminal Inc. Reed Crushed Stone presently operates the largest crushed stone quarry in the United States. Ideal Basic Industries of Denver, CO, started shipping limestone by barge from its newly completed Crystal River quarry in Florida to its Mobile, AL, cement plant.

Limestone

The 1989 output of crushed limestone, including some dolomite, increased slightly to 807 million tons valued at \$3.2 billion, compared with the 1987 totals. In addition to the quarries reporting producing only limestone, 41 quarries reported producing both limestone and dolomite without making a distinction between the two kinds of stone. Their production was included with the limestone, and therefore, the limestone totals shown in this chapter include an undetermined amount of dolomite in addition to the dolomite reported separately. Limestone was produced by 1,102 companies at 2,444 quarries in 47 States. Leading States, in decreasing order of tonnage, were Florida, Texas, Pennsylvania, Illinois, and Tennessee; these five States accounted for 38.3 % of the total U.S. output. Leading U.S. producers were, in order of volume, Vulcan Materials Co, Beazer USA, Martin Marietta Aggregates, General Dynamics, and the Rogers Group. These five companies accounted for about 20 % of total U.S. output of limestone.

Dolomite

Production of dolomite remained relatively unchanged from the 1987 reported totals. Crushed dolomite was reportedly produced by 92 companies at

⁸Excludes quartzite.

⁹Excludes limestone.

¹⁰Excludes shell.

¹¹Data may not add to totals shown because of independent rounding.

136 quarries in 27 States. An additional undetermined amount of dolomite is included in the total crushed limestone. Leading States in the production of dolomite, in decreasing order of tonnage, were Pennsylvania, Ohio, Michigan, Tennessee, and New York; these five States accounted for 67% of the total U.S. output. Leading U.S. producers were Stabler Co., Glasgow Inc., Asarco, Michigan Minerals Associates, and Dravo Lime; their combined production represented 38% of the total U.S. dolomite production.

Marble

Production of crushed marble increased 119% to 12 million tons valued at \$137 million. Crushed marble was produced by 14 companies at 59 quarries in 12 States. Leading States, in decreasing order of tonnage, were Georgia, Virginia, Alabama, Vermont, and Texas; these five States accounted for 98% of the total U.S. output. Leading producers of crushed marble, in decreasing order of tonnage, were Georgia Marble Co., Beazer USA, and Jim Walter Corp; their combined production represented 82% of the total U.S. output.

Calcareous Marl

Output of marl increased 23% to 5.1 million tons valued at \$11.6 million. Marl was produced by 15 companies at 15 quarries in 8 States. South Carolina accounted for 61% of total U.S. output. Leading producers, in decreasing order of tonnage,

were Dundee Cement Co., Medusa Aggregates Co., and Giant Group LTD; their combined production represented 64% of the total U.S. output.

Shell

Shell is mainly derived from fossil reefs or oyster shell. The output of crushed shell decreased 18% to 6.9 million tons valued at \$35 million. The decrease is mostly owing to the restrictions imposed on the industry in Louisiana as a result of concerns that shell dredging produces irreversible damage to the environment. Crushed shell was produced by 15 companies from 18 operations in 5 States. The major producing States were Florida and Louisiana, and the leading producers, in decreasing order of tonnage, were Dravo Lime Co., Ashland Oil Inc., Leisey Shell Corp., Pontchartrain Dredging Corp., and Quality Aggregates Inc.; their combined production represented 80% of the U.S. output.

Granite

Compared with that of 1987, the 1989 output of crushed granite decreased 6.4% to 168 million tons valued at \$865 million. Crushed granite was produced by 134 companies at 375 quarries in 32 States. Leading States, in decreasing order of tonnage, were North Carolina, Georgia, Virginia, South Carolina, and California; these five States accounted for 76% of the U.S. output. Leading U.S. producers, in decreasing order of tonnage, were Vulcan Materials

Co., Martin Marietta, Beazer USA, Tarmac America, and Luck Stone Corp; their combined production represented 56% of the U.S. total.

Traprock

Production of crushed traprock decreased 4% to 99 million tons valued at \$524 million. Traprock was produced by 242 companies at 441 quarries in 27 States. Leading States, in decreasing order of tonnage, were Oregon, New Jersey, Washington, Connecticut, and Virginia; these five States accounted for 57% of U.S. output. Leading U.S. producers, in decreasing order of tonnage, were Traprock Industries Inc., Tilcon Inc., Beazer USA, and Luck Stone Corp; their combined production accounted for 25% of the total U.S. output.

Sandstone and Quartzite

The combined output of crushed sandstone and quartzite remained relatively unchanged at 32 million tons valued at \$149 million. Crushed sandstone was produced by 113 companies at 216 quarries in 27 States, while crushed quartzite was produced by 23 companies at 24 quarries in 17 States. Leading States in decreasing order of production of sandstone were Arkansas, California, and Pennsylvania, and for quartzite California, Georgia, and South Dakota; the three States accounted for 55% of the U.S. output of sandstone and 76% of the U.S. output of quartzite. Leading producers, in decreasing order of tonnage, were Arkola Sand and Gravel Co., American Rock and Asphalt Inc., and Weaver Construction Co. for crushed sandstone, and Martin Marietta, Beazer USA, and Sweetman Construction Co. for crushed quartzite.

Slate

Compared with that of 1987, the 1989 output of crushed slate decreased 10% to 2.1 million tons valued at \$12.9 million. Crushed slate was produced by six companies at seven quarries in six States. Leading States, in decreasing order of tonnage, were North Carolina and Georgia. Leading producers, in order of tonnage, were Martin Marietta, Big River Industries, and Lesuer-Richmond Slate Corp. The top three producers accounted for most of the U.S. output of crushed slate.

Volcanic Cinder and Scoria

Production of volcanic cinder and scoria showed a slight decrease to 3.6 million tons

TABLE 9

CRUSHED CALCAREOUS MARL SOLD OR USED BY PRODUCERS IN THE UNITED STATES IN 1989, BY STATE

(Thousand short tons and thousand dollars)

State	Quantity	Value
Florida	266	800
Michigan	12	28
South Carolina	3,133	6,178
Other ¹	1,705	4,608
Total ²	5,100	11,600

¹Includes data for Georgia, Indiana, Maine, North Carolina, and Texas.

²Data may not add to totals shown because of independent rounding.

valued at \$20 million. Volcanic cinder and scoria were produced by 32 companies from 37 operations in 11 States. Leading States, in decreasing order of volume were, California, Arizona, Oregon, and Wyoming; their combined production accounted for 79% of the total U.S. output. Leading producers, in decreasing order of tonnage, were Martin Marietta, the U.S. Forest Service, and Superlite Block Co.; their combined production accounted for 44% of U.S. output.

Miscellaneous Stone

Output of other kinds of crushed stone increased 48% to 28 million tons valued at \$120 million. Miscellaneous stone was produced by 91 companies from 104 quarries in 27 States. Leading States, in decreasing order of volume, were Pennsylvania, Florida, and Maryland; their combined production accounted for 55% of the total U.S. output. Leading producers, in decreasing order of tonnage, were Vecellio & Grogan Inc., Rockville Crushed Stone, and Lone Star Industries.

CONSUMPTION AND USES

Crushed stone production reported to the Bureau of Mines is material that was either sold or used by producers. Stockpiled production is not reported. Therefore, the "sold or used" tonnage represents the amount of production released for domestic consumption or export in a given year. Because some of the crushed stone producers did not report a breakdown by end use, their total production is reported under

W Withheld to avoid disclosing company proprietary data; included with "Other."

¹Includes data for Hawaii and Washington.

²Includes data for Hawaii and North Carolina.

³Data may not add to totals shown because of independent rounding.

"Other unspecified uses, actual." The estimated production of nonrespondents is reported under "Other unspecified uses, estimated."

In 1989, U.S. consumption of crushed stone was 1.2 billion tons valued at \$5.3 billion, a 2.8% decrease from the estimated consumption of 1988 and a slight increase over the reported consumption of 1987. About 52% of this tonnage was used as construction aggregates, mostly for highway and road construction and maintenance; 9% for cement and lime

manufacturing; 2% for agricultural purposes; 1% for other chemical and metallurgical purposes; 1% for special uses and products; and 35% for other unspecified uses.

Limestone

Of the 807 million tons of crushed limestone consumed, 48% was used as construction aggregates, 13% for cement and lime manufacturing, 2% for agricultural purposes, 1% for chemical and

metallurgical uses, 1% for special uses and products, and 34% as other unspecified uses. Any analysis of limestone uses should take into account the 278 million tons of limestone included under "Other unspecified uses, actual and estimated." It is recommended that in any such review, the quantities and values included in "Other unspecified uses" be distributed among the reported uses being analyzed, based on the following calculation: The percentage for each reported use should be calculated as a percentage of the U.S. total minus "Other unspecified uses"; the resulting percentages then should be applied to "Other unspecified uses" and the resulting quantities and values added to the reported uses published in the table.

Dolomite

Of the 49 million tons of crushed dolomite consumed, 51% was used as construction aggregates, 6% as agricultural lime, 3% for dead-burned dolomite, 1% as flux stone, 1% for lime manufacturing, and 33% for other unspecified uses. An additional undefined amount of dolomite consumed in a variety of uses is reported with the limestone.

Marble

Of the 12 million tons of crushed marble consumed, 8% was used as fillers and extenders, 7% for miscellaneous uses, and 85% was used for other unspecified uses.

Calcareous Marl

Of the 5 million tons of marl consumed, 93% was used for cement manufacturing, 2% as road base material, and 5% for other unspecified uses.

Shell

Of the 6.9 million tons of crushed shell consumed, 39% was used as construction aggregates and 61% for other unspecified uses.

Granite

Of the 168 million tons of crushed granite consumed, 71% was used as construction aggregates, of which 5% was for railroad ballast, and 28% was used for other unspecified uses.

Traprock

Of the 99 million tons of crushed traprock consumed, 57% was used as construction aggregates and 41% was used for other unspecified uses.

TABLE 13
CRUSHED STONE SOLD OR USED BY PRODUCERS IN THE
UNITED STATES IN 1989, BY USE
(Thousand short tons and thousand dollars)

Use	Quantity	Value
Coarse aggregate (+ 1½ inch):		
Macadam	9,797	39,575
Riprap and jetty stone	21,817	111,406
Filter stone	9,111	38,744
Other coarse aggregate	1,964	7,525
Coarse aggregate, graded:		
Concrete aggregate, coarse	113,871	534,709
Bituminous aggregate, coarse	72,731	346,788
Bituminous surface-treatment aggregate	22,155	106,053
Railroad ballast	18,015	78,129
Other graded coarse aggregate	4,320	22,605
Fine aggregate (-3/8 inch):		
Stone sand, concrete	19,932	94,748
Stone sand, bituminous mix or seal	19,466	80,851
Screening, undesignated	32,027	133,535
Other fine aggregate	1,742	8,955
Coarse and fine aggregates:		
Graded road base or subbase	178,900	682,472
Unpaved road surfacing	28,517	109,901
Terrazzo and exposed aggregate	3,637	22,629
Crusher run or fill or waste	52,079	201,329
Other coarse and fine aggregates	747	2,537
Other construction materials ¹	21,033	97,561
Agricultural:		
Agricultural limestone	18,934	89,283
Poultry grit and mineral food	3,191	25,682
Other agricultural uses	910	4,834
Chemical and metallurgical:		
Cement manufacture	97,432	278,381
Lime manufacture	16,168	85,051
Dead-burned dolomite manufacture	1,366	7,441
Flux stone	5,604	23,743
Chemical stone	458	1,911
Glass manufacture	302	3,605
Sulfur oxide removal	1,159	4,536
Special:		
Mine dusting or acid water treatment	715	8,077
Asphalt fillers or extenders	1,870	13,396
Whiting or whiting substitute	1,642	69,752
Other fillers or extenders	4,525	81,869
Roofing granules	3,084	14,063
Other miscellaneous uses:		
Waste material	2,017	7,039
Other uses not listed ²	2,030	15,929
Unspecified:		
Actual	333,085	1,482,690
Estimated	87,081	388,431
Total³	1,213,400	5,325,800

¹Includes stone used in drain fields.

²Includes stone used in lightweight aggregate (slate), abrasives, building products, paper manufacture, and pipe bedding.

³Data may not add to totals shown because of independent rounding.

Sandstone and Quartzite

Of the 32 million tons of combined crushed sandstone and quartzite consumed, 64% was used as construction aggregates, of which 5% was for railroad ballast; 1% for cement manufacturing; and 31% for other unspecified uses.

Slate

Of the 2 million tons of crushed slate consumed, 74% was used for a variety of unspecified industrial applications and 26% was used as construction aggregates.

Volcanic Cinder and Scoria

Of the 3.6 million tons of volcanic cinder and scoria consumed, 50% was used as construction aggregates, mainly for road construction and maintenance, and 47% was used for other unspecified uses.

Miscellaneous Stone

Of the 42 million tons of miscellaneous crushed stone consumed, 46% was used as construction aggregates and 40% for other unspecified uses.

TRANSPORTATION

Of the total crushed stone produced, 54% was transported by truck from the processing plant or quarry to the first point of sale or use, 4% was transported by rail, and 3% by waterway. For about 39% of the total crushed stone produced in 1989, no means of transportation was reported by the producers, indicating that at least part of that production was used on-site.

PRICES

Compared with those of 1987, the 1989 average unit prices of crushed stone showed a slight increase of only 0.5% to \$4.39. By kind of stone, the average unit prices showed increases of 36% for volcanic cinder, 23% for marl, 8% for traprock, 4% each for dolomite and miscellaneous stone, 3% for granite, 2% for limestone, and 1% each for marble and slate. At the same time, the average unit prices decreased by 17% for shell, 4% for sandstone and quartzite, and 2% for limestone.

As a result of rising costs of labor, energy, and mining and processing equipment, the average unit value of crushed stone increased from \$1.58 per ton, f.o.b.

⁷Data may not add to totals shown because of independent rounding.

plant, in 1970 to \$4.39 in 1989. However, the unit value in constant 1982 dollars fluctuated between \$3.48 and \$3.91 per ton for the same period. Increased productivity achieved through increased use of automation and more efficient equipment was mainly responsible for these trends. Despite having one of the lowest average per ton values of all mineral commodities, the constant dollar price of crushed stone has changed relatively little over the past 20 years. Increased operating costs have been mostly offset by automation and other means of increasing operating efficiency. Constant dollar prices are expected to rise in the future because of increased energy costs and more stringent environmental and land use regulations.

FOREIGN TRADE

The widespread distribution of domestic crushed stone deposits and the high cost of transportation limits foreign trade mostly to local transactions across international boundaries. U.S. imports and exports are small, representing less than 0.5% of the domestic consumption. However, shipments of crushed stone by water from Canada and Mexico are increasing.

Exports

Exports of crushed stone increased 7.1% to 3.9 million tons compared with 1988, while value decreased 23.2% to \$23.3 million. About 96% of the exported crushed stone was limestone, Canada being the major destination with 98% of the total.

Imports

Imports of crushed stone increased 34.2% to 4.4 million tons compared with 1988, while the value increased 241% to \$35.6 million. About 78% of this tonnage was limestone, 58% of which came from Canada, 23% from the Dominican Republic, and 16% from the Bahamas.

Imports of natural calcium carbonate fines showed a drastic decrease, most probably owing to some reporting errors to the U.S. Bureau of the Census that could not be identified by the time this chapter was published. About 88% of processed calcium carbonate was imported from France.

Shipments of crushed stone from the Bahamas, Canada, Nova Scotia, and Mexico, into the United States continued in 1989. The imported crushed stone, used

mostly as construction aggregates, was distributed in Florida, Louisiana, New York, North Carolina, South Carolina, and Texas. This trend is expected to continue and the volume of imports to increase.

WORLD REVIEW

Canada

The 1988 production of stone in Canada was 122 million metric tons, a decrease of 2.3% over the 1987 total, valued at \$642 million. About 98% of this output was crushed stone. The Province of Ontario continued to be the largest producer of stone, with 58.5 million tons valued at \$313 million, followed by Quebec with 46.5 million tons valued at \$235 million. The two Provinces accounted for 86% of the total stone production. Preliminary estimates for 1989 stone production indicate a decrease of 2.3% to 122 million tons, but an increase in value to \$633 million. The Provinces of Ontario and Quebec continued to be the largest producers of stone with about 86% of the total output.

United Kingdom

The 1988 production of crushed stone in the United Kingdom (Northern Ireland not included) was 184 million metric tons, of which 161 million tons was for construction purposes, as reported by the British Aggregate Construction Materials Industries Association (BACMI). About 67% of this output was limestone and dolomite. South West was the largest producing region with 40.5 million tons, followed by East Midlands with 40.4 million tons and Wales with 25 million tons. Preliminary estimates made by BACMI indicate that a total of 195 million metric tons of crushed stone was

produced in 1989, a 6% increase compared with that of 1988, of which 170 million tons was used for construction purposes.

CURRENT RESEARCH

The 5-year \$150 million Strategic Highway Research Program (SHRP) reached its midpoint in 1989. Management of ongoing research, rather than the initiation of contracts, became the focus of SHRP's activities. SHRP's mission is to produce usable research results targeted toward technical areas where there is potential for

²Data do not add to total shown because of independent rounding.

rapid progress that could yield significant cost savings. The four areas of research are asphalt, concrete and structures, highway operations, and long-term pavement performance.

SHRP's main objective in asphalt research is to produce new performance-based specifications for asphalt binders.⁴ A wide range of advanced materials characterization techniques such as nuclear magnetic resonance and spectroscopy and computer-aided tomography (CAT) scans are being tested. The CAT scan research conducted at the University of Southern California at Los Angeles could provide a powerful new nondestructive test technique for diagnosing problems in asphalt pavements.

The concrete and structure program includes research in the area of improved concrete materials and corrosion of concrete structures. Under this program, a rapid laboratory test that will determine aggregate reactivity in less than 2 weeks has been developed. Current tests require 9 months to 3 years.

About \$20 billion is spent on highway maintenance in the United States each year, representing about one-third of total highway spending. This expenditure is growing at a rate of about 9% annually. More cost-effective maintenance methods, equipment, and materials are badly needed. SHRP is addressing this problem through its highway operations program by conducting a series of nationwide field

performance tests. The Texas A&M Research Foundation has designed an experiment to compare the cost-effectiveness of six preventive maintenance methods to be tested under various climate and traffic conditions. The performance of the maintenance methods will be monitored over 5 years at specially constructed side-by-side test sections on inservice roads throughout the country.

Snow and ice control is another area of interest for the highway operations program. The Department of Mechanical Engineering of the University of Wyoming is using computer simulation, model studies, and full-scale prototyping to design and test more efficient and flexible snow and ice control equipment and methods.

The University of Washington is developing a rapid laboratory test method for identifying aggregates that are susceptible to freeze-thaw damage. Concrete bridge corrosion is a major problem affecting a large number of structures around the country. The evaluation of the effectiveness of electrochemical chloride removal technology, an experimental but promising technique for extracting chloride from concrete using electrical current, is advancing under SHRP's concrete and structures program.

SHRP's long-term pavement performance (LTPP) program is a first-ever major effort to measure pavement performance in different climate and soil conditions at about 1,000 inservice test sections in all 50 States and in Canada. The LTPP program has been planned to run for 20 years, with SHRP being funded to conduct the first 5 years of data-gathering and analysis. The data collected as part of the SHRP program are expected to provide sufficient information to refine pavement design that will significantly improve the performance of new pavements.

The Third International Symposium on Unbound Aggregates in Roads was held on April 11-13, 1989, at the University of Nottingham, United Kingdom.⁵ This symposium was dedicated entirely to the utilization and characterization of unbound aggregate bases.

Some of the topics discussed at this year's symposium were: the in situ testing of compacted pavement layers; innovative methods for placing unbound aggregates to obtain a more uniform end product with a leveled surface; and the use of vibrating hammers or computerized vibratory rollers for compacting both unbound base material and asphalt concrete.

FIGURE 2

TOTAL PRODUCTION AND UNIT VALUE IN ACTUAL AND 1970 CONSTANT DOLLARS OF CRUSHED STONE IN THE UNITED STATES FOR 1970-89

In response to growing concern over rutting of asphalt concrete pavements, in July 1987, the American Association of State Highway and Transportation Officials (AASHTO) organized a joint task force of Federal, State, and industry representatives to study the problem. Participating agencies included AASHTO, the National Asphalt Pavement Association (NAPA), the Asphalt Institute, the National Stone Association (NSA), the National Aggregates Association (NAA), the Construction Industry Manufacturers Association (CIMA), the National Cooperative Highway Research Program (NCHRP), SHRP, and the Federal Highway Administration (FHWA).⁶ About 70% of all paved public roads and streets and 57% of the interstate highways are surfaced with flexible pavements (asphalt). Asphalt concrete rutting is a longitudinal deformation that develops under the action of channelized loads. It occurs because of consolidation or shear failure in the subgrade or pavement structure. Aggregates make up about 95% of the weight of asphalt concrete and provide most of the pavement's load carrying capacity. The quality and physical properties of aggregates, especially gradation, are critical in preventing rutting and in improving pavement performance in general. One way to make a mix more resistant to rutting is to increase friction between the particles by using more crushed aggregates. FHWA Technical Advisory T5040.27 recommends that natural sands be limited to 15% to 20% of the total weight of aggregates for high-volume roads. Another gradation problem that causes rutting is an excessive amount of minus No. 200 material in the mix. FHWA's technical advisory recommends that mixes be designed with dust to asphalt ratio between 0.6 and 1.2. The task force final report was published in February 1989. It concludes that most of the causes of rutting are known, and the solutions to the rutting problem are now available. The report also indicates that FHWA Technical Advisory T5040.27, "Asphalt Concrete Mix Design and Field Control," is a state-of-the-art technical document.

About 240,000 highway bridges in the United States are currently classified as "structurally deficient," mainly because of bridge-deck deterioration. Reinforced concrete bridge decks and piers are particularly vulnerable to salt penetration. The salt affecting the reinforced concrete structures comes from deicing salts as well as from seawater. The combination of chloride ions

from the salt, reinforcing bars, and moisture leads to an electrochemical process that causes the rebars to corrode and expand in size. As the bars expand, they exert internal pressure on the concrete, which splits along the rebars and leads to rapid deterioration of the concrete. The deterioration process of reinforced concrete can be significantly reduced through cathodic protection that reverses the flow of electrical current developed when corrosion occurs. Several anode systems for cathodic protection of bridges now available were evaluated in two reports published by FHWA.⁷

OUTLOOK

The demand for crushed stone in 1990 is expected to be about 1.2 billion tons, at about the same level as in 1989. The weakness in the nonresidential and multifamily residential building construction markets is expected to be compensated by a stronger demand in road construction and repair work. Gradual increases in demand for construction aggregates are anticipated after 1990, based on increased volume of work on the infrastructure. It is

estimated that the demand for crushed stone will reach 1.4 billion tons in 1995. The projected increases will be influenced by construction activity primarily in the public construction sector.

The release of the Department of Transportation comprehensive report on national transportation policy⁸ indicates that a significant increase in the volume of work on the infrastructure should be expected in the next 5 to 10 years. The value of public construction work as part of the gross national product has declined constantly from about 3% in the 1950's and 1960's to less than 2% in the 1980's. If this trend begins to reverse in the 1990's, a significant increase in spending for public construction work could be expected that will dramatically alter the above forecasts.

Crushed stone f.o.b. prices are not expected to increase significantly, even if the demand for construction aggregates will rise over the forecasts. However, the delivered prices of crushed stone are expected to increase, especially in and near metropolitan areas, mainly because more aggregates are transported from distant sources.

BACKGROUND

Crushed stone is a term applied to rock that has been broken and/or crushed after quarrying. It is a low-value product characterized by its "place value," a term that describes the importance of the location of the geologic deposit in reference to the market. Stone in its multitude of forms represents a very significant part of the Earth's crust. As one of the most accessible natural resources, it has been used since the earliest days of our civilization. First used as a tool or weapon, it was then used as a construction material, and later, in its crushed form, as one of the basic raw materials for a wide variety of uses, ranging from agriculture and chemicals to complex industrial processes.

The beginnings of the crushed stone industry are difficult to trace, but it is known that the Greeks, and later the Romans, the first great road builders, used limestone and lime extensively.⁹ The modern crushed stone industry began in England in about 1815 and expanded rapidly after the invention of the mechanical rock crusher in 1858.¹⁰

In the United States, railroad ballast was the principal market for the crushed stone

industry during the last half of the 19th century. Passage of the Federal Aid Highway Act in 1916 acknowledged the national importance of highways, and subsequent highway construction created a new and significantly larger market. The crushed stone industry grew tremendously, especially in the second half of this century. Production increased from 130 million tons in 1928 to a high of 1.25 billion tons in 1988, mainly owing to rapidly increasing demand for highway, railroad, and other construction work. Today the volume of crushed and broken stone produced is greater than that of any other mineral mined in the United States. The United States is, in general, self-sufficient in crushed stone, producing enough to meet most of the domestic needs. Small quantities of crushed stone, used mostly as construction aggregates, are being imported by water from the Bahamas, Canada, Mexico, and to a smaller extent Scotland, United Kingdom.

Crushed stone is used mostly for construction purposes, mainly as aggregate with or without a binder. Road base or road surfacing material, macadam, riprap, and railroad ballast are the major uses without a binder. Aggregate for cement and bituminous concrete in highway and road construction and repair and in residential and nonresidential constructions are the major uses for aggregates with a binder.

Other uses include cement and lime manufacture, agriculture, metallurgical flux, and fillers and extenders.

Although crushed stone resources are widespread and in adequate supply in most parts of the United States, local shortages exist. Land use conflicts and environmental problems associated with rapid urban expansion are major factors contributing to these shortages. Demand pressures, land use regulations, and the cost of meeting environmental and reclamation requirements are factors that will cause a rising price trend. Larger operations with more efficient equipment, more automation, and better planning and design will be the trend of the industry in the future.

Definitions, Grades, and Specifications

Crushed and broken stone is a term applied to rock that has been broken and/or crushed into smaller, irregular fragments, or ground to specified particle sizes. Crushed stone is also classified by kind of stone, including limestone, dolomite, marble, shell, granite, traprock, sandstone, quartzite, slate, volcanic cinder and scoria, and miscellaneous stone. The terminology used by the crushed stone industry is not always consistent with mineralogical definitions. Limestone and dolomite are rocks composed, respectively, of the minerals

calcite, CaCO₃, and dolomite, CaMg (CO₃)₂; however, they are usually called limestone by the industry, and intermediate varieties are seldom distinguished. Some deposits of limestone consist chiefly of the mineral aragonite, which has the same composition as calcite, but has a different crystal structure. Marble may include any calcareous rock that will accept a polish. Marl is calcitic and contains varying amounts of shale or clay. Granite includes the coarser grained igneous rocks such as true granite and syenite. Gneisses, although metamorphic rocks, are usually included with granite. Quartzite is a well-cemented sandstone that is indurated to the extent that, when fractured, it breaks across the grain. Traprock includes all dense, dark, and fine-grained igneous rocks such as basalt, diabase, and gabbro.

Crushed stone in its different rock types and particle sizes is used in a wide variety of applications in many industries, including construction, chemical, metallurgical, and agriculture. For the purpose of collecting and disseminating production information, the Bureau of Mines generally accepts the rock type classification and the

principal end uses and their definitions as reported by the crushed stone producers.

Specifications for crushed stone are numerous because of the large number and the variety of uses, the diversity of stone types, and the variations in physical and chemical requirements for different uses. Various national specifications and tests exist for crushed stone products, but the most active organizations in preparing and reviewing them are the American Society for Testing and Materials (ASTM)¹¹ and AASTO. For construction aggregates, these are regarded by industry as guide or reference specifications. State specifications are often much more stringent and

vary from State to State. The most common specifications and tests relate primarily to gradation, but soundness, shape, abrasion resistance, porosity, chemical compatibility, and content of soft particles are also important.¹² Specifications for construction aggregates are written by commercial users, government agencies including Federal, State, county, and city construction and highway departments, and the ASTM. Problems arise for the producers of construction aggregates when their product is sold or used in several different cities, counties, or States, many of which may have different specifications. Some progress is being made toward the

standardization of aggregate sizes for similar requirements. A need exists for a more active interchange of data and experience among aggregate consumers and producers.

Specifications for limestone used in portland cement manufacture require a content of more than 75% calcium carbonate (CaCO_3) and less than 3% magnesium carbonate (MgCO_3). For white portland cement, the iron content of the raw materials should be very low, less than 0.01%. Because raw materials are finely ground for processing, chert nodules or coarse quartz grains are undesirable. Limestone for lime manufacture should contain more than 90% calcium carbonate, often more than 97% or 98%, less than 5% magnesium carbonate, and less than 3% of other impurities. For lime produced in vertical kilns, 5- to 8-inch stone is recommended, while in rotary kilns 3/8- to 2½-inch stone may be used. Limestone and dolomite should be sufficiently hard so as not to decrepitate when heated. High-magnesium lime made from dolomite should contain more than 40% magnesium carbonate.

Specifications for the use of limestone or dolomite as fluxstone vary with the pyrometallurgical process, the kind of ore processed, and the final use of the slag; silica content should not exceed 2% to 5%, magnesia content should be less than 4% to 15%, and sulfur less than 0.1%. Size specifications also vary and include ranges from 1 to 4 inches, 2 to 4 inches, and 3 to 6 inches. The limestone or dolomite used for glass making should contain at least 98% CaCO_3 or MgCO_3 , respectively, and less than 0.05% to 0.02% iron oxide. Size specifications vary with the manufacturer and the kind of glass being produced, but uniformity is a major requirement; usually 100% of the material should pass Number 10 sieve (2 millimeters) and 96% to 100% should be retained on a Number 100 sieve (0.15 millimeters).

Requirements for agricultural limestone are not very rigid and depend on the specific use: as direct application to soil, as filler and conditioner for fertilizers, in animal mineral feeds, or as poultry grit. In all of these applications, CaCO_3 or MgCO_3 equivalent or content is of major significance. Many individualized specifications exist for a wide variety of industrial applications, mostly pulverized limestone for rock dusting, or as asphalt, plastic, rubber, paper, or paint fillers or extenders.¹³

Products for Trade and Industry

The ultimate use of crushed stone determines the specification for particle size and gradation, shape, rock type, and chemical composition. Crushed stone can be used without any binder, for a variety of construction or industrial applications, or it may be mixed with a matrix binding material such as bituminous or portland cement. The most common use of crushed stone for construction purposes is as aggregate without a binder, including road base or road surfacing material, macadam, riprap, railroad ballast, filter stone, etc. The second largest use of crushed stone is as aggregate for cement and bituminous concrete in a variety of forms and applications in residential and nonresidential construction, highway and road construction and repair, airports, dams, sewers, and foundations. Sized crushed stone is used to make asphaltic concrete aggregate and road bases. Broken surfaces adhere to the hot asphaltic mixture better than rounded surfaces do and provide interlocking surfaces that tend to strengthen the asphaltic concrete. Broken particles pack better and tend to move less under load than rounded particles do and, therefore, make better road

bases for highway and road construction. This is essential because bases and asphaltic concrete tend to flow when placed under great or long duration stresses. Other uses include limestone for cement and lime manufacturing and as agricultural limestone used as direct application to soil, as filler and conditioner for fertilizers, in animal mineral feeds, or as poultry grit. Smaller amounts of crushed stone are used for a wide variety of applications ranging from metallurgical fluxing of antimony, copper, iron, lead, and zinc to the manufacture of glass, ceramic pottery, paper, and as fillers and extenders in asphalt, paint, rubber, and plastics.

A growing amount of limestone is being used in the removal of sulfur oxides from stack gases, primarily from coal-burning electric generating stations, and for mine dusting to enhance mine safety by reducing the explosion risk of highly combustible coal dust.

Industry Structure

Because of the low unit value, crushed stone is usually produced near the point of use; therefore, the industry is concentrated mostly in or nearby large, rapidly expan-

ding urban areas. Crushed stone is produced in every State except Delaware, with more than 73% of the national total coming from two major geographic regions, the South and Midwest. The largest quarries tend to be concentrated in the States with the largest population and largest production of crushed stone.¹⁴

Although limestone is produced in all States except Delaware, Louisiana, New Hampshire, and North Dakota, the major producing States are east of the Rockies. Crushed marble is produced mostly in the eastern part of the United States in Alabama, Georgia, and Pennsylvania. Crushed granite is produced primarily in Appalachia, with Georgia, North Carolina, South Carolina, and Virginia being the largest producing States. Crushed traprock is produced mainly in the northeast and the Pacific Coast States, with California, Connecticut, Massachusetts, New Jersey, Oregon, and Washington the largest producing States. Crushed sandstone and quartzite are produced in 31 States led by Arkansas, California, and Pennsylvania. Most crushed slate is produced in the Eastern part of the United States, mainly in Arkansas, Georgia, and Virginia. Shell, primarily oyster residue, is produced by dredging along the gulf coast. Volcanic cinder is produced in the West, mainly in Arizona, California, and New Mexico.

On the basis of tonnage, the crushed stone industry is the largest nonfuel mineral industry in the United States. The industry is widespread and has a large variation in operation size, kind of stone, and size of material produced. The individual companies range in size from small independent producers with 1 quarry to large diversified corporations with 50 or more crushed stone operations.

In 1989, 1,716 companies produced crushed stone from about 3,416 active quarries. Individual crushed stone quarries range in size from those producing between 1 and 11 million tons annually to those reporting less than 50,000 tons per year. However, most of the tonnage comes from large operations. In 1989, for example, 86 operations each reporting production of more than 2 million tons per year represented only 2.3% of the total number of operations, but accounted for 22% of total crushed stone production. The large operations are owned or operated by a small number of companies. In 1989, the combined production of the top 10 producers operating 477 quarries accounted for 27.8% of the total output of crushed

stone in the United States. The 10 leading producers were Vulcan Materials Co., Beazer USA Inc., Martin Marietta Aggregates, Tarmac America Inc., Dravo Corp., General Dynamics Corp., The Rogers Group Inc., Lone Star Industries Inc., Genstar Stone Products Inc., and Florida Rock Industries Inc.

In the past several years, significant changes in the structure of the crushed stone industry have occurred, caused primarily by mergers and acquisitions, some of them associated with the influx of foreign capital. Two of the top five crushed stone producing companies in 1989 are subsidiaries of foreign companies.

The United States is the largest producer of crushed and broken stone among the market economy countries. Other major producing countries are Australia, Canada, the Federal Republic of Germany, France, Japan, and the United Kingdom. Some information about the production of crushed stone in foreign countries may be found in the Bureau of Mines Minerals Yearbook Volume III, Area Reports: International. For nonreporting countries, estimates of crushed stone outputs can be based on indirect sources such as the level of cement consumption.

Geology-Resources

Bedrock deposits are classified on the basis of their origin into sedimentary, igneous, and metamorphic rocks. Sedimentary rocks were produced from the consolidation of loose sediments through chemical or mechanical sedimentation. Limestone, which is primarily calcium carbonate (CaCO_3), and dolomite, which is calcium-magnesium carbonate ($\text{CaMg}(\text{CO}_3)_2$), are the most common sedimentary rocks produced through chemical or biochemical sedimentation. Limestone and dolomite formations are widespread in the United States, with most of the deposits being of Paleozoic age, with a few of Mesozoic and Tertiary age. Most States have adequate reserves for use in construction and other applications that do not require chemically pure stone.¹⁴ High-calcium limestone and high-purity dolomite make up only a small fraction of all limestone and dolomite formations, and they occur in restricted areas, mostly in the eastern part of the United States, with some formations in the western States as well.¹⁵ High-purity dolomite deposits are more limited in occurrence than the high-calcium limestone. Of the clastic sedimentary rocks that are produced

through mechanical sedimentation, only sandstones, rocks consisting predominantly of cemented sand-size particles, are, to a limited extent, used as crushed stone.

Igneous rocks, rocks that solidify from molten volcanic magma, are classified as intrusive and extrusive rocks. Intrusive or plutonic rocks are those that were formed deep beneath the ground surface, are coarse grained, and include granite, diorite, and gabbro as rock types. Extrusive or volcanic rocks are igneous rocks that were formed from molten volcanic magma at the Earth's surface, are fine grained, and include andesite, rhyolite, and basalt. Plutonic and volcanic rocks are further subdivided on the basis of mineralogy in light-colored igneous rocks with high-silica content that include granite, diorite, rhyolite, and andesite, and dark-colored igneous rocks low in silica content that include gabbro, diabase, and basalt, commonly called traprock. Granite and traprock are the most common igneous rock-types used as crushed stone. Granite occurs primarily in the eastern part of the United States from Maine to Georgia, along the Appalachian Range where major producing States are located. It also occurs in Arkansas, Minnesota, Missouri, Oklahoma, Texas, and Wisconsin and in all Western States except Utah. Most of the traprock occurs in California, Hawaii, Idaho, Oregon, and Washington in the West, in Connecticut, Maryland, Massachusetts, New Jersey, New York, North Carolina, Pennsylvania, and Virginia in the East, and to a smaller extent in Minnesota and Texas.

Metamorphic rocks are formed from preexisting rocks through mineralogical, chemical, and structural changes produced by high heat and pressure. The metamorphic rocks include gneisses, marbles, quartzite, slates, and schists. Marble, quartzite, and slate are the major types of metamorphic rocks used to some extent as crushed stone. Marble occurs primarily in Alabama, Georgia, New York, Vermont, and Virginia in the East and in California and Texas in the West.

A comprehensive report showing geologic occurrences of potential sources of crushed stone and sand and gravel of the conterminous United States for use as natural aggregates was published by the U.S. Geological Survey.¹⁶

On the basis of geologic evidence, stone resources of the United States and the world are sufficient to meet demands, although not always precisely at the locations where needed. Reserves, which are

measurable amounts of crushed stone that can be produced profitably with current technology under existing economic and political conditions, are controlled mostly by land use and/or environmental constraints. The actual volume of stone available is so vast as to preclude the necessity of measurement on a large scale. The local shortages that occasionally exist are caused less by a lack of stone than by urban encroachment or zoning regulations that force closure of operating quarries or prevent the development of new ones.

Technology

Major technological developments have been instrumental in maintaining adequate production at relatively stable real costs in the crushed stone industry. Equipment manufacturers usually conduct most of the research related to improvements in the mining and processing of crushed stone operations. Larger, more efficient equipment is being developed and improved constantly. The use of computerized control systems in plant operation and quality control has increased significantly in recent years. Automatic controls, along with monitoring by closed-circuit television coordinated with automated counting and recording and radio communications systems, have been installed in many of the larger and newer operations. Automated plants have significantly improved operating efficiency and produce the optimal product mixture to fit market requirements at lower cost.

As part of the national drive to reduce air pollution, significant progress is being made toward the desulfurization of stack gases resulting from coal-burning electric generating stations and some industrial installations.¹⁷ Limestone and lime are used as chemically reactive agents in most of the dry or wet scrubbing processes as well as in the treatment of acidified waters, specifically lakes and streams.

Exploration.—A large number of geologic formations that have economic potential as a source of crushed stone have been mapped and described in the literature over the years. Consequently, detailed exploration and development work for any new crushed stone operation will most probably be done on one of these formations. However, in the event that a new stone deposit is discovered, more exploration and evaluation work would be required before development. Preliminary examination can

establish the extent and nature of the deposit. This is followed by a detailed exploration program aimed at obtaining reasonably accurate information about the quality of the available material, including the kind of stone, its chemical composition and degree of cementation, and the degree of uniformity throughout the deposit. Also, the nature and the amount of waste material and the economic feasibility of its removal, processing, and marketing must be studied. In most cases, an environmental impact study is required by local or State agencies.

If the raw material cost and quality are proven to be adequate and sufficient reserves are demonstrated, the development stage of the operation can be started. Economic feasibility and marketing studies include analysis of the availability of power and water supply; mining and processing costs and requirements; the condition of nearby roads and highways and the proximity of rail haulage; the cost of compliance with local, State, and Federal regulations; and the proximity and density of local population, as well as its attitude toward such a project.

Mining.—Most crushed and broken stone is mined from open quarries; however, in many areas, factors favoring large-scale production by underground mining are becoming more frequent and more prominent.

Surface mining equipment varies with the kind of stone mined, the production capacity needed, the size and shape of the deposit, estimated life of the operation, location of the deposit with respect to urban centers, and other important factors. Ordinarily, drilling is done with tricone rotary drills, long-hole percussion drills, and churn drills. Blasting in smaller operations may still be done with dynamite, but in most medium- to large-size operations ammonium nitrate-fuel oil mixtures (AN-FO), which are much lower in cost, are used.

Underground operations are becoming more common, especially for limestone mining in the central and eastern parts of the United States, as the advantages of such operations are increasingly recognized by the producers. By operating underground, a variety of problems usually connected with surface mining such as environmental impacts and community acceptance are significantly reduced. Underground room-and-pillar mines can be operated on a year-round basis, do not require extensive removal of overburden, and produce a

minimum of environmental disturbance. The need for less surface space is also an important factor in areas of high land costs. Subsidence has not been a problem in areas mined, and the conventional practice has been to leave 12% to 15% of pillar areas and 6 to 8 feet of stone in the mined roof. A specific advantage of underground quarries is the creation of valuable storage facilities. In many cases, the value of the sale or rental of the storage space may exceed the value of the stone mined. Thus, the incentives for producing stone from underground mines can be enhanced by the economic advantages of subsequent use of the excavated areas.

Loading and hauling equipment has grown larger as increased demand for stone has made higher production capacities necessary. Track-mounted equipment is still used extensively, but hydraulic, tire-mounted hauling equipment is predominant.

Processing.—Processing plants have become larger and more efficient, in part because of an increase in the use of computerized control systems. Programmable controllers and/or computers are viewed today as valuable tools that improve operating efficiency and product quality. Belt conveyors are being used extensively to haul material within the quarry because they provide continuous operation, low maintenance costs, low work force requirements, and reduced noise levels. Primary crushing is often done at or near the pit, usually by jaw or gyratory crushers, but impact and other special types of crushers are also used for nonabrasive stone or stone that tends to clog conventional crushers. The use of in-pit movable primary crushers is also increasing. For secondary crushing, a variety of comminution equipment is used, depending on plant size, rock type, and kind of material being produced. Cone crushers and gyratory crushers are the most common types used, but impact crushers, including hammer mills, and roll crushers are often used.

Screening is the single most important part of the processing cycle of crushed stone particles. A wide variety of screen types exists, and their selection is a function of the material processed as well as the final product required. Inclined vibratory screens are most commonly used in stationary installations, while horizontal screens are used extensively in portable plants. For screening large sizes of crushed stone, grizzly bars, rod decks, and heavy

punched steel or plastic plates are used; for smaller sizes, woven wire, welded wire cloth, rubber, or plastic screens are used.

Processed crushed stone is usually stored in open areas except for relatively small quantities that go to the load-out bins. In the more efficient plants, the crushed stone is transported from the storage piles on belt conveyors through tunnels installed under the piles, thus facilitating the blending of any desired mixture of sizes from different piles.

Recycling.—As the Nation moves into an age of increased environmental consciousness, recycling of old concrete and asphalt, used mostly in pavements, is increasing. Local scarcity or high cost of construction aggregates in some areas as well as waste disposal problems are making recycling more attractive economically. In some States, limited recycling, especially in road construction, is either encouraged or required by law. The best utilization for recycled cement concrete is as road base material, because the matrix of concrete cannot be converted back to cement, and also because of the lower strength of concrete compared with that of natural aggregates. Sound crushed concrete can make good coarse aggregate, but the fines produced in crushing the concrete have a higher absorption, are more friable, and will require a higher amount of asphalt in asphaltic concrete and a higher amount of mixing water in portland cement.¹⁸

The amount of asphalt roads recycled is significantly larger than that of concrete roads, mainly because asphalt can be rejuvenated with oil additives and used in pavements, significantly reducing the cost of the finished road. Experience has shown that about 35% of crushed asphalt pavement can be recycled into new asphalt mixtures. Proper testing under engineering supervision in all construction projects using recycled materials as aggregates should be performed to ensure that the technical specifications are met.

Byproducts and Coproducts

Clay of good quality is sometimes encountered in limestone overburden and is mined as a coproduct. Gypsum is often encountered beneath beds of limestone and is mined as a coproduct. Amphibolite rock often occurs as formations paralleling spodumene-bearing pegmatitic dikes and is mined concurrently with these, notably in North Carolina. This coproduct of lithium

mining is marketed primarily as roadstone. Stone is also mined in conjunction with many metallic ores and nonmetallic minerals, but seldom does a market exist for it.

Economic Factors

Crushed stone is a high-volume, low-value commodity. The industry is highly competitive and is characterized by thousands of operations serving local or regional markets, largely because stone is an abundant mineral. Production costs are determined mainly by the cost of labor, equipment, energy, and water, in addition to the costs of compliance with environmental and safety regulations. These costs vary depending on geographic location, the nature of the deposit, and the number and type of products produced. But despite the rising cost of labor, energy, and land values, competition among stone producers and the nearness of supply areas to markets have kept the relative cost of crushed stone low. Constant dollar unit values have been quite steady during the past 20 years. Increased operating costs have been somewhat offset by automation and other means of increasing efficiency. The delivered price of the product, in addition to quality, is a particularly important element in any major transaction because of the low unit value of crushed stone, and therefore, producers that are closest to markets have a significant advantage. Sophisticated equipment backed by technical knowledge combined with solid sales expertise is becoming very important. For this reason, large companies are better able to compete in the crushed stone business, especially when there is a need for a wide variety of products. Smaller, less efficient operations become less economical as operating costs, as well as costs associated with meeting various Federal, State and local regulations, continue to increase. The only alternatives these producers have are to supply local markets with a limited number of products. The gradual trend toward larger operations has continued, mostly because the stone industry is capital intensive, and it is becoming less economical to operate small quarries. The viability of small operations is dependent on the demand in the local markets, mining costs, and the degree of processing required to supply the final product.

A 5% depletion allowance based on gross income is allowed for crushed stone used in construction, including aggregates.

The depletion allowance for chemical and metallurgical crushed stone is 14%.

Operating Factors

Many States, counties, and cities in the United States have zoning laws, and land within each governmental unit is usually zoned to indicate acceptable land uses. If mining is permitted in a zone and a crushed stone company owns or leases land within that zone, the company may apply for a use permit or its equivalent to begin an operation. If the parcels to be quarried are on lands under both city and county jurisdiction, permits usually must be obtained from each. An acceptable reclamation plan that meets the guidelines or regulations of the appropriate governmental agency must also be approved. Environmental concerns such as noise, dust, beautification, and storage of wastes must be accounted for in a manner satisfactory to the governmental entity involved. Wastewater discharge requirements must be planned for and met. If the deposit to be worked is on land controlled by a State or Federal agency, that agency's requirements must also be satisfied.

In most States, permits for crushed stone operations require an Environmental Impact Report (EIR) or Environment Impact Statement (EIS). A reclamation plan and a use permit application may also be required, with considerable overlap of subject matter with the EIS. A complete EIS may cover all the problem areas at once and facilitate acceptance.

Environmental Requirements.—Many of the environmental problems facing crushed stone producers arise because a great number of stone quarries and processing plants are located in suburban areas near the major crushed stone markets. Major environmental considerations that must be dealt with in mining and processing of crushed stone are emission of particulate matter into the air, discharge of processing water, noise abatement, and employee and public health and safety. Air pollution constitutes a major problem in processing plants, especially in the drying and packaging stages of fine particle products such as limestone used as fillers or extenders. Both wet and dry methods of dust control are used. The most important water pollutant is clay in suspension that results from washing and screening crushed stone. Because of the large quantities of water used to process stone and the need for compliance

with often stringent regulations, the treatment of discharge water by crushed stone producers is becoming a necessity that may require sophisticated and expensive processing methods. Significant progress has been made in reducing noise pollution both inside and outside of the quarries, including noise and vibration produced by blasting and movement of heavy trucks. Therefore, the industry must be concerned first about any practices that can affect the community environment. An effective effort must be made to reduce noise, air, and water pollution and to improve the overall appearance of the operating mine, processing plant, and transportation facilities. Second, the industry and community must recognize the time and costs required to protect the environment and the importance of agreeing on fair and realistic environmental standards. Because crushed stone is a local industry, the effect of supply deficiencies and cost of material will affect the local community first. Undue delay and unreasonably high cost can strongly affect the movement of crushed stone into the marketplace. Also, stringent controls by the local governments that prevent permits being issued to operators can have adverse economic effects on the communities around them. These conditions can make it difficult to assess the timing and even the possibility of plants going on-stream and can therefore affect the supply of crushed stone into the marketplace.

Although much progress is being made through premining planning, the crushed stone industry continues to have problems with environmental controls, land use conflicts, and reclamation practices. Many of these problems are acute because extraction areas and plants must be reasonably near to consumers who are largely in metropolitan areas.

Transportation.—Transportation is a major factor in the delivered price of construction crushed stone. The cost of moving crushed stone from the plant to the market often equals or exceeds the sales price of the product at the plant. Because of the high cost of transportation, crushed stone continues to be marketed locally. However, increasing land values combined with local environmental concerns are moving crushed stone quarries farther from the end-use locations, increasing prices of delivered material. Economies of scale, which might be realized if fewer, larger operations served larger marketing areas, would probably not offset the increased transportation costs.

Truck haulage is the main form of transportation used in the crushed stone industry. Many producers have their own truck fleet and deliver their own raw materials and products. A significant and increasing amount of crushed stone, however, is being hauled by independent truckers because of the cost of maintaining a truck fleet, particularly when the market is highly variable or down. Rail and water transportation combined account for about 7% to 10% of total crushed stone shipments.

DIMENSION STONE

By Harold A. Taylor, Jr.

Mr. Taylor, a physical scientist with the Branch of Industrial Minerals, has covered dimension stone for 9 years. Domestic survey data and trade data were prepared by Ms. Maria Arguelles, minerals data assistant, Branch of Data Collection and Coordination.

Production of dimension stone increased slightly to 1.21 million short tons valued at \$208 million. More than one-half of the dimension stone produced was granite. Limestone, marble, sandstone, and slate were also produced.

Exports of dimension stone increased 7% in value to \$35 million. The value of dimension stone imports for consumption increased slightly to \$525 million, equivalent to 252% of the value of domestic production.

DOMESTIC DATA COVERAGE

Domestic production data for dimension stone are developed by the Bureau of Mines from voluntary surveys of U.S. producers of rough and finished dimension stone. Of the 368 dimension stone operations surveyed, including those that were idle, 317, or 72%, responded, representing 96% of the total value sold or used by producers shown in table 1. Production data for nonrespondents were estimated using preliminary production reports, adjusted prior years production levels, and employment data.

PRODUCTION

Dimension stone was produced by 176 companies at 282 quarries in 34 States. Leading States, in order of tonnage, were Indiana, Georgia, and Vermont, together producing 38% of the Nation's total. Of the total production, 53% was granite, 27% was limestone, 11% was sandstone, 3% was slate, 2% was marble, and the remaining 4% was miscellaneous stone. Miscellaneous stone included argillite, schist, soapstone, and traprock (basalt). Leading producing companies in terms of tonnage were Cold Spring Granite Co., principally in California, Minnesota, South Dakota, and Texas;

^eEstimated. ^rRevised.

Rock of Ages Corp. in New Hampshire and Vermont; and Fletcher Granite Co., Inc. in Massachusetts and New Hampshire.

Granite

Dimension granite includes all coarse-grained igneous rocks. Production decreased slightly to 640,000 tons and increased 23% in value to \$130.2 million. Granite was produced by 62 companies at 111 quarries in 20 States. Georgia continued to be the leading State, producing 23% of the U.S. total, followed by Vermont and Massachusetts. These three States together produced more than 46% of the U.S. total. Cold Spring Granite, Rock of Ages, and Fletcher Granite were the leading producers and accounted for 42% of U.S. production by tonnage.

Fletcher Granite was acquired by Pioneer International Ltd. of Australia, an industrial and resource firm, in early 1989. Pioneer has been present in the domestic aggregate industry for some time and recently bought two more aggregate operations.

Georgia-Carolina Quarries Inc. recently opened a granite curbing plant near Elberton, GA. This is the second such plant in Georgia, the other one belonging to Frat-to Construction Inc.

Limestone

Dimension limestone includes bituminous, dolomitic, and siliceous limestones. It

was produced by 35 companies at 54 quarries in 13 states. Indiana, the leading State, was followed by Wisconsin and Texas. Leading producers were Indiana Limestone Co. Inc., Independent Limestone Co., and Victor Oolitic Stone Co. The top three companies accounted for 32% of U.S. output.

Marble

Dimension marble includes certain hard limestones, travertines, and any other calcareous stone that can be polished. Dimension marble was produced by 7 companies at 10 quarries in 7 States. Georgia, Vermont, and New Mexico tied with Alabama, in order of tonnage, were the four leading States, accounting for approximately 86% of U.S. output. Leading producers were Georgia Marble Co., Vermont Marble Co., and Rocky Mountain Stone Co. The top three companies accounted for 75% of U.S. output.

Sandstone

Dimension sandstone includes calcareous- and siliceous-cemented sandstones or conglomerates. Quartzite, which is also included, may be described as any siliceous-cemented sandstone. It was produced by 34 companies at 47 quarries in 15 States. The leading three States were, in order of volume, Ohio, New York, and Pennsylvania. Briar Hill Stone Co., Waller Bros.

Stone Co., and Standard Slag Co. were the leading producers and accounted for 41% of U.S. production. In addition to the quantities shown in table 5, dimension quartzite totaled 19,451 tons worth \$1,465,315.

Slate

Dimension slate was produced by 17 companies at 27 quarries in 5 States. The two leading States, Pennsylvania and Vermont in order of volume, accounted for 70% of U.S. output. The top three producers, A. Dally and Sons Inc., Le Sueur-Richmond Slate Co. Inc., and Williams and Sons Slate and Tile Inc., accounted for an estimated 50% of U.S. output by volume.

Miscellaneous Stone

Miscellaneous dimension stone, including traprock, was produced by eight companies from seven quarries in four States, and totaled 24,637 tons value at \$1,619,256.

CONSUMPTION AND USES

Dimension stone was marketed over wide areas. Industry stockpiles were not monitored, and production during 1989 was assumed to equal consumption.

Consumption of domestic dimension stone increased slightly to 1.21 million tons valued at \$208.3 million. Ashlars and partially squared, dressed pieces were 21% of the total value of consumption, followed by rough monumental stone with 15%; slabs and blocks for building and construction with 13%; dressed monumental stone with 12%; curbing with 12%; and other uses, 27%.

Of the total consumption of domestic granite, 24% by value was rough monumental stone, 18% was ashlar and partially squared pieces, and 18% was curbing.

Consumption of domestic limestone totaled 327,050 tons valued at \$42.2 million, of which 38% by value was slabs and blocks for building and construction, 27% was ashlar and partially squared pieces, and 25% was rough blocks for building and construction.

In a long-enduring trend before 1980, building dimension stone was replaced to a large extent by concrete, glass, brick, stainless steel, aluminum, porcelain-enameled steel, and plastics. These materials are used in the manufacture of modern mass-produced building modules

and precast building panels. The installed cost of many of these alternate materials has been lower than that of stone. Since 1980, stone has been increasingly preferred for more dignified buildings where its architectural adaptability, permanence, and prestige are of prime importance. A movement back to stone has occurred because of the greater impact of rising energy

costs on these substitutes. Resin-bonded stone panels made from stone chips are becoming an important substitute for dimension stone.

Slate has to meet competition from many sources. As a roofing material, alternates such as sheet metal, wood shingles, asbestos-cement shingles, and tile are available. For blackboards, it competes

with colored glass, porcelain-enameled steel, and special painted surfaces.

PRICES

The average price for dimension stone increased to \$173 per ton, up 5 % from \$165 in 1988.

FOREIGN TRADE

Exports.—Exports of dimension stone, about one-half of which was granite, probably increased 7 % in value.

Imports.—Imports of dimension stone increased slightly in value to \$525 million. The United States changed its tariff classification to the Harmonized Tariff Schedule on January 1, 1989. Because import and export data are classified by tariff category, the 1988 and 1989 import and export statistics are often noncomparable. A number of import categories have had to be estimated because of this and other problems.

WORLD REVIEW

Dimension stone is quarried in most countries of the world. As usual, Italy produced about half of world production. The major importing countries were the United States, Japan, and for rough stone, Italy. Other significant producers were Brazil, China, Finland, India, Norway, Portugal, Spain, Sweden, Turkey, and the United States.

Brazil

The United Nations published a comprehensive study of the Brazilian dimension stone industry, covering it quarry by quarry in each State. For each quarry it describes the geology, commercial name of its stone, and location. In addition, it gives the physical properties of many of the stones, the color, and costs and technology of extraction.¹

Italy

The north end of the island of Sardinia usually accounts for the majority of Italian granite production, or about 650,000 tons. The industry is centered around the towns of Budduso and Tempio Pausania, west of

Olbia. Around 145 granite quarries produce seven major types, mostly light pink or grey. The production is mostly rough blocks that are finished on the Italian mainland. The Sardinian granite producers are expanding production moderately and shifting to doing more of their own finishing work. Industry sources stated that two additional granite tile plants are being built.

The granite in the quarry is usually extracted by drilling and blasting with primacord; only a few diamond wire saws

are in use in granite on the island of Sardinia.

United Kingdom

A new publication, the United Kingdom Minerals Yearbook 1988, gave production statistics for dimension stone. Net production of limestone for building purposes totaled 270,000 tons in 1987, mostly quarried in England. Granite production was not separated out, but was believed to be about 25,000 tons. Architectural slate pro-

duction was about 75,000 tons, excluding granules and powder.

Burlington Slate Ltd. has been on a campaign to upgrade and modernize its facilities. As part of this, it has begun to use diamond wire saws for horizontal cuts in its quarries, eliminating the need for blasting. The change has also significantly reduced the amount of waste rock created.

CURRENT RESEARCH

A United Nations related primer on the dimension stone industry has just been published. It covers terminology, physical properties, types of deposits, locating resources, structural geology, and methods and technology of stone extraction, including tools. It discusses different types of uses, hints for trouble-free installation, and the latest automated technology for stone cutting, polishing, and finishing.²

OUTLOOK

Projected demand for dimension granite totaled 1.7 million tons for 1995 and 2.5 million tons for the year 2000. Projected demand for dimension marble totaled 750,000 tons for 1995 and 1.1 million tons for 2000. Demand for dimension limestone totaled 350,000 tons for 1995 and 380,000 tons for the year 2000, while demand for slate ought to be 55,000 tons in 1995 and 57,000 tons in the year 2000. This relatively slow rate reflects the expected maturing of the market for building stone. Certain segments will continue to grow rapidly, such as the uses in kitchens and bathrooms. The supply will be adequate and is likely to shift in favor of domestic producers.

BACKGROUND

Definitions, Grades, and Specifications

Dimension stone is a natural rock material that has been selected, trimmed, or cut to specified or indicated shapes or sizes, with or without one or more mechanically dressed surfaces. This includes rough stone, rubble, ashlar, blocks, panel, and curvilinear shapes. Finished surface requirements may vary from a controlled fractured surface to ground and polished. The most prominent required

qualities of dimension stone are strength, toughness, hardness, and resistance to environmental damage. Color and grain structure contribute largely to price and marketability. The principal types of dimension stone used in construction are granite, marble, limestone, sandstone, and slate.

Stone classification by type in the dimension stone industry is somewhat ambiguous and does not correspond in some respects

with the same terms used in mineralogical rock descriptions. The Bureau of Mines generally accepts the classification reported by producers, or commercial classification. Granite includes all feldspathic crystalline rocks of predominantly interlocking texture and with mineral grains visible to the naked eye; these include igneous and metamorphic rocks, including quartz diorites, syenites, quartz porphyries, gabbros, anorthosites, and gneisses. White, gray, black,

pink, and red are the common colors for granite, but greens, browns, and other shades are produced in some localities.

Limestone includes dolomitic types as well as calcitic. The latter contain less than 5% magnesium carbonate ($MgCO_3$). Dolomitic limestone contains 5% to 40% $MgCO_3$. Marble is a recrystallized (metamorphosed) limestone containing grains of calcite or dolomite or both. In commercial usage, it is any calcareous crystalline rock or serpentine, a hydrous magnesium silicate, capable of taking a polish. Travertine is a type of marble similar to onyx except that it is precipitated from warm or hot water; it has a banded cellular structure and contains cavities up to one-half inch in width that are lined with microstalactites. Dark green serpentines are classified as marble in the industry because they are often crisscrossed with marble-like veinlets of lighter materials, chiefly calcite or dolomite, and because of their ability to take a high polish.

Commercial sandstone is a sedimentary rock consisting mostly of quartz, sometimes with feldspar, or rock fragments of clastic texture bonded by silica, clay, calcite, or iron oxide. Bluestone is a dense, hard, fine-grained feldspathic sandstone that splits easily along a plane into thin, smooth slabs. It is commonly dark or slate gray in color, and its name no longer has color significance. Brownstone is a feldspathic sandstone of brown to reddish-brown color caused by abundant interstitial iron oxide. Flagstone may be either a sandstone or a slate that splits into large, thin slabs.

Quartzite is a metamorphic equivalent of sandstone that has been firmly cemented by secondary silica or by recrystallization so that it is essentially homogeneous and fractures through rather than around the original sand grains. Slate is a fine-grained metamorphic rock derived from shale, siltstone, or claystone. It has prominent cleavage that is oriented independently from the original sedimentary bedding. Mineral constituents are quartz, mica, sericite, or chlorite with assorted minor accessories. Shale is composed mostly of original clay minerals, and cleavage is parallel to the bedding.

Traprock is a commercial term for all dark, igneous rocks too fine in grain size to be called black granite. In addition to extrusive flow rocks such as basalt, andesite, or dacite, traprock includes intrusive igneous rocks such as diabase, diorites, gabbros, pyroxenites, amphibolites, and peridotites.

Total	33,608	17,716

¹Includes a minor amount of slate used for billiard tabletops, blackboards, and unspecified uses.

Miscellaneous stones used for dimension purposes include schist, scoria, soapstone, wollastonite, argillite, and many others.

Geology-Resources

Domestic resources of most types of dimension stone are practically unlimited. There is considerable interstate transportation of certain types of stone such as Indiana limestone, Georgia marble and granite, and Vermont granite, marble, and slate. A lack of deposits of certain specific varieties of dimension stone especially noted for their esthetic qualities in architecture and artifact manufacture is an important cause of importation of these varieties; for example, brightly colored marbles from Italy.

Technology

Mining.—Present mining methods range from antiquated and very inefficient to modern and technically superior. Quarrying methods include use of various combinations of diamond saws, wire saws, diamond wire saws, chain saws, channeling machines, drilling machines, wedges, and broaching tools. The choice of equipment depends on the type of dimension stone, size and shape of deposit, production capacity, labor costs, economics, and management investment attitudes.

Little blasting is done in the mining of dimension stone. Blocks cut from the face are sawed or split into smaller or thinner blocks for ease in transportation and handling and taken to processing plants, often located at the quarry site, for final cutting and finishing operations.

Processing.—Stone-finishing equipment includes large circular saws 10 feet or more in diameter, some with diamond inserts and some using steel shot or other abrasives; diamond circular saws of smaller size; reciprocating diamond-bladed or loose-abrasive gang saws for multiple cuts; and various types of diamond and other equipment for smoothing, polishing, edging, and decorating the finished stone products.

Economic Factors

Tariffs.—Current import duties (tariffs) are shown in table 17. The depletion allowance for dimension stone is 14%. Dimension stone quarries are generally located in mountainous or hilly areas remote from area of dense population.

Because land use for other purposes is limited, the cost of land is reasonable.

Operating Factors

Environmental Requirements.—Environmental requirements vary from State to State and are often a cause of conflict

between State or local governments and the quarry operators.

Toxicity.—Stone primary and waste products are not toxic, nor are the supplies utilized in their production. However, sufficient exposure to silica-rich stone dust can cause silicosis.

Employment.—The approximate number of employees in the dimension stone industry by stone kind are granite, 9,600; limestone, 1,100; marble, 1,500; slate, 950; and sandstone and other dimension stone, 850. Of the total 14,000, about 3,100 are employed in quarrying and approximately 10,900 in finishing operations. Major States for employment were Georgia with 2,100 employees, Vermont with 1,700, Minnesota with 1,250, North Carolina with 850, Texas with 700, and Indiana with 650.

Energy Requirement.—Fuel is used to power quarrying equipment and electricity is used for sawing and finishing. Water is used in some quarries to cool equipment such as chain saws and in sawing and finishing plants to cool the equipment; water consumption is relatively minimal in all instances.

Transportation.—Transportation costs for dimension stone are high because of its weight and because special handling methods are required to prevent damage to the finished stone. A single stone panel broken in transit not only results in the loss of the many employee-hours of skilled labor required to produce it, but also can cause construction delays that are even more costly. Nevertheless, dimension stone is routinely shipped long distances by motor and rail freight, and special domestic varieties are shipped by ocean freight to foreign countries.

STRONTIUM

By Joyce A. Ober

Mrs. Ober, a physical scientist with 12 years of industry and Bureau of Mines experience, has been the commodity specialist for strontium since 1986. Domestic survey data were prepared by Maureen Nash, mineral data assistant, and the international production table was prepared by Gio Jacarepaqua, international data assistant.

The production of color television picture tube faceplate glass was once again the largest consumer of strontium compounds domestically and internationally. Strontium carbonate, recovered from the mineral celestite, was the most important strontium compound produced. Chemical Products Corp. (CPC) of Cartersville, GA, was the only U.S. producer of strontium compounds from celestite. CPC produced compounds from imported material because there were no active celestite mines in the United States.

DOMESTIC DATA COVERAGE

The sole U.S. strontium carbonate producer voluntarily provided domestic production data to the Bureau of Mines. However, production and stock data were withheld from publication to avoid disclosing company proprietary data.

The Bureau also estimated the distribution of strontium compounds by end use. Of the 10 operations to which a survey request was sent, 8 responded. The information collected from this survey represents nearly 100% of the end-use data shown in table 2. Consumption for the nonrespondents was estimated using reported prior-year consumption levels.

PRODUCTION

Although there have been no active celestite mines in the United States since 1959, celestite deposits have been identified nationwide. During World War II, domestic mining of celestite resources occurred in Texas and Cali-

fornia. U.S. celestite mines had at that time been inactive since World War I, and all demand for strontium minerals was met from foreign sources.

Strontium carbonate, the most important strontium compound by far, was produced by one major company in the United States. CPC was the only company that produced strontium chemicals from celestite. The majority of the celestite CPC used was from Mexican deposits. CPC utilized the black ash method of strontium carbonate production at its facility. The black ash method and the soda ash method were the two most common recovery techniques. The black ash method, known alternatively as the calcining method, produced chemical-grade strontium carbonate, which contained at least 98% strontium carbonate. The soda ash or direct conversion method produced technical-grade strontium carbonate, containing at least 97% strontium carbonate.

The black ash method received its name because the first step in the procedure involves mixing the crushed and

screened celestite with powdered coal, making a black mixture. The mixture is then reduced at about 1,100° C, expelling oxygen in the form of carbon dioxide from the insoluble strontium sulfate to form water-soluble strontium sulfide.

Strontium sulfide is dissolved in water and the resulting solution filtered. Carbon dioxide then passes through the solution or soda ash is added. Either compound provides the necessary carbon and oxygen for strontium carbonate to form and precipitate from the solution. The precipitated strontium carbonate is then removed from the solution by filtering and is dried, ground, and packaged. The sulfur released in the process is either recovered as elemental sulfur or in other byproduct sulfur compounds.

In the soda ash method, ground celestite is washed and most of the water removed. The thickened mixture is then mixed with soda ash and treated with steam for 1 to 3 hours. During this time, celestite and soda ash reacted to form

¹ The strontium content of celestite is 43.88%, which was used to convert units to celestite.

² Export data are obtained from the Journal of Commerce Port Import/Export Reporting Service.

³ Excludes China and the U.S.S.R.

strontium carbonate and sodium sulfate. Sodium sulfate dissolves in water, making it possible to separate the insoluble strontium carbonate by centrifuging. Although the soda ash method is a simpler process, the lower grade of the product causes it to be the less preferred method of recovery. The black ash method is the most common method of strontium carbonate production, and new production facilities were under construction using black ash technology.

CPC purchased the strontium nitrate production facilities from FMC Corp. in Modesto, CA, when that company discontinued production in 1984. The company moved the equipment to Cartersville and now is also the sole U.S. producer of strontium nitrate.

There are several U.S. companies that produced strontium compounds from strontium nitrate. Mallinkrodt Inc. of St. Louis, MO, produced strontium chloride, and Mineral Pigments Corp. of Beltsville, MD, produced strontium chromate. A few other companies produced downstream strontium compounds, but on a very small scale.

Domestic strontium deposits were operated in 1944 near Blanket, in Brown County, TX; in Nolan County, TX; in the Fish Mountains in Imperial County, CA; and near Ludlow, CA.¹ At that time, the major use for strontium chemicals was for pyrotechnic applications such as signal flares and tracer bullets required for the military effort. Immediately following the war, this demand disappeared, causing domestic production to decrease quickly and eventually taper off to nothing.

Resources in the United States have been estimated at 3.2 million metric tons, with an identified reserve base of 1.4 million tons. The reserve figure includes material containing no more than 60% strontium sulfate, which is much too low grade to meet today's rigid specifications. In addition to deposits operated in the early 1940's, celestite has been discovered in Arizona, Arkansas, Kentucky, Michigan, Missouri, New York, Ohio, Pennsylvania, Tennessee, Utah, and Washington.²

The metric system is the official system of measurement of most countries. The Bureau of Mines, in an effort to provide statistical data on strontium that are consistent with international usage, will henceforth report data in kilograms and metric tons unless otherwise noted.

CONSUMPTION AND USES

Approximately 80% of all strontium was consumed in ceramics and glass manufacture, primarily in television faceplate glass and ceramic ferrite magnets, but in smaller amounts in other ceramic and glass applications. In the past 20 years, color television production has become the major consumer of strontium. Because of unique properties that strontium compounds possess, technologies have developed that take advantage of those properties for specific applications. All color televisions and other devices containing color cathode-ray tubes sold in the United States were required by law to contain strontium in the faceplate glass of the picture tube. Strontium blocks X-rays better than barium, which was previously used, and although lead is a better X-ray barrier than strontium, it causes a browning of the glass, which makes its use undesirable.³ Major manufacturers of television picture tube glass incorporate about 8%, by weight, strontium oxide in their glass faceplate material. The strontium is added to the glass melt in the form of strontium nitrate, and during processing, it is converted to strontium oxide.⁴ In addition to blocking X-rays, the strontium improves the appearance of the glass, increasing the brilliance and improving the quality of the picture.

Trends in television production show a shift to larger, flatter, tubes that require thicker glass, and therefore, more strontium.⁵ Although the television industry in the United States is considered mature, there is a continuing demand for replacement televisions as well as additional sets in large numbers of households. The trend to personal computers and sophisticated, computerized instrumentation increased the demand for strontium in color monitors for these devices. However, development of flat-screen technology that could replace cathode-ray tubes continued. Commercialization of flat screens consisting of liquid-crystal displays or some other advanced technology could eventually render cathode-ray tubes obsolete.

Permanent ceramic magnets were another large end use for strontium compounds, in the form of strontium ferrite. When these magnets were first developed, they were used primarily as mag-

netic closures for refrigerator doors. Applications have expanded to include extensive use in small direct current (dc) motors, especially for automotive applications such as windshield-wiper motors, as well as loudspeakers, other electronic equipment, toys, and magnetically attached decorative items.

Strontium ferrites are used in permanent ceramic magnets because they have high coercive force, high thermal and electrical resistivity, and are chemically inert.⁶ They retain their magnetism well, are not adversely affected by electrical currents or high temperatures, and do not react with most chemical solvents. Other properties that make the strontium magnets more attractive for specific applications are their resistance to demagnetization and lower density, making them more desirable in applications where weight is a factor.

Barium or lead can replace the strontium in ferrite magnets, but strontium ferrites have been found to possess the best combination of properties necessary for superior magnets.

One of the most consistent and continuing applications for strontium has been in pyrotechnic devices. Strontium burns with a brilliant red flame, and no other material has been found to be better in this application.

The strontium compound used most frequently in pyrotechnic devices was strontium nitrate. Some strontium compounds are slightly hygroscopic, but strontium nitrate takes on very little water and imparts the desired brilliant red. Strontium carbonate, strontium oxalate, strontium sulfate, and strontium chlorate were used in pyrotechnic applications, but strontium nitrate was used in significantly larger quantities than any of these.⁷

Pyrotechnic devices were used in military and nonmilitary applications. Military pyrotechnic applications that contained strontium included tracer ammunition, military flares, and marine distress signals. Nonmilitary applications included warning devices and fireworks.

Strontium was used to remove lead impurities during the electrolytic production of zinc. Zinc used in die-casting alloys is required to contain less than 0.003% lead. Addition of strontium carbonate in sulfuric acid to the electrolyte reduced the lead content of

the electrolyte and of the zinc that is deposited on the cathode.

The addition of strontium chromate to paint creates a coating that is resistant to corrosion. It is an effective coating for aluminum, most notably on aircraft fuselages and ships. These paints are used to some degree on aluminum packaging to prevent package corrosion. The nitrate and chloride contents of strontium chromate paint pigment are very strictly controlled to prevent corrosion.

Consumption of metallic strontium was still a very limited factor in total strontium consumption. Small amounts of strontium are added to molten aluminum to improve the castability of the metal, making it much more suitable for casting items that have been traditionally made from steel. The addition of strontium to the melt improves the machinability of the casting.⁸ The use of cast aluminum parts is currently gaining popularity in the automotive industry. Aluminum parts have not been practical before modification techniques were developed. The reduction in the car weight by using cast aluminum parts instead of steel helps to improve energy efficiency of the automobiles incorporating these parts.

At the present time other strontium end uses consume only small amounts of strontium and strontium compounds. As mentioned previously, the presence of strontium in glass applications improves the brilliance of the glass. It also improves the quality of certain ceramic glazes as well as eliminating the toxicity that may be present in glazes containing lead or barium.⁹

TABLE 2

U.S. ESTIMATED DISTRIBUTION OF PRIMARY STRONTIUM COMPOUNDS, BY END USE

(Percent)

End use	1987	1988	1989

Other	3	3	3
Total	100	100	100

One high-tech strontium ceramic is strontium titanate, which is sometimes used as substrate material for semiconductors and also in some optical and piezoelectric applications.

Strontium chloride was used in toothpaste for sensitive teeth. For this application, impurities must be strictly controlled, with limits of some of them in the parts per million range.¹⁰

Strontium phosphate was used in the manufacture of fluorescent lights, and the entire range of strontium chemicals was used in analytical chemistry laboratories.¹¹

PRICES

The average customs value for celestite imported from Mexico, the only source in 1989, was about \$76 per ton (\$70 per short ton). This value was approximately the same as the average customs value reported for 1988. Values of imported strontium compounds varied according to the type of compound and the country of origin.

FOREIGN TRADE

According to the Port Import/Export Reporting Service of The Journal of Commerce, U.S. exports of strontium compounds were about 5,300 tons, a 10% decrease from the exports reported from the same source in 1988. Of these exports, 98.5% was strontium carbonate

that went to Japan, Taiwan, and the Republic of Korea. Other reported strontium exports were chloride, chromate, ferrite, nitrate, and peroxide, all in relatively small quantities.

The Bureau of the Census began using the Harmonized Tariff Schedule in 1989 to identify material passing through U.S. Customs. This system makes classification codes for imports and exports consistent internationally. With the adoption of the new codes, imports and export codes for strontium changed, and some formerly listed details are no longer available. Trade information for strontium metal was grouped with barium under a classification of other alkaline earth metals, making specific information concerning strontium unavailable. Strontium chromate data were eliminated. Other strontium compounds experienced changes in classification numbers, and the grouping of compounds differed. Because of these changes, foreign trade information for strontium was available for most materials, but the actual reported figures for celestite from the Bureau of the Census differed from what was expected based on recent trends in foreign trade. A decrease in imports of celestite was expected, but a decrease of nearly 40% did not correspond with reports from other sources.

According to Census, Mexico became the most important source for imported strontium compounds, and the Federal Republic of Germany was second. Imports of strontium carbonate increased about 50%; imports from Mexico were more than twice the level

reported in 1988. Strontium carbonate from Germany decreased nearly 30% as Mexico took over that market. Imports of strontium nitrate nearly tripled after 2 years of decreases.

WORLD REVIEW

Capacity

The data in table 5 are annual rated capacity for chemical processing plants as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Two types of strontium capacity exist, ore production capacity and compound production capacity. Strontium compound capacity was deemed the more important for several reasons. Essentially all strontium is consumed in compound form, primarily as the carbonate and to a lesser extent as the nitrate. Strontium carbonate is also the intermediate product in production of downstream compounds. At least 12 countries mined celestite in 1989. Virtually all of the celestite mined annually is consumed in the production of strontium carbonate and other strontium compounds. Very little strontium was consumed directly in the mineral form.

Listing both ore and compound production capacity could be misleading, possibly resulting in double-counting of strontium capacity. Because most ore is produced for market by means of very simple sorting and beneficiation techniques, capacity can easily be raised to meet increased demand. Strontium carbonate production capacity is the limiting factor in strontium production, requiring complicated and sophisticated processing facilities. Therefore, strontium carbonate production capacity, reported in terms of contained strontium, was selected for tabulation. Construction to expand strontium carbonate capacity has increased because of the continued

growth in international sales of color television sets.

Capacity data for the United States were estimated based on celestite imports, assuming an 85% recovery of strontium from celestite containing a minimum ore grade of 90% strontium sulfate. Capacity information for other countries was compiled from published reports.

Algeria

Celestite was mined in Algeria from a surface deposit near Beni Mansour. Estimated reserves were more than 1 million short tons. The deposit was mined by Enterprise des Produits Non-Ferreux et des Substances Utiles (ENOF) and was controlled by L'Enterprise Nationale de Developpement Minière (Edemines), a division of Société Nationale de Recherches et d'Exploitations Minières (SON-AREM). No strontium has been exported in recent years, but in the past, up to 3,600 tons per year has been exported to Soviet Bloc nations and the

^cEstimated. ^PPreliminary.

¹Table includes data available through May 23, 1990.

²In addition to the countries listed, China, Poland, and the U.S.S.R. produce strontium minerals, but output is not reported quantitatively, and available information is inadequate to make reliable estimates of output levels.

³Revised to zero.

⁴Data are for year beginning Mar. 21 of that stated.

⁵Reported figure.

Federal Republic of Germany. Although the celestite was relatively low grade, only about 70% strontium sulfate, it contained low concentrations of barite, silicate, gypsum, and iron, making it possible to concentrate the ore to acceptable levels using only gravity separation. The deposit has not been fully exploited, but there is interest in further development.¹²

Argentina

Celestite mining was controlled by the Argentine Mining Union at the San Juan Mine in the Province of Mendoza. Celestite has been identified at several other small mines, the Maria Del Carmen and Don Luis Mines also in Mendoza Province and the Rayoso, Julio, Cerro Partido, and Liao Liao Mines in the Province of Neuquen. It is unlikely that any production was carried out on a regular basis at these mines. Most Argentine production was exported to Brazil.¹³

Canada

Canada has produced celestite ore in the past from the McRae deposit, also known as the old Kaiser Celestite Mining Ltd. mine. It is located at Enon, Cape Breton County, Nova Scotia. Mineral rights were acquired by Timminco Metals, a division of Timminco Ltd. of Toronto. Exploration identified

reserves of more than 1 million tons of celestite, with grades ranging from 60% to 65% strontium sulfate. Reopening the mine has been considered, but the low grade of the ore makes economic feasibility questionable. Other strontium deposits have been identified in British Columbia, Newfoundland, and Ontario,¹⁴ but none as significant as the deposit in Nova Scotia. Timminco Metals was the largest producer of strontium metal in the world and the only producer of strontium metal in North America. The company recently completed a new processing facility in Westmeath, Ontario, which increased the potential strontium output by more than 40%.¹⁵ The strontium production facilities in Westmeath and the old facilities in Haley, Ontario, produce strontium metal by the aluminothermic reduction of strontium oxide.

China

Celestite was mined in China almost exclusively for domestic consumption. An ore-dressing facility at the Nanjing Mine in Jiang Su Province has a capacity of 10,000 tons per year. The Nanjing deposit is reported to be high grade and close enough to the surface for open pit mining.¹⁶ Past import data indicated that strontium chemical plants must exist, but no specific details were available. Reports indicated that Japan im-

ports strontium carbonate from China and that strontium carbonate from China has also been reported in the United States.

Cyprus

Celestite mining began in Cyprus in 1985 at Vassliko, near Limassol, in southern Cyprus. The mine was operated by Hellenic Mining Co. Ltd. The ore averaged about 54% strontium sulfate and, therefore, required concentration to make it marketable. The ore was beneficiated through a flotation process to reach 94% strontium sulfate. The reserves have been determined to be 200,000 tons of celestite.¹⁷ No mining has occurred for the past 2 years.

Germany, Federal Republic of

Kali-Chemie AG of Hannover produced strontium carbonate from imported celestite at its plant at Bad Hoenningen. The major western European producer used the black ash method in the recently expanded production facilities. Plant capacity is estimated to be 15,000 tons per year. Kali-Chemie imported most of its celestite from Spain and Turkey; it exported 80% to 90% of the production, most of which goes to the United States and the Republic of Korea. Kali-Chemie also produced strontium hydroxide and strontium nitrate. The nitrate was produced by its Italian subsidiary, Societa Bario e Derivati SpA, in Massa.¹⁸

Iran

One of the world's largest celestite deposits is in the northwestern part of the Dasht-e-Kavir salt desert. The deposit was mined by Iran Strontium Co., a subsidiary of Cherkate Sahami Sanati Va Maadani Irani (Simiran). Average strontium sulfate values for the deposit were reported at more than 91%, but there were unfavorably high levels of barium sulfate and calcium sulfate. Proven reserves total 1.8 million tons of celestite, 430,000 tons of which have no overburden.¹⁹ Most of the celestite produced from this deposit is believed to go to the U.S.S.R.

Italy

Mining has been done by Minera Chimica Farnesiana SpA in Tarquinia, near Rome. Most production of this 75% strontium sulfate and 5% barium

sulfate product was sold domestically.²⁰ Annual production capacity at the mine was 7,300 tons per year, but production ceased in 1988. Some of the processed ore has been exported to the U.S.S.R. in the past.²¹ Other deposits are known to exist in the interior of Sicily, although none are presently being mined. Societa Bario e Derivati, a subsidiary of Kali-Chemie of the Federal Republic of Germany, produced strontium nitrate at Massa. Production and capacity figures were not available, but it was known that most of the production goes to the United States.²²

Japan

No celestite was mined in Japan, but that country was the largest consumer of strontium carbonate in the world, mostly due to its large television and electronics industry. Four companies produce strontium carbonate from imported celestite. Honjo Chemical Corp. operated a production facility for 18,000 tons per year of carbonate at Neyagawa in Osaka using celestite from Spain and China. Sakai Chemical Industries Co. also produced strontium carbonate, by the black ash method, in Osaka at a 12,000-ton-per-year plant using Chinese, Mexican, and Spanish celestite. Japan Special Chemicals (Nihon Tokushu Kasei) and Dowa Chemicals also produced strontium carbonate, but on a much smaller scale. The total capacity for both companies was only about 1,100 tons per year. These two companies used celestite from Spain.²³

Korea, Republic of

Although celestite deposits have not been identified in Korea, its growing electronics and television industry has prompted a European company to form a joint venture with a Korean firm. The companies planned to build production facilities for strontium carbonate and barium carbonate. Kali-Chemie, in a joint venture with Samsung Corning Ltd., Korea, formed Daehan Specialty Chemicals Co. Ltd. and built a strontium carbonate and barium carbonate plant. The plant was expected to begin operation in May 1990 with a production capacity of 40,000 tons per year of strontium carbonate and barium carbonate, combined. The production will be targeted

to the growing television industry in that country. The black ash method will be used.²⁴

Mexico

Mexico was the world's largest producer of celestite in 1989. The most recent Directory of Mexican Non-Metallic Minerals Trust lists 11 companies currently mining celestite. Compañia Minera La Valenciana SA (CMV) mined celestite from the San Agustín deposit near Torreón and Compañia Minera Ocampo SA mined a deposit near Saltillo in Nuevo Leon State, as well as some small production in Hidalgo, Aguascalientes, and Chihuahua States. Reserves of the San Agustín Mine alone have been estimated at more than 725,000 tons. Sales y Oxidos (SYOSA), formerly 49% owned by a U.S. company, Church and Dwight, mines west of Monterrey. Kali-Chemie bought Church and Dwight's share of SYOSA. Other small operations occur in Coahuila, Aguascalientes, Chihuahua, and Nuevo Leon. Mexican celestite is primarily high grade, and only hand sorting is required to achieve at least 92% strontium sulfate with low barium content. Abandoned mines and easily identified deposits that have not yet been developed are common throughout a large area in northern Mexico. These deposits have not been extensively explored, but reserves are believed to be vast.²⁵

Strontium carbonate production has been a recent development in Mexico. Because of the huge celestite resources in the country, this is a very attractive location for additional production facilities. After a major U.S. strontium carbonate and strontium nitrate producer (FMC Corp.) closed its plant in 1984, Cia. Minera La Valenciana SA bought the strontium carbonate processing equipment from the FMC plant in California. The plant, which utilized the soda ash method of carbonate production and was converted to the black ash method, was relocated to Torreón in Coahuila State, near a company-operated a mine. The plant capacity was expanded to 22,000 tons per year in 1989. Shipments from the plant, targeted for the television and electronics industry in the Far East, commenced in May 1987. SYOSA expanded strontium carbonate capacity at its plant near Monterrey to 15,000 tons per year. SY-

OSA, which produced carbonate by the black ash method from celestite it mines nearby, is marketing its production in the United States.²⁶

Pakistan

All mines in Pakistan are the property of Provincial governments and are operated by private companies for the governments. Recent celestite production figures have been reported for two active mines, one near Dawood Khail and one near Karachi.²⁷ Tawakkal Mineral Exports Corp. recovered celestite from these mines in the Dadu District of Sind Province. No beneficiation was necessary to produce 94% strontium sulfate. Reserves of celestite have not been quantified at this location.²⁸ Other deposits with 500,000 tons of reported reserves have been identified in the Punjab Province.²⁹

Spain

Spain was another of the largest celestite producers worldwide. Celestite was produced from the Montevive deposit, which was operated by Herederos de Aurelio Farjardo Vilches, with sales and marketing handled by Bruno SA. Selective mining and hand sorting was all that was necessary to produce ore grades of more than 92% strontium sulfate, although a concentration plant has been constructed. Reserves are believed to be at least 2 million tons. Most Spanish production is exported to Japan, although some remains in Spain, and the rest is exported to the Federal Republic of Germany.³⁰ Promotora de Industria del Sur (Proinsur SA) produced strontium carbonate and strontium nitrate at a combined facility near Granada. The plant has a theoretical design capacity of 8,000 tons per year of carbonate but has never reached this capacity. Strontium carbonate was produced by the soda ash method. The plant also has a production capacity of about 3,000 tons per year of nitrate, which has not yet been fully utilized.³¹

Turkey

Turkey competes with Mexico, Spain, and Iran in claiming the world's largest strontium reserves. Barit Maden Turk AS produced celestite from a mine near Sivas. Run-of-mine ore was gravity separated to produce a concentrate with a minimum of 95% strontium sulfate. Because of the harsh cli-

mate in the region, the mine can only be operated on a seasonal basis, from May to October. Another mine near Sivas was formerly operated by Bilfer Madencilik AS, which reestablished concessions for future celestite mining. Identified reserves have been placed at 550,000 tons, and further reserve potential is estimated to be greater than 2 million tons. Turkish celestite was primarily exported to the Federal Republic of Germany.³²

U.S.S.R.

Very little is known about Soviet production of strontium minerals. Deposits are known in the Karakum Desert, Zaunguz Plateau; Permian deposits near Bashkir; caprocks of the Romy and Isachkov salt domes; Pinega area, Archangel Province; Yakutsk, eastern Siberia; and in Turkestan from eastern Fergana to the shores of the Caspian Sea, and from southeastern Bucharra to the shores of the Sea of Aral. Reserves are believed to be very large, but the ore grade is probably not high.³³ No details are available concerning the production of strontium carbonate in the U.S.S.R. except that there is production, probably from domestic celestite as well as from imports from Iran and Turkey.

United Kingdom

Celestite deposits, which occur in the Bristol area, were mined by Bristol Minerals Co. Ltd. The ore is crushed, washed, and graded to achieve a product with 95% strontium sulfate. Reserve estimates vary from 100,000 to 500,000 tons.³⁴ The British deposits continue to be encroached upon by large-scale housing developments, limiting possible exploitation of the minerals to the near future. This was one of the few sites where celestite deposits are not in remote locations.³⁵

OUTLOOK

The future looks bright for the strontium industry for the near term. Continued growth is expected in the color television industry, and larger screens are expected to increase in popularity. Demand for strontium carbonate for television application should expand likewise. Other markets will probably

continue at their current, slower rate. Development of a technology to produce an affordable flat television display could severely reduce the demand for strontium carbonate. Although a high-quality, large, flat screen is not yet available, small models are, and research continues to perfect the technology. The question remains whether a new display system can be developed that will be economically attractive to the general public. Initial devices are expected to find application in military hardware and other sophisticated medical and scientific instrumentation. But flat screen display systems may eventually replace cathode-ray tubes, and, at that point, strontium producers may experience a serious setback.

BACKGROUND

Resources

Strontium occurs commonly in nature, averaging 0.034% of all igneous rock; however, only two minerals, celestite and strontianite, contain strontium in sufficient quantities to make its recovery practical. Of the two, only celestite has been found to occur in deposits of sufficient size to make development of mining facilities currently attractive.³⁶ Celestite, the most common strontium mineral, consists primarily of strontium sulfate. Strontianite, the second most common mineral, consists primarily of strontium carbonate. Strontianite would be the more useful of the two common minerals because strontium is used most commonly in the carbonate form, but few deposits have been discovered that are suitable for development.³⁷ In almost all instances, celestite deposits occur in remote, undeveloped locations far from population centers in areas where inexpensive labor is available for mining. Huge deposits of high-grade celestite have been discovered throughout the world. Strontium commonly occurs along with barium and calcium, two elements properties very similar to strontium, thus making separation difficult. Because removing many impurities from celestite is difficult and energy intensive, current strontium chemical producers require material to contain at least 90% strontium sulfate. Most of the currently operating celestite facili-

ties can produce sufficient supplies with only minimal processing necessary to achieve acceptable specifications. Hand sorting and some washing are all that are necessary at many strontium mines; only a few operations use froth flotation or gravity separation to beneficiate their ore.

Detailed information on most world resources is not readily available. Many of the large deposits are in remote, sparsely inhabited areas, and very little formal exploration has been done. Other deposits may be well identified but are located in countries from which specific mineral information is not easily obtained.

SULFUR

By David E. Morse

Mr. Morse, a physical scientist with 14 years Bureau of Mines experience, has been the commodity specialist for sulfur since 1981. Domestic survey data were prepared by Mrs. Jessie G. Austin, mineral data assistant; and the international data table was prepared by Mr. Harold D. Willis, international data assistant.

The United States retained its position as the world's foremost producer and consumer of sulfur and sulfuric acid in 1989. Production from U.S. Frasch mines increased significantly to nearly 3.9 million metric tons. One Frasch mine was deactivated and plans were announced for the development of a major salt dome discovery on Federal lease block Main Pass 299 in the Gulf of Mexico, which had been acquired from the U.S. Department of the Interior in 1988.

Production of recovered elemental sulfur, a nondiscretionary byproduct of petroleum refining and natural gas processing, continued to increase and set a record-high production standard. Recovered elemental sulfur shipments to domestic consumers were greater than Frasch shipments and recovered sulfur exports, primarily from California where sulfur supplies exceeded local demands, were higher than Frasch sulfur exports.

Byproduct sulfuric acid from the Nation's nonferrous smelters and roasters, essentially mandated by laws concerning sulfur dioxide (SO₂) emissions, supplied a significant quantity of sulfuric acid to the domestic merchant acid market. Marketing sulfuric acid continued to be difficult for some producers because smelters were located near western copper mines and far from major sulfuric acid markets.

Total world production of sulfur in all forms increased slightly compared to 1988; Frasch sulfur output increased because of activities in the United States and Iraq. Recovered elemental production increased in Asia, decreased slightly in Western Europe and North America because of declining production from gas plants, and fell significantly in Eastern Europe because of continuing technical problems at gas processing facilities in the U.S.S.R.

Nearly five-eighths of the world's elemental sulfur production came from recovered sources; the quantity of sulfur supplied from these sources was dependent on the world demand for fuels and petroleum products, not on

the demand for sulfur.

World consumption decreased, especially in the fertilizer-producing countries of North Africa. Consumption for a myriad of industrial uses continued to be pressured by environmental con-

TRENDS IN THE SULFUR INDUSTRY IN THE UNITED STATES

straints placed on the products produced or effluents from the chemical processes utilizing sulfur or its major derivative, sulfuric acid. World trade of elemental sulfur decreased, by more than 2.8 million metric tons. Although individual country sulfur inventories showed important variations from yearend 1988, total world producers stocks of elemental sulfur were essentially unchanged, which was a departure from the annual decreases that had been characteristic of the 1980's.

DOMESTIC DATA COVERAGE

Domestic production data for sulfur are developed by the Bureau of Mines from four separate, voluntary surveys of U.S. operations. Typical of these surveys is the "Elemental Sulfur" survey. Of the 177 operations to which a survey request was sent, 175 responded, representing 99.99% of the total production shown in tables 1 and 2. The production of the nonrespondents was estimated using prior production histories adjusted to reflect trends in output of their primary products.

PRODUCTION

Sulfur is one of the few elements that occurs in the native, or elemental, state. It also occurs combined with iron and base metals as sulfide minerals, and with the alkali metals and alkali earths as sulfate minerals. In petroleum, sulfur is found in a variety of complex organic compounds, and in natural gas as hydrogen sulfide (H₂S) gas. In coal, sulfur occurs in complex organic compounds and as "coal brasses" (pyrites/marcasite). Commercial production of sulfur in the United States is accomplished by a variety of methods dictated by the source of sulfur.

Frasch

Native sulfur associated with the caprock of salt domes and in sedimentary deposits is mined by the Frasch hot water method, in which the native sulfur is melted underground and brought to the surface by compressed air. In January 1989, the United States had six

Frasch mines operating in Texas and Louisiana. Mines in Louisiana were Freeport Sulphur Co., at Garden Island Bay on the Mississippi River Delta, and Grand Isle and Caminada Pass, 7 miles and 9 miles, respectively, offshore in the Gulf of Mexico. Mines in Texas were Pennzoil Sulphur Co., at Culbertson, and Texasgulf Inc.(TG), at Boling Dome in Wharton County and at its Comanche Creek facility near Fort Stockton in western Texas. TG deactivated the Comanche Creek mine at the end of October, citing low prices and high operating costs as the underlying reasons for the closure. At yearend the Frasch mining industry was operating at about 80% of rated capacity.

In December 1988, Freeport McMoran Resource Partners, operator for a consortium that included the IMC Fertilizer Group, Inc. and Felmont Oil Co., reported a geologic reserve of 50

million long tons of sulfur on its Federal lease block, Main Pass 299, which is offshore in the Gulf of Mexico 17 miles from the mouth of the Mississippi River. The announcement was based on the results of five exploratory holes. Additional drilling in 1989 which delineated the size of the salt dome deposit brought the total reserve to 67 million long tons, which made Main Pass 299 the second largest domestic sulfur deposit yet discovered. Freeport planned to bring Main Pass 299 into production in late 1991 or early 1992, which would require an investment of over \$550 million. Pennzoil performed exploratory drilling operations on two of the three offshore Federal leases that it had acquired in 1988. Placer Dome U.S., Inc. as operator in a joint-venture agreement with Gold and Mineral Exploration NL and Laverton Gold NL, (both of Australia) drilled six explor-

² F.o.b. mine.

atory holes on the Mustang Draw property in Glasscock County, TX. Preliminary estimates of the inplace sulfur resource were 4.5 to 7.9 million tons of sulfur with the depth to the top of the sulfur bearing interval ranging from 2,500 feet to 2,800 feet. In addition to the Mustang Draw prospect, Placer began an exploration program that covers an additional 13 west Texas counties.

TG celebrated the 60th year of commercial operations at New Gulf sulfur mine on Boling Dome. It has been the most prolific sulfur operation in the United States, having produced over 80 million long tons of sulfur. The mine was projected to continue operations until 1995.

Frasch sulfur output increased 700,000 tons from the quantity produced in 1988. Total shipments to domestic and overseas consumers decreased, however, by more than 550,000 tons. Frasch sulfur accounted for 34% of domestic production in 1989. Approximately 91% of Frasch sulfur shipments was for domestic consumption, and 9% for export. The total value of Frasch sulfur shipments decreased by over \$52 million.

Recovered

Recovered elemental sulfur, a nondiscretionary byproduct from petroleum refining, natural gas processing, and coking plants, was produced primarily to comply with environmental regulations that were applicable directly to emissions from the processing facility or indirectly by restricting the sulfur content of the fuels sold or used by the facility. Fuel processing plants accounted for 56% of the total domestic output of sulfur in all forms, compared with 60% in 1988. Production and shipments reached alltime high levels owing to record production from the Nation's petroleum refineries and natural gas processing plants. Recovered elemental sulfur was produced by 57 companies at 154 plants in 26 States, 1 plant in Puerto Rico, and 1 plant in the U.S. Virgin Islands. Most of these plants were of relatively small size, with only 15 reporting an annual production exceeding 100,000 tons. By source, 61% was produced at 84 refineries or satellite plants treating refinery gases and 3 coking plants. The remainder was produced by 27 companies at 67 natural gas treatment plants. The five

largest recovered-sulfur producers in 1988 were Chevron U.S.A. Inc., Exxon Co. U.S.A., Shell Oil Co., Standard Oil Co. (Indiana), and Star Enterprise. The 54 plants owned by these companies accounted for 62% of recovered elemental sulfur output during the year.

Refinery sulfur output was restricted by abnormally cold weather during De-

cember that adversely effected petroleum refinery operations in the south and midwest. The Hess refinery in the U.S. Virgin Islands was shut down for several weeks by a major Atlantic hurricane that devastated St. Thomas.

W Withheld to avoid disclosing company proprietary data; included in "Total."

lead, molybdenum, and zinc roasters and smelters amounted to 10% of the total domestic production of sulfur in all forms. Seven acid plants operated in conjunction with copper smelters, and eight were accessories to lead, molybdenum, and zinc smelting and roasting operations. The five largest acid plants accounted for 72% of the output, and production in five States was 88% of the total. The five largest producers of byproduct sulfuric acid were ASARCO Incorporated, Cyprus Miami Mining Corp., Kennecott, Magma Copper Co., and Phelps Dodge Corp. Their eight plants produced 86% of the 1989 total.

Pyrites, Hydrogen Sulfide, and Sulfur Dioxide

The total sulfur contained in these products did not constitute a significant portion of total domestic sulfur production.

CONSUMPTION AND USES

Domestic consumption of sulfur in all forms continued the strong performance of 1988. In 1989, 82% of the sulfur consumed was obtained from domestic sources, compared with 84% in 1988. The sources of supply were domestic recovered elemental sulfur, 46%; domestic Frasch sulfur, 27%; and combined domestic byproduct sulfuric acid, pyrites, hydrogen sulfide, and sulfur dioxide, 9%. The remaining 18% was supplied by imports of Frasch and recovered elemental sulfur.

The Bureau of Mines collected end-use data on sulfur and sulfuric acid according to the Standard Industrial Classification of industrial activities. Shipments by end use of elemental sulfur were reported by 60 companies, and shipments of sulfuric acid were reported by 56 companies. Shipments of both elemental sulfur and sulfuric acid were reported by eight companies.

Sulfur differs from most other major mineral commodities in that its primary use is as a chemical reagent rather than a component of a finished product. Its predominant use as a chemical reagent generally required that it first be converted to an intermediate chemical product prior to its initial use by

FIGURE 2

TRENDS IN THE PRODUCTION OF SULFUR IN THE UNITED STATES

industry. The largest sulfur end use, sulfuric acid, represented 90% of shipments for domestic consumption. Some identified sulfur end uses were tabulated in the "Unidentified" category because these data were proprietary. Data collected from companies that did not identify shipment by end use were also tabulated as "Unidentified." Although there is no supporting data, it could be reasonably assumed that a significant portion of the sulfur in the "unidentified" category was shipped to sulfuric acid producers or was exported. The difference between exports reported in the canvass and exports of 1 million tons reported by the Bureau of the Census may have been caused by differences in accounting between company records and compilations by the Census Bureau, or by sales to other parties that exported sulfur and were not included in the Bureau of Mines canvass.

Sulfuric acid, because of its desirable properties, retained its position, both domestically and worldwide, as the most universally used mineral acid and the largest volume inorganic chemical in terms of the quantity produced and consumed. U.S. shipments of sulfuric acid (100% basis) increased by more than 0.7 million tons in 1989 because of continued high demand for the production of phosphoric acid, the largest single end use. Shipments of sulfuric acid for petroleum refining and other petroleum and coal products, the second largest end use, decreased significantly from those of 1988. Sulfuric acid demand for copper ore leaching increased 300,000 tons to nearly 1.8 million tons because solvent extraction-electrowinning (SX-EW) operations could produce high-purity copper at a significantly lower cost than by conventional smelting methods.

According to the 1989 canvass reports, company receipt of spent or contaminated sulfuric acid for reclaiming totaled 2.6 million tons. The largest source of this spent acid continued to be the petroleum refining industry, which accounted for 52% of the total returned. The petroleum refining industry was a net user of 689,000 tons of sulfuric acid. About 1.0 million tons of spent acid was reclaimed from plastic and synthetic materials producers. The remaining reclaimed acid was from manufacturers of soaps and detergents,

steel, industrial organic chemicals, inorganic chemicals, other chemical products, storage batteries, explosives, agricultural chemicals, and some unidentified sources.

The largest use of sulfur in all forms, for agricultural purposes, increased slightly from 9.0 million tons in 1988 to nearly 9.1 million tons. The quantity of sulfur needed to manufacture exported agricultural products increased, however, by over 300,000 tons to 4.65 million tons indicating that consumption for domestic purposes declined despite an increase in acreage planted by U.S. farmers.

STOCKS

Yearend inventories held by Frasch and recovered elemental sulfur producers increased 17% from those of 1988, but remained well below historical levels. Combined yearend stocks amounted to approximately a 45-day supply compared to 38-day supply in 1988 and an 82-day supply in 1987, based on domestic and export demands for Frasch and recovered sulfur.

PRICES

The posted price for liquid sulfur ex-terminal Tampa, FL, began the year at \$142, decreased to \$138 per long ton in June, fell to \$130 in July, and dropped an additional \$12.50 per long ton in September to \$117.50. Spot prices and contract prices for sulfur, f.o.b. Vancouver, British Columbia, Canada, were \$100 to \$108 per metric ton during the first half of the year; Vancouver spot prices decreased to \$90 per ton in July, fell further to about \$80 per ton well before the end of the third quarter, and remained at that level through the fourth-quarter.

On the basis of total shipments and value reported to the Bureau of Mines, the average value of shipments of Frasch sulfur, f.o.b. mine, for domestic consumption and exports combined increased from \$85.75 to \$86.62 per ton. The average value, f.o.b. plant, for shipments of recovered elemental sulfur varied widely by geographic region: lowest in the Rocky Mountain States, higher on the west coast, somewhat higher in the midcontinent, and near the values for Frasch sulfur in the East and South. The disproportionately low average value for Wyoming distorted the average calculation for all recovered elemental sulfur shipments.

FOREIGN TRADE

Exports of elemental sulfur from the United States, including the U.S. Virgin Islands, decreased 16% in quantity and 19% in value. According to the Bureau of the Census, exports from the west coast were 473,000 tons or 56% of total U.S. exports.

The United States was a net importer of sulfur, and imports exceeded exports by more than 1.2 million tons in 1989. Frasch sulfur from Mexico and recovered elemental sulfur from Canada, both delivered to U.S. terminals and consumers in the liquid phase, continued to furnish nearly all U.S. sulfur import requirements. Total elemental sulfur imports increased 13% in quantity; imports by rail from Canada increased 26%, while waterborne shipments from Mexico were slightly higher than in 1988. An estimated 380,000

tons of sulfur shipped to the west coast of Mexico from Canada and the United States was exchanged for Mexican sulfur delivered to Florida and U.S. east coast ports.

The United States also had significant trade in sulfuric acid. Sulfuric acid exports decreased slightly from those of 1988. Imports, which were significantly greater than exports, were mostly by rail from Canada. The tonnage increased 31% from the quantity reported in 1988; the value of imported sulfuric acid, however, increased by

only 26%. Approximately 220,000 tons of acid was imported into the Tampa, FL, area. Two new sulfuric acid terminals were established there. One of these was established by the Sulfuric Acid Trading Co. at what was previously the Texasgulf sulfur terminal. The other was established by Boliden Chemicals, Inc. at Port Sutton on the eastern shore of Hillsborough Bay, which was in close proximity to the Pan American and Pennzoil sulfur terminals. Total sulfuric acid storage capacity at the two terminals was nearly 78,000 tons.

WORLD REVIEW

International and domestic sulfur prices experienced a severe downturn in the third quarter of 1989, retreating to levels not seen since 1983. Canadian international sulfur sales, in the first half, dropped by \$150 million compared to the year earlier. As a result of precipitously lower exports, Canadian sulfur was offered at \$20 to \$30 per metric ton below first half 1989 levels during the second half. By early Septem-

ber the price of sulfur stood at \$78 to \$85 per ton f.o.b. Vancouver, British Columbia. Because Canada continued to be the world's largest sulfur exporting nation, the severe drop in Vancouver prices had a ripple effect on prices worldwide. The per-long-ton posted price for liquid Frasch sulfur exterminal Tampa, FL, was reduced \$4 in July, \$8 in August and \$12.50 in September, ending at \$117.50. Middle East prices declined \$15 to \$25 to \$90 per metric ton, and liquid prices from terminals in northwest Europe were reduced \$11 per metric ton to \$122 per metric ton.

A combination of events and sulfur consumers' decisions were responsible for the severe drop in sulfur prices in the third quarter of 1989. Throughout 1988, international fertilizer sales were good; U.S. fertilizer producers anticipated a 1989 increase in domestic sales of from 9% to 12% because of the 1988 drought in North America. Strong international sulfur movements resulting in a tight supply condition during the latter half of 1988 and coupled with a

projected increase in demand in 1989, encouraged consumers to buy forward to offset costs associated with an anticipated increase in 1989 sulfur prices. Additionally, some major world fertilizer consumers also bought forward. An artificially strong apparent world sulfur demand characterized the last quarter of 1988. By yearend, an estimated 1.5 to 1.8 million tons of sulfur or sulfur equivalent in finished products was accumulated by fertilizer producers and consumers.

International sulfur prices were raised by \$9 to \$15 per metric ton in January 1989; prices for finished fertilizers and phosphoric acid were also raised substantially. The price increases were resisted by consumers of fertilizers and sulfur. India declined to purchase Moroccan phosphoric acid at the new price levels and Morocco curtailed sulfur imports in the first half by 1.15 million tons compared to 1988. Worldwide, first half (1989) sulfur movements were nearly 26% below the first half of 1988; Canadian exports were

1989	100.18	78.70	86.62

off nearly 1.6 million tons or almost 40% and represented more than 60% of the dropoff in world sulfur trade. Total world sulfur movements were off nearly 18% in 1989 compared with 1988 trade volumes.

While international sulfur movements and prices were in considerable disorder, U.S. demand remained strong because India replaced phosphoric acid imports with finished fertilizer imports, primarily diammonium phosphate (DAP), from the United States. Sulfur movements from Vancouver increased to more normal volumes from August onward through the end of the year. Canadian exports to the U.S.S.R. resumed in August after a 30-month hiatus.

Industry Structure

In 1989, the sulfur industry was divided into two sectors, discretionary and nondiscretionary. In one, the mining of sulfur or pyrites was the sole objective; this voluntary production of

Source: Bureau of the Census.

native sulfur or pyrites was based on the orderly mining of discrete deposits, with the objective of obtaining as nearly a complete recovery of the resource as economic conditions permit. In the other, sulfur or sulfuric acid was recovered as an involuntary byproduct, the quantity of output subject to demand for the primary product irrespective of sulfur demand. In 1989, involuntary sources represented nearly 64% of the elemental sulfur produced worldwide, and the combination of recovered elemental sulfur and byproduct sulfuric acid equaled over 57% of total world production of sulfur in all forms.

Large quantities of Frasch sulfur were produced from mines in only five countries: Iraq, Mexico, Poland, the U.S.S.R., and the United States. Poland and the U.S.S.R. also produced significant quantities of native sulfur using conventional mining techniques; small quantities of native sulfur were pro-

duced in Asia, Europe, and South America. Pyrites were the prime sulfur source in China, Spain, and the Republic of South Africa and an important source in Scandinavia and the U.S.S.R.

Recovered elemental sulfur was the predominant sulfur source in Canada, France, the Federal Republic of Germany, Kuwait, Saudi Arabia, and the United States. Additionally, recovered elemental sulfur was an important source in Iran, Iraq, Japan, and the U.S.S.R.

International sulfur trade was dominated by a limited number of exporting countries; exports from Canada, Poland, Iraq, Mexico, the United States, Saudi Arabia, the Federal Republic of Germany, and France accounted for 90% of sulfur trade in 1989. Major sulfur importers in 1989 were India, the United States, the U.S.S.R., Brazil, Morocco, Tunisia, the United Kingdom, Australia, the Republic of South Africa, and Jordan in descending order

of importance.

World Capacity

The data in table 20 are rated capacity for Frasch mines, elemental sulfur mining facilities and attendant beneficiation plants, pyrites mines and plants, and sulfur-sulfuric acid recovery units associated with petroleum refineries, natural gas processing plants, metal smelting operations, electric powerplants, and coke ovens as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the facility, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that in the judgment of the author can be brought into production within a short period of time with a minimum of capital expenditure. Rated capacity is not equivalent to engineering (design) capacity of installed equipment.

Frasch mines operate continuously, and capacity is related to the quantity of superheated water that can be injected into the associated sulfur deposit. The nature of Frasch mining makes capacity quite variable over time and depends on the number of "steaming wells," water injection rates, water losses from the formation, location of wells within the deposit, and length of time that the deposit has been worked. The rated capacity or realizable capacity of a Frasch mine generally decreases as the deposit becomes depleted.

Petroleum refineries, large, very costly, and complex processing facilities designed to produce a spectrum of fuels and petrochemical products, operate continuously. Sulfur recovery units make up only a small segment of these facilities; because sulfur recovery is mandated by environmental considerations, the installed sulfur recovery capacity at petroleum refineries generally exceeds the expected sulfur production. To ensure that the loss of a sulfur recovery unit does not require the shutdown of the entire refinery, multiple sulfur recovery units, each capable of servicing the petroleum refinery, are installed. The quantity of sulfur recov-

ered by domestic petroleum refineries in the United States during 1989 was equal to slightly more than 50% of the installed engineering capacity. Rated capacity for petroleum refineries is assumed to be 50% of installed engineering capacity.

Natural gas processing plants may be installed to service gasfields and/or oilfields that contain significant quantities of associated gas. Gas plants are designed to accommodate the natural gas from a specific field that may contain in addition to methane, which is sold as pipeline gas, varying amounts of nitrogen, carbon dioxide, helium, condensable hydrocarbon liquids, and poisonous hydrogen sulfide. The poisonous nature of hydrogen sulfide makes its removal from pipeline gas imperative. Sulfur removal and recovery plants in natural gas facilities vary in size from small units rated at 5 to 10 tons per day to multiple-train plants capable of recovering thousands of tons per day. In general, sulfur recovery rates from gasfields approximate installed engineering capacity, based on a 340- to 345-day-per-year operation of all units, in the first 7 years of operation. In succeeding years, sulfur recovery declines steadily because the gas apparently becomes "sweeter" over time and because gas flow rates drop as the field is depleted. Rated capacity for gas processing plants is based on the age of the plant and its recent production history.

Rated capacity for plants operating in conjunction with metal smelters, powerplants, and coking operations is assumed to approximate engineering capacity. Where information on design capacity is unknown, rated capacity was estimated to be equal to the greatest output recorded by a plant or country in the past 5 years. World rated sulfur annual production capacity is significantly lower than the installed world engineering capacity of approximately 92 million tons.

Canada

Shipments of sulfur in all forms were about 7.4 million tons, or 0.7 million tons greater than production. Elemental sulfur exports decreased significantly from 7.4 million tons in 1988 to 5.8 million tons in 1989; offshore exports from Vancouver, British Columbia, fell 1.8 million tons from 1988 to 4.65 mil-

lion tons; despite the dropoff in exports, Canada remained the world's largest sulfur exporting country.

Natural gas processing plants in Alberta continued to supply the major share of Canadian sulfur production. In Alberta, gas-recovered sulfur output decreased about 350,000 tons from 1988 despite a slight increase in natural gas production. Severe cold weather in February adversely affected sulfur production from Husky Oil Ltd.'s Ram River plant, which reduced output for over a month. Sulfur production from gas plants in British Columbia increased to a record high of over 410,000 tons.

Mobil Oil Canada Ltd., Norcen Energy Resources Ltd., PanCanada Petroleum Ltd., and Shell Canada Ltd. began field construction on the Bearberry, Alberta, demonstration project to develop facilities to extract sulfur from the field's ultra sour gas (90% H₂S). A 200-ton-per-day pilot plant was due for completion in late 1990, and a 5-year study was planned by the developers. The sulfur resource at Bearberry was estimated to be between 70 and 100 million tons.

Esso Resources Canada Ltd. was developing the Obed sour gas field (25% H₂S) near Edson, Alberta. Gas from the field was to be pipelined to the

Chevron Standard Ltd.'s Kaybob III plant for processing. Production of sulfur from Obed sour gas was expected by the end of 1990 and would increase Kaybob III output by 300,000 to 350,000 tons per year.

Expansion of Petro-Canada Inc.'s Brazu River, Alberta, natural gas processing plant was essentially completed during 1989. The expansion tripled capacity at the facility to 100,000 tons per year.

Husky Oil Ltd. and Shell Canada Ltd. were seeking approval for their respective plans to develop the Caroline gas-condensate field near Sundre, Alberta. The Caroline was discovered by Shell, which heads a consortium that holds 80% of the rights to the natural gas reservoir; the field has been estimated to contain nearly 2 trillion cubic feet of sour natural gas (30% to 35% H₂S). The Alberta Province Energy Resources Conservation Board was to determine which of the two plans to accept in early 1990, and development of the field was expected to be completed during 1993.

Noranda Inc. completed construction of a 350,000-ton-per-year sulfuric acid plant at its Horne copper smelter in Rouyn-Noranda, Quebec. The acid

plant was to reduce SO₂ emissions from the smelter by more than 50%.

Inco Ltd. proceeded with engineering work at its Sudbury, Ontario, nickel smelter to reduce sulfur dioxide (SO₂) emissions. The company plans to construct two flash furnaces and an additional sulfuric acid plant by late 1991. Ore dressing circuits were to be revamped to maximize pyrrhotite rejection and reduce sulfur input to the furnaces. The overall projected, scheduled for completion by 1994, was designed to reduce SO₂ emissions by 60% and increase annual sulfuric acid output by 100,000 tons.

Chile

Corporación Nacional del Cobre de Chile was in the midst of expanding sulfuric acid production from its Chuquibambilla copper smelter. Most of the acid was for processing Chuquibambilla's oxide zone copper ore in a heap-leach, SX-EW system that was scheduled to recover 80,000 tons per year of copper by 1990.

Iraq

Sulfur exports increased to an estimated 600,000 tons; domestic consumption was about 400,000 tons. Production was increased at the Misraq Mine and from the Kurkuk gas plant. Expansion of water heating capacity, which was designed to double the Misraq mine's capacity to 2 million tons per year, began in 1989.

Mexico

Frasch sulfur production decreased slightly from 1988. Efforts continued to expand production from the recently commissioned Otapan Mine, and exploration for new resources continued. Sulfur imports from Canada and the U.S. west coast were nearly 380,000 tons, which did not appear in official Mexican trade statistics. Most of these imports occurred by means of exchange agreements for deliveries of Mexican Frasch sulfur to the United States.

Morocco

Morocco was a major world importer of elemental sulfur because of consumption at its phosphate fertilizer facilities at Safi and Jorf Lasfar. Imports decreased from 2.9 million tons in 1988 to approximately 1 million tons

in 1989. A major dispute concerning phosphoric acid prices and exports to India curtailed phosphoric acid production and the need for sulfur imports. In addition, several hundred thousand tons of sulfur that had been inventoried in 1988 were apparently consumed in 1989, which further reduced import requirements.

Poland

Sulfur exports decreased from 3.85 million tons in 1988 to 3.65 million tons. More than 1.9 million tons was shipped to Eastern Europe and 0.8 million tons to Western Europe; most of the remainder was shipped to Brazil, India, Morocco, and Tunisia.

Poland was the largest world producer of native sulfur with major mines at Jezioro, Grzybow, and Machow. The Machow open pit mine continued to operate with an ever increasing overburden to sulfur ore stripping ratio; because of the social, political, and economic restructuring that began in Poland during 1989, Machow may have a limited life. The construction of the new Osiek Mine was delayed for environmental reasons. The mine should come on-stream in two phases, one in 1992 and the second in 1993.

Saudi Arabia

Sulfur production from natural gas processing plants and oil refineries increased slightly. Exports decreased substantially to 930,000 tons from 1.46 million tons in 1988. India received more than 50% of Saudi sulfur exports.

U.S.S.R.

Production of elemental sulfur decreased substantially because of reduced output from the Astrakhan natural gas processing plant. Technical problems and environmental concerns restricted the output from Astrakhan to 25% of capacity. Construction of the second phase to double the size of the Astrakhan facility was completed during the year. The second phase was not commissioned because of the problems plaguing the first phase. The engineering works for the first of three gas processing plants at the Tengiz oil-gas-condensate field near the northeast shore of the Caspian Sea were completed; each plant had a design annual

sulfur capacity of 450,000 tons.

A Russian language journal¹, published in Moscow, described the U.S.S.R. sulfuric acid industry. U.S.S.R. sulfuric acid production grew from 12.1 million tons in 1970 to 29.4 million tons in 1988. The quantity produced from elemental sulfur represented 23.6% of output in 1970 and 63.5% in 1988. The quantity produced from pyrites decreased from 45.8% to 19.2% during the same time period. Metallurgical exhaust gases provided 23.2% of production in 1970 and 14.3% in 1988. Hydrogen sulfide, primarily at petroleum refineries, accounted for 7.2% and 3% in 1970 and 1988, respectively.

OUTLOOK

World sulfur demand, from 1990 to the year 2000, is forecast to increase at an annual rate of about 2% per year. World demand is projected to attain 65.5 million tons in 1995 and increase to over 72.5 million tons in the year 2000. In the short term, U.S. sulfur demand is forecast to decline from 12.7 million tons consumed in 1989; demand will probably decrease to 12.1 million tons in 1991, and increase only marginally thereafter. U.S. sulfur demand is forecast to be 12.5 million tons in 1995 and reach 13.2 million tons in the year 2000.

Agriculture is by far the most important of the sulfur end-use categories, accounting for over 70% of U.S. demand and 57% of world consumption. The principal individual requirement is for the manufacture of phosphatic fertilizers, in which sulfuric acid is the essential intermediate chemical product. The production of phosphoric acid by the wet acid process involves the acidulation of phosphate rock with sulfuric acid. The phosphoric acid is primarily an intermediate product, which is used to manufacture a spectrum of high-grade fertilizers; the acid itself may also be used for direct application to soil in order to supply the needed plant nutrition. Other fertilizers that require sulfuric acid in their production, but in comparably lower quantities, include ammonium and potassium sulfates, and single super phosphate, which is produced by the partial acidulation of phosphate rock to form a lower analysis fertilizer, on a nutrient

basis, than is produced from phosphoric acid. Nonfertilizer sulfur uses in agriculture include direct application of sulfur and sulfuric acid to soils, pesticide manufacture, and for animal feed supplements. Over 95% of U.S. agricultural sulfur demand and nearly 80% of world agricultural sulfur consumption was for the manufacture of phosphoric acid in 1989.

World demand for phosphate fertilizers is forecast to increase at a rate of 2.2% annually through 1995 and slightly less than 2% for the remainder of the century. It is assumed that 90% of the growth will be for the production of phosphoric acid to produce high-analysis fertilizers, which will directly affect world sulfur demand. Consumption of sulfur for phosphate fertilizer manufacture in the United States is divided into two main components: (1) demand for phosphate fertilizers consumed by domestic farmers; (2) demand for exported phosphate fertilizers. In 1989, 4.66 million tons of sulfur were required to manufacture the phosphatic fertilizers exported from the United States compared to 3.98 million tons of sulfur for domestic phosphoric acid uses. Sulfur demand for domestically consumed phosphates is forecast to increase to nearly 4.6 million tons by 1995 and remain relatively stable thereafter. The export component is not expected to repeat the strong performance of 1989 until sometime after 1995, if at all during the 1990's, because of increasing foreign competition in world markets. U.S. sulfur consumption for agricultural purposes could drop significantly if domestic phosphate fertilizers' producers are not able to compete successfully in the international arena.

The broad spectrum industrial or nonagricultural sulfur use category accounted for nearly 30% of U.S. sulfur consumption and over 43% of world sulfur demand. While significant variations in demand for the diverse elements within this broad category are expected in the United States and other geographic areas, world industrial demand is expected to average a 1% to 1.2% increase annually through the remainder of the century, reaching 29 million tons in the year 2000.

The necessity for the removal of sulfur from solid, liquid, and gaseous effluents for environmental protection has caused the production of sulfur

and sulfur compounds from these sources to exceed production from primary sources of supply. The long-term prospect is that 85% or more of the world sulfur supply will come from environmentally regulated sources and that output from these sources will be produced regardless of world sulfur demand. As a result, it is probable that, after the turn of the century, no new operation that produces sulfur as its primary product will be developed, except where it may be deemed necessary for political or social reasons.

In 1980, voluntary sources of production, Frasch, native sulfur and pyrites, accounted for 50% of world output of nearly 55 million tons. In 1989 these same sources supplied only 43% of world production of 58.3 million tons. Not only did the voluntary producers share of production decrease, the volume of output fell by 2.78 million tons or over 10%; U.S. Frasch production accounted for most of the drop, plunging from 6.39 million tons to 3.89 million tons. Additionally, world sulfur stocks fell from nearly 27 million tons to about 10 million tons during the period 1980 through 1989; over 16 million tons was removed from vatted Canadian stocks, which had been built during the 1970's at natural gas processing plants.

It is anticipated that, in the short term, 1990 through mid-1992, world sulfur demand will surpass output and that stocks will continue to decline. A temporary severe shortage could develop by late 1991. Any sulfur shortage would be of short duration because of the size and number of new production facilities planned or under development.

In Canada, projects nearing completion should raise output from existing gas plants 400,000 to 500,000 tons by 1992. The development of the Caroline gas field should increase Canadian capacity by 1.2 million tons in 1993. Expansion of the Misraq mine in Iraq should increase its output 500,000 tons by late 1992. The development of the Osiek mine in Poland should result in a net increase in Polish sulfur output of 100,000 tons by 1993. In the U.S.S.R., an 800,000-ton-per-year expansion at the Orenburg gas plant should be completed by late 1992. The new associated gas processing facility at Tengiz (Tengiz I-1990, Tengiz II-1992, Tengiz III-1993) should be capable of producing

1.2 million tons per year by 1993. If the technical problems with Astrakhan I can be remedied, both Astrakhan I and II should be on-stream by yearend 1992, producing 4 million tons per year compared to the estimated 700,000 tons produced at Astrakhan in 1989. Freeport plans to have its new Main Pass 299 mine on-stream by early 1992 and be producing at a rate of over 2 million tons per year by early 1993, increasing U.S. Frasch capability 1 million tons compared to 1989. Net additions to world production from expansions and new facilities at oil refineries and gas processing plants should amount to between 800,000 and 1 million tons by 1993. A worldwide sulfur surplus will probably develop in 1993, a surplus that could persist for much of the remainder of the century. World sulfur production will likely increase to 67 million tons in 1993, attain a level of 68 million tons in 1995, and exceed 72.5 million tons in the year 2000.

While the outlook for a substantial worldwide sulfur surplus in the mid-1990's can be amply justified, one may question the ability of some producers to get the product to the marketplace and also the ability to maintain production at the forecast levels. Because of the enormous size of the Astrakhan facility in the U.S.S.R., it has been, since the mid-1980's, the focus of considerable discourse among industry planners and consultants outside of the Soviet Union. All were trying to answer these questions: How much sulfur, if any, will there be? When and where will it be marketed, internally or exported? Can the needed transportation infrastructure be built and properly managed? The underlying reason for so much concern was that this single facility could put the world sulfur supply-demand balance into one of surplus or into deficit in the 1990's.

BACKGROUND

Sulfur, known as brimstone, "the stone that burns," was used in small quantities for thousands of years. Man was probably first drawn to native sulfur by its bright yellow color and pungent odor. Early man used sulfur as a colorant for cave drawings, as a fumigant, for medicinal purposes, and as

incense. As early as 2000 B.C., the Egyptians used sulfur in the bleaching of linen textiles. In the Odyssey, Homer refers to its use as a fumigant. During the Peloponnesian War, fifth century B.C., the Greeks employed the burning of a sulfur-pitch mixture to generate suffocating gases. The Romans combined brimstone with tar, pitch, and other combustible materials to produce the first incendiary weapons. Muslims during the "Golden Age of Arabic Science," from about A.D. 700, developed alchemy and were probably the first producers of sulfuric acid. Sulfur is a necessary ingredient in gunpowder, which was developed as a pyrotechnic in China by the 10th century. Gunpowder's introduction into Europe led to its use in warfare in the 14th century and made sulfur an important mineral commodity for the first time.

However, it was not until the birth of the science of chemistry in the 1700's and the growth of chemical industries in the 1800's that sulfur became of major importance to the world outside of its use in warfare. Early chemists soon recognized the importance of sulfuric acid as the cheapest and most versatile of the mineral acids, and it rapidly became the most common acid in the chemical industry.

Products for Trade and Industry

Elemental sulfur of commerce, sometimes called crude sulfur or brimstone, may be marketed in either the liquid or the solid phase, generally with a minimum sulfur content of 99.55%. Most elemental sulfur marketed in North America is sold as liquid sulfur. In worldwide commerce, sulfur is shipped either as broken sulfur or formed sulfur. Formed sulfur, prills, slates, and pastilles, is generally preferred to broken sulfur because it is less prone to dusting and the release of fugitive dust at terminals where sulfur is stored and transferred from one transportation mode to another. Sulfuric acid may be sold at various strengths, usually depending on the requirements of the consumer. The acid is generally marketed on a 100% basis but is normally shipped at 66° Baume (93% H₂SO₄), as 98% acid, or as 20% to 22% fuming oleum, which is sulfur trioxide dissolved in sulfuric acid.

Industry Structure

Over the centuries, many fundamental changes have occurred in man's sources of sulfur supply. Early civilizations obtained their meager requirements from native sulfur deposits in or around volcanoes. The increase in demand for sulfur in the late 1700's and early 1800's was largely satisfied from extensive native sulfur deposits in Sicily. Monopolistic practices by the owners of sulfur mining facilities in Sicily, which led to exorbitant sulfur prices, caused consumers to adopt iron pyrites as the second major sulfur source during the mid- to late-19th century. The development in 1895 of the Frasch process for mining the large native deposits associated with salt domes in Louisiana and Texas brought a new and important source of sulfur to the United States and world markets. Frasch sulfur and pyrites maintained their joint predominance as world sulfur sources through the mid-1970's.

With small beginnings in the 1930's and increasing significantly from the 1950's onwards, environmentally mandated or involuntary sulfur from natural gas processing and petroleum refining grew to surpass Frasch sulfur and pyrites as the world's major source of sulfur. In addition, increasing quantities of byproduct sulfuric acid from smelting operations have been produced to comply with pollution control laws and environmental regulations worldwide.

Sulfur in its various forms is produced worldwide, with no single nation predominating as a producer or supplier to world markets. In 1989, world sulfur production and consumption amounted to 58.3 and 58.9 million tons, respectively. The United States and the U.S.S.R. were the world's largest producers; both nations, however, were net importers of over 1.2 million tons of sulfur. Canada and Poland, respectively, the third and fourth largest world producers, ranked first and second among the world's exporting nations. China, the world's fifth largest producer and largest pyrites producer, was the third largest sulfur consumer; China, however, satisfied most of its sulfur requirements from internal sources.

Economic Factors

Prices.—Over the past 20 years, world

sulfur price leadership has shifted from dominance by the U.S. Frasch producers to the Canadian exporters. The transfer was aided in the 1980's by Canada's ability to export most of its production from the port of Vancouver and by its willingness to ship large volumes of sulfur from vatted stocks. The maturation of Sultran Ltd., dealing almost exclusively with sulfur destined for the offshore market, into a well organized and skilled transportation arm of the Canadian sulfur industry, aided immeasurably in Canada's ascension to world price leadership.

In the United States, the quoted liquid Frasch sulfur price, f.o.b. terminal Tampa, FL, is the benchmark price. Recovered sulfur producers, in many cases, consider the economic desirability of producing sulfur subordinate to the necessity of producing it. As a result, domestic recovered elemental sulfur producers normally offer sulfur at a price \$5 to \$15 per ton below the Tampa quote to ensure prompt sale and reduce storage costs. This marketing strategy has re-

^e Estimated. ^P Preliminary. ^r Revised. W Withheld to avoid disclosing company proprietary data; included with "Byproduct: Unspecified sources."¹ Table includes data available through May 16, 1990.² In addition to the countries listed, a number of nations may produce limited quantities of either elemental sulfur or compounds (chiefly H₂S or SO₂) as a byproduct of petroleum, natural gas, and/or metallurgical operations, but output, if any, is not quantitatively reported, and no basis is available for the formulation of reliable estimates of output. Countries not listed in this table that may recover byproduct sulfur from oil refining include Albania, Bangladesh, Brunei, Burma, Costa Rica, Guatemala, Honduras, Jamaica, Malaysia, Nicaragua, Paraguay, and the People's Democratic Republic of Yemen. Albania and Burma may also produce byproduct sulfur from crude oil and natural gas extraction. No complete listing of other nations that may produce byproduct sulfur from metallurgical operations (including processing of coal for metallurgical use) can be compiled, but the total of such output is considered as small. Nations listed in the table that may have production from sources other than those listed are identified by individual footnotes.³ The term "source" reflects both the means of collecting sulfur and the type of raw material. Sources listed include the following: (1) Frasch recovery; (2) native, comprising all production of elemental sulfur by traditional mining methods (thereby excluding Frasch); (3) pyrites (whether or not the sulfur is recovered in the elemental form or as acid); (4) byproduct recovery, either as elemental sulfur or as sulfur compounds from coal gasification, metallurgical operations including associated coal processing, crude oil and natural gas extraction, petroleum refining, tar sand cleaning, and processing of spent oxide from stack-gas scrubbers; and (5) recovery from the processing of mined gypsum. Recovery of sulfur in the form of sulfuric acid from artificial gypsum produced as a byproduct of phosphatic fertilizer production is excluded because to include it would result in double counting. It should be noted that production of Frasch sulfur, other native sulfur, pyrites-derived sulfur, mined gypsum-derived sulfur, byproduct sulfur from extraction of crude oil and natural gas, and recovery from tar sands are all credited to the country of origin of the extracted raw material; in contrast, byproduct recovery from metallurgical operations, petroleum refineries, and spent oxides is credited to the nation where the recovery takes place, which in some instances is not the original source country of the crude product from which the sulfur is extracted.⁴ Revised to zero.⁵ Data may not add to totals shown because of independent rounding.⁶ Reported figure.⁷ In addition, may produce limited quantities of byproduct sulfur from oil refining.⁸ Includes only the elemental sulfur equivalent of sulfuric acid produced as a byproduct from metallurgical furnaces; additional output may be included under "Byproduct: Unspecified sources."⁹ Less than 1/2 unit.¹⁰ Includes recovery from gypsum, if any.¹¹ Official Polish sources report total Frasch and native mined elemental sulfur output annually, undifferentiated; this figure has been divided between Frasch and other native sulfur on the basis of information obtained from supplementary sources.¹² Estimates for 1985-89 include byproduct production from synthetic fuels.

sulted in restricting Frasch sulfur sales from many market areas that they formerly served.

During the 1980's, the sulfur price showed a significant degree of volatility compared to its prior history (see figure 1.). The worldwide recession of 1982 and the U.S. Department of Agriculture PIK program in 1983 reduced world sulfur production and demand. Tampa prices fell from \$147.50 per long ton to \$122.50 from mid-1982 to yearend 1983. Vancouver, British Columbia, export prices were down from \$127.50 in mid-1981 to \$85.50 in December 1983. Prices escalated rapidly in 1984 because of a tremendous increase in demand in the United States and worldwide. The quoted Frasch price at Tampa, FL, increased \$25 per long ton during the year and the spot price from Vancouver, British Columbia, jumped \$60 per ton. A downward

spiral began in mid-1986 because of a slight softening in demand and increased competition for world markets. The Tampa price decreased \$20 from August 1986 to September 1987, and Vancouver prices were off nearly \$37 during the same time period. Tampa prices were stable for about a year and then increased \$12.50 per long ton during the latter part of 1988. Vancouver prices declined another \$2 to \$3 per ton in late 1987 and held steady until the latter part of 1988 when they rose nearly \$10 per ton. The price of sulfur decreased rapidly in mid-1989, as recounted earlier.

TALC AND PYROPHYLLITE

By Robert L. Virta

Mr. Virta, a physical scientist with 14 years Bureau of Mines experience, has been the commodity specialist for talc and pyrophyllite since 1986. Domestic survey data were prepared by Linder Roberts, mineral data assistant, and international data tables were prepared by Peter Roetzel, international data coordinator.

Domestic production of talc and pyrophyllite increased slightly from that of 1988 to 1,253,128 metric tons. Sales of crude and processed talc and pyrophyllite increased 10% to 1,145,097 tons and decreased slightly in value. Imports for consumption decreased 2% to 77,716 tons and decreased slightly in value to \$12,128,000. Exports increased 23% in tonnage to 319,329 tons and 35% in value to \$28,949,000. Over the past 10 years, talc and pyrophyllite production averaged 1,135,000 tons; sales, 1,071,000 tons; domestic consumption, 940,000 tons; exports, 243,000 tons; and imports, 44,000 tons. The major use for talc was in ceramics, which accounted for 32% of the domestic consumption, followed by paint, 15%; paper, 14%; roofing, 10%; plastics, 10%; and other, 19%. The major use for pyrophyllite was in ceramics, which accounted for 60% of the market followed by refractories, 18%; insecticides, 9%; and other, 13%.

DOMESTIC DATA COVERAGE

Domestic production and sales data for talc and pyrophyllite are developed by the Bureau of Mines from a voluntary survey of U.S. mines and mills. Survey forms were sent to 19 companies that operated 55 mines and mills. Fifteen companies that account for approximately 58% of the domestic production responded to the survey. Production data for one nonrespondent were obtained from a company annual report. Data for two nonrespondents that accounted for approximately 5% of the domestic production were estimated from reported prior-year production levels adjusted by trends in employment and other guidelines. Beginning in 1989, production and trade data for talc and pyrophyllite will

be reported in metric units.

LEGISLATION AND GOVERNMENT PROGRAMS

The Occupational Safety and Health Administration (OSHA) extended through November 30, 1990, an admin-

istrative stay on its 1986 regulation governing worker exposure to the non-asbestiform varieties of actinolite, anthophyllite, and tremolite. During the stay, OSHA continued to analyze the impact of using the asbestos standard to regulate the nonasbestiform varieties of the minerals. An exposure limit of 2 fibers per cubic centimeter will remain in effect during the stay.¹

¹ Data may not add to total shown because of independent rounding.

² Does not include value for pyrophyllite.

³ Excludes powders—talcum (in package), face, and compact.

⁴ Production, plus imports, minus exports, plus adjustments in Government and industry stock changes. Does not include imported pyrophyllite.

OSHA revised its standards for exposures to talc and soapstone. The permissible 8-hour time weighted average exposure limit is 2.0 milligrams per cubic meter (mg/m³) for talc (containing no asbestos), 3 mg/m³ for respirable soapstone dust, and 6 mg/m³ for total soapstone dust.²

The Mine Safety and Health Administration proposed revisions to its air quality, chemical substances, and respiratory protection standards. The proposed permissible 8-hour time weighted average exposure limit is 2.5 mg/m³ for talc (containing no asbestos), 3 mg/m³ for respirable soapstone, and 6 mg/m³ for total soapstone dust. The nonasbestiform varieties of tremolite, anthophyllite, and actinolite would be covered under the proposed respirable mine dust standard.³

ISSUES

The question of whether or not the nonasbestiform varieties of tremolite, anthophyllite, and actinolite pose a health risk continued to concern a portion of the talc industry. OSHA maintains that although nonasbestiform amphiboles may not pose as great a health risk as asbestos, the risk posed is great enough to warrant their regulation. Industry representatives believe that there are insufficient data to demonstrate a health risk and that a regulation is not required. Much of the controversy surrounds the choice of study and control populations, the mineralogy and concentration of airborne dusts at the time of exposure, prior worker exposure to carcinogens, and smoking patterns.

PRODUCTION

Talc

Fourteen companies, operating 23 mines in 10 States, produced talc, soapstone, and steatite. These companies generally were structured to cover all aspects of talc mining, from mining to processing. Only a few companies hired custom grinders to mill the ore. The largest of the domestic producers were Cyprus Industrial Minerals Co. Inc., Dal-Tile Inc. (Texas Talc), Gouverneur

Talc Co., Montana Talc Co., and Pfizer Inc. The major producing deposits were in Montana, New York, Texas, and Vermont.

Commercial talc production was from deposits that were formed through hydrothermal alteration of ultrabasic rocks and low-grade metamorphism of siliceous dolomites. They generally occur as lenses or pods in the country rock. Magnesite, quartz, chlorite, magnetite, serpentine, anthophyllite, tremolite, dolomite, and actinolite may be present as accessory minerals.

Most of the domestic talc production was from open pit mining operations. Underground mining was used only when a large waste rock to ore ratio made open pit mining uneconomical. Typically, overburden was removed and blasting was used to fracture the ore. The companies then used selective mining and manual or automated sorting to produce a high-grade feed for the mill. Jaw crushers were used to reduce the size of the mill feed, and ball mills or roller mills were used to produce the final product. Fluid-energy mills or pulverizing mills were used for ultrafine grinding of the talc ore. In a few instances, the ore was calcined prior to milling to increase its whiteness.

Flotation processes were used when the desired product purity was not obtained by using conventional processing. The milled ore was chemically treated, passed through rougher and cleaner cells to separate the talc from the gangue material, dried in a flash dryer, and ground in a pulverizer. Ore composition, reagent type, pulp density, pH of the flotation system, and

residence time in the flotation circuits determined flotation efficiency.

U.S. mine production of crude talc increased 3% in tonnage and decreased 6% in value. Mines that operated in Montana, New York, Texas, and Vermont accounted for 94% of domestic talc production. Montana led all States in the tonnage and value of talc produced.

Pfizer Inc. finalized plans and began construction of a talc beneficiation plant in Montana. The company will use flotation processing to remove impurities from the ore. The flotation process will permit the company to recover talc from pond tailings, mill rejects, and ore stockpiles and compete in markets that it did not previously service.⁴

Pyrophyllite

Pyrophyllite was produced by four companies operating five mines in two States. Production was from hydrothermally altered volcanic deposits of acidic composition. The deposits consisted of pyrophyllite with sericite, andalusite, and/or quartz as accessory minerals. After removing the overburden, the ore was either stripped using bulldozers and scrapers or extracted using conventional open pit mining techniques. The ore was dried and then jaw crushers and gyratory crushers were used to reduce the size of the mill feed. Ball, pebble, or roller mills were used to produce the final product.

U.S. mine production of crude pyrophyllite decreased 17% in tonnage due primarily to the closure of one mine in North Carolina. North Caro-

² Does not include value for pyrophyllite.

³ Data may not add to totals because of independent rounding.

lina accounted for most of the domestic production.

CONSUMPTION AND USES

Talc was used in a wide variety of products because of its softness (1 on the Mohs' scale), purity, fragrance retention, whiteness, luster, moisture content, oil and grease adsorption, chemical inertness, low electrical conductivity, high dielectric strength, and high thermal conductivity. These properties were not universal to all talcose materials because of differences in their mineralogical composition and particle shape. Mineral content was extremely important because it determined the end use for the material. Generally, only two or three of these properties were critical for any one application.

U. S. consumption of talc increased 7% in 1989. The major consumer of talc was the construction industry, with applications in ceramic tiles and sanitary ware, joint compounds, paint, plastics, and roofing. The end-use distribution was ceramics, 32%; paint, 15%; paper, 14%; roofing, 10%; plastics, 10%; cosmetics, 5%; and insecticides, refractories, rubber, and other, 14%.

Pyrophyllite, being different in com-

position from talc, did not have the same applications as talc. Properties such as softness (1 to 2 on the Mohs' scale), whiteness, chemical inertness, high melting point, low electrical conductivity, and high dielectric strength made pyrophyllitic materials useful for ceramics and refractories.

U. S. consumption of pyrophyllite decreased 11% in tonnage in 1989. The largest portion, 60% of domestically produced ground pyrophyllite, was used in ceramics; 18% in refractories, 9% in insecticides, and 13% in paint, plastics, roofing, rubber, and other.

PRICES

Talc prices varied depending on the quality and on the degree and method of processing. The unit value of crude talc was \$23 per ton. The average unit value of processed talc was \$107 per ton. The average unit values of crude and processed pyrophyllite were slightly higher in 1989 than in 1988. Unit values for imported crude and ground talc ranged from \$62 per ton to \$278 per ton for quantities greater than 1,000 tons. The average unit value for all imported talc was \$157 per ton. Unit values for exported talc ranged from \$17 per ton

to \$162 per ton for quantities greater than 1,000 tons and averaged \$90 per ton for all exports.

Prices, quoted by the American Paint & Coatings Journal, December 26, 1989, in U.S. dollars per metric ton for paint-grade talc in carload lots were as follows:

Canada: Fine micron, Hegman No. 6	\$226
Montana: Ultrafine grind, Hegman No. 6	243
New York:	
Nonfibrous, bags, mill:	
98% through 325 mesh	99
99.6% through 325 mesh	115
Trace retained on 325 mesh	182

Approximate equivalents, in dollars per metric ton, of price ranges quoted in Industrial Minerals (London), December 1989, for talc, c.i.f. main European ports, were as follows:

Norwegian:	
Ground (ex store)	\$168-\$185
Micronized (ex store)	221- 309
French, fine-ground	212- 336
Italian, cosmetic-grade	309
Chinese, normal (ex store):	
UK 200 mesh	254
UK 325 mesh	265
New York, paint, minimum 20-ton lot	165

FOREIGN TRADE

Beginning in 1989, the U. S. Bureau of the Census adopted the Harmonized System for reporting commodity imports and exports. Talc export categories under the Harmonized System were unchanged from those of previous years. All talc imports under the Harmonized System will be reported as crude, ground, or cut. The category "Talc, n.s.p.f." was discontinued.

Talc exports increased 23% in tonnage and 35% in value. Mexico remained the largest importer of talc, followed by Canada, Japan, and Belgium-Luxembourg. Talc imports decreased 2% in tonnage and 1% in value. Australia and Canada provided 77% of all talc imports.

WORLD REVIEW

The United States remained the world's largest talc producer, and Japan remained the largest pyrophyllite producer. China, Japan, and the United States accounted for 44% of the world's talc and pyrophyllite production.

Capacity

The data in table 6 are annual rated capacity for mines and refineries as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Austria

Talkumwerke Naintsch Ges.mbH, Österreichische Talkumindustrie Ges.-mbH., and Naintsch Mineralwerke Ges.-mbH were reorganized as Naintsch Mineralwerke Ges.mbH. With the consolidation of these companies, Naintsch Mineralwerke Ges.mbH is the only operator in the Rabenwald talc district. Three mines and mills will be operated for a total production capacity of 150,000 tons per year. Markets include bitumen, ceramics, paints, paper, and plastics.⁵

China

The United Nations Fund for Natural Resources Exploration signed an agreement with China to explore for pyrophyllite deposits in Fujian province. The project will entail geological mapping, trenching and pitting, drilling, and sampling. Previous work indicated reserves of 19 million tons of pyrophyllite in the province.⁶

United Kingdom

The Shetland Islands Council granted permission to Shetland Talc

Ltd. to begin mining a talc-magnesite deposit at Cunningsburgh. The deposit contains 19,000 tons of rock with a composition of 95% talc and whiteness of 90 to 92. Shetland Talc is a joint venture between Anglo-European Minerals Ltd. and Dalriada Mineral Ventures Ltd.⁷

OUTLOOK

The average annual growth in domestic demand for talc and pyrophyllite was 1.4% between 1970 and 1989 and 0.4% between 1980 and 1989. Demand averaged between 900,000 and 1,000,000 tons per year for this period. Relative increases and decreases in demand have been the result of minor market fluctuations rather than long-term trends. Demand for talc and pyrophyllite is expected to continue to fluctuate around 1 million tons per year in the near future.

Ceramics will continue to be the major domestic end use for talc, followed by consumption in paint, paper, plastics, roofing, and cosmetics, in descending order. For pyrophyllite, the major domestic end uses will continue to be in ceramics and refractories.

^e Estimated. ^p Preliminary. ^r Revised.¹ Table includes data available through May 11, 1990.² In addition to the countries listed, Czechoslovakia and Turkey produce talc, but available information is inadequate to make reliable estimates of output levels.³ Reported figure.⁴ Total of beneficiated production, salable direct shipping production, and that consumed by consumers.⁵ Data based on Nepalese fiscal year beginning mid-July of year stated.

THALLIUM

By Thomas O. Llewellyn

Mr. Thomas O. Llewellyn is a physical scientist with the Branch of Nonferrous Metals. He has covered thallium for 3 years. Domestic survey data were prepared by Lura Nightlinger, Nonferrous Metals Data Section.

In 1989, domestic demand for thallium metal was met by imports.

Thallium is a trace element with an estimated average abundance of 2.2 parts per million in zinc sulfide ores, and is a byproduct recovered from flue dust and residues collected in the smelting of zinc as well as copper and lead ores. There are a number of rare thallium minerals found in nature, which have no commercial importance as sources of thallium metal.

CONSUMPTION AND USES

Based on import data and discussions with metal traders, the domestic consumption of thallium in 1989 was estimated to be 950 kilograms, about 5% higher than 1988. Thallium was used in superconductivity research, gamma

radiation-detection equipment, additives for changing the refractive index and density of glass, low-temperature mercury-thallium alloy switches, high-density liquids, alloys, photosensitive devices, and radioactive isotopes for cardiovascular diagnostic procedures. Very few foreign countries used thallium sulfate as an ingredient in rodenticide. These countries were in the process of banning its use for such purposes because of its high toxicity to humans.

PRICES

Thallium metal was sold at various prices during the year according to its purity. Metal traders reported that the average price of thallium metal in 100-kilogram lots ranged from \$170 per kilogram for 99.9%-pure thallium

metal to about \$230 per kilogram for 99.999%-pure metal. The average value per kilogram of unwrought thallium metal and waste and scrap imported into the United States was estimated to be about \$105 per kilogram.

FOREIGN TRADE

Thallium materials were imported from Belgium, the Federal Republic of Germany, and Japan. Belgium remained the principal source of imported material and increased its share of total U.S. thallium imports from 72% in 1988 to approximately 95% in 1989.

Effective January 1, 1990, the import duty for unwrought thallium, and waste and scrap (Harmonized Code 8112.91.6000) was 5.5% ad valorem for most favored nations (MFN) and 25% ad valorem for non-MFN.

TABLE 1
U.S. IMPORTS FOR CONSUMPTION OF THALLIUM,¹ BY COUNTRY

Country	Compounds			Unwrought and waste and scrap	
	Gross weight (kilograms)	Content ² (kilograms)	Value	Gross weight (kilograms)	Value
1988:					
Belgium	250	200	\$36,955	306	\$38,409
Germany, Federal Republic of	77	61	10,898	—	—
Japan	175	140	11,372	—	—
Total	502	401	59,225	306	38,409
1989: ³					
Belgium	—	—	—	1,135	116,402
Germany, Federal Republic of	—	—	—	15	3,104
Japan	—	—	—	23	3,895
Total	—	—	—	1,173	123,401

¹ Because of the implementation of the Harmonized Tariff System in Jan. 1989, import categories for 1989 are not necessarily comparable to those in 1988.

² Estimated by the Bureau of Mines.

³ Beginning in 1989, only data for unwrought and waste and scrap are available.

Source: Bureau of the Census.

WORLD REVIEW

Reserves

World production data for thallium were not available. The U.S. reserves in zinc ores were estimated to be 32,000 kilograms. Rest-of-world reserves were estimated to be 345,000 kilograms of thallium.

OUTLOOK

In the short-term, the United States is not expected to resume recovery of refined thallium. The toxicity of thallium is the factor that was expected to continue to influence domestic dependence on foreign sources for its supply.

BACKGROUND

Technology

In February 1988, University of Arkansas scientists were the first to report the use of thallium in bulk superconductor formulations. Superconductors are materials that have no resistance to electric currents, when they are cooled to a sufficiently low temperature, called the critical temperature. Current low-

temperature superconductors, principally made from alloys of the metals niobium and titanium, become superconductors when chilled to a liquid-helium temperature of about 4 K (-269°C). The critical temperature of the thallium-based superconductors were among the highest of superconductors developed.

In 1989, scientists at the International Business Machines Corporation received the first patent in the United States for a high-temperature superconductor compound formulation using thallium.¹ The new high-temperature superconductors, principally made of ceramic materials such as oxides of thallium, barium, calcium, and copper, become superconductors when chilled to above liquid-nitrogen temperature of 77 K (-196°C). Liquid-nitrogen is easier to handle, cheaper to produce, and a much more efficient coolant than liquid-helium.

A survey study by the Argonne National Laboratory in Gaithersburg, MD, was made to determine whether future commercialization of superconductors could be impaired by price or availability of the constituent elements. This survey of the supply and demand factors affecting certain high-temperature superconductor materials, such as bismuth, barium, rare-earths, strontium, thallium, and yttrium lead the researchers to con-

clude that, only in the case of thallium were large price increases and shortages likely to occur.

Operating Factors

Toxicity.—Thallium metal and its compounds are highly toxic; they should be handled with extreme care and require the use of rubber gloves. It can be absorbed into the human body by skin contact, ingestion, or by inhaling dust or fumes. The element is not quickly eliminated from the body, therefore, absorption of subtoxic quantities eventually may accumulate to a toxic level.

THORIUM

By James B. Hedrick

Mr. James B. Hedrick, a geologist and physical scientist with the Federal Government for 12 years, has been the commodity specialist for thorium since 1982. Domestic survey data were prepared by Mr. Kevin Bacon, mineral data assistant. International data tables were prepared by Mr. Harold Willis, international data assistant.

Domestic consumption of refined thorium products declined, according to the Bureau of Mines, U.S. Department of the Interior. Most thorium produced in the world was recovered as a byproduct of refining monazite for the rare earths. Thorium-bearing monazite was recovered primarily as a byproduct of mineral sands mined for titanium and zirconium minerals or tin minerals in Australia, Brazil, China, India, Malaysia, Republic of South Africa, Taiwan, Thailand, and the United States. None of the domestically produced monazite was refined in the United States. Essentially all of the thorium compounds and alloys used by the domestic industry

were derived from either imports or stockpiled material.

Limited demand for thorium, relative to the rare earths, continued to create an extensive world oversupply of thorium residues. Excess thorium, not designated for commercial use, was either stored for potential use as a nuclear fuel or disposed of as a radioactive waste. Major nonenergy uses were in refractory applications and mantles for incandescent lanterns. Thorium continued to be used as a source of nuclear energy at one electric powerplant in Colorado.

Thorium's natural radioactivity represented a significant problem to those companies involved in its mining, processing, and disposal.

LEGISLATION AND GOVERNMENT PROGRAMS

Public Law 100-180, the U.S. Department of Defense Authorization Act for Fiscal Years 1988 and 1989, authorized the disposal of 4,536 kilograms (10,000 pounds) of thorium nitrate from the National Defense Stockpile (NDS) in fiscal year 1989. In fiscal year 1990, Public Law 100-456, The National Defense Authorization Act of 1989, authorized the disposal of all stocks of thorium nitrate in excess of the NDS goal of 272,155 kilograms (600,000 pounds). Thorium nitrate in excess to goal at yearend 1989 totaled 2,973,752 kilograms (6,556,000 pounds).

PRODUCTION

Associated Minerals (USA) Ltd., a wholly owned subsidiary of the Australian-based firm of Renison Goldfields Consolidated Ltd. of Australia, was the principal producer of thorium-containing monazite in the United States. Monazite was produced by Associated Minerals as a byproduct of processing mineral sands mined for titanium and zirconium minerals at Green Cove Springs, FL. Imperial Mining Co., primarily an industrial sand and gold producer, recovered byproduct monazite as a constituent of a mixed heavy-mineral concentrate at Marion, NC.

CONSUMPTION AND USES

Domestic thorium producers reported consumption of an estimated 57.2 tons of thorium oxide equivalent in 1989, a decrease of 6.4 tons from the 1988

TABLE 1

TABLE 2
**U.S. COMPANIES WITH THORIUM PROCESSING AND
FABRICATING CAPACITY**

Company	Plant location	Operations and products
Atomergic Chemetals Corp.	Plainview, NY	Produces oxide, fluoride, metal.
Bettis Atomic Power Laboratory	West Mifflin, PA	Nuclear fuels, Government research and development.
Cerac Inc.	Milwaukee, WI	Produces ceramics.
Ceradyne Inc.	Santa Ana, CA	Produces advanced technical ceramics.
Chicago Magnesium Casting Corp.	Blue Island, IL	Magnesium-thorium alloys.
Coleman Co. Inc.	Wichita, KS	Produces thoriated mantles.
Controlled Castings Corp.	Plainview, NY	Magnesium-thorium alloys.
GA Technologies Inc.	San Diego, CA	Nuclear fuels.
W.R. Grace & Co., Davison Chemical Div.	Chattanooga, TN	Produces thorium compounds from monazite.
GTE Sylvania	Towanda, PA	Produces thoriated welding rods.
Hitchcock Industries Inc.	South Bloomington, MN	Magnesium-thorium alloys.
Phillips Elmet	Lewiston, ME	Produces thoriated welding rods.
Rhône-Poulenc Inc.	Freeport, TX	Produces thorium nitrate from an intermediate compound of monazite.
Spectrulite Consortium Inc.	Madison, IL	Magnesium-thorium alloys.
Teledyne Cast Products	Pomona, CA	Magnesium-thorium alloys.
Teledyne Wah Chang	Huntsville, AL	Produces thoriated welding rods.
Union Carbide Corp., Nuclear Div.	Oak Ridge, TN	Nuclear fuels; tests quantities.
Wellman Dynamics Corp.	Creston, IA	Magnesium-thorium alloys.
Westinghouse Materials Co. of Ohio ¹	Cincinnati, OH	Produces compounds and metals; manages DOE thorium stocks.

¹Manager of Department of Energy stocks.

level. Nonenergy uses accounted for most of the total consumption. The decrease was the result of lower demand in refractory and ceramic applications. The approximate distribution of thorium by end use, based on data supplied by producer, processors, and several consumers, was as follows: refractory applications, 75%; lamp mantles, 15%; aerospace alloys, special use light bulb elements, welding electrodes, and other applications, 10%.

Thorium oxide (thoria) has the highest melting point of all metal oxides, 3,300° C, a property that contributed to its use in several refractory applications. Applications included high-strength, high-temperature ceramics, investment molds, and crucibles.

Thorium nitrate was used in the manufacture of mantles for incandescent "camping" lanterns and in natural gas and oil lamps. Thorium nitrate was also used to produce thoriated tungsten

welding electrodes. Thoriated tungsten electrodes were used to join stainless steels, nickel alloys, and other alloys that require a continuous and stable arc to achieve quality welds.

The nitrate form was also used to produce thoriated tungsten elements used in the negative pole of magnetron tubes. Thorium was used because of its ability to emit electrons at relatively low temperatures when heated in a vacuum. Magnetron tubes were used to emit electrons at microwave frequencies to heat food in microwave ovens and in radar communication.

Thorium was used in other types of electron-emitting tubes, elements in special use light bulbs, high-refractivity glass, radiation detectors, computer memory components, catalysts, photoconductive films, target materials for X-ray tubes, and fuel-cell elements.

Most thorium used in metallurgical applications was alloyed with magne-

sium. Magnesium-thorium alloys used by the aerospace industry are lightweight and have high-strength and excellent creep resistance at elevated temperatures. Small quantities of thorium were used in dispersion-hardened nickel alloys for high-strength, high-temperature applications.

Thorium's only domestic energy application was as a nuclear fuel in the thorium-232/uranium-233 fuel cycle at one commercial reactor at Fort St. Vrain, CO.

STOCKS

Government stocks of thorium nitrate in the NDS were 3,223,993 kilograms (1,541,810 kilograms of equivalent thorium oxide) on December 31, 1989. The NDS goal at yearend was 272,155 kilograms of thorium nitrate (130,153 kilograms of equivalent thorium oxide). All stocks in excess of goal were authorized for disposal.

The U.S. Department of Energy's inventory at yearend was 1,244,027 kilograms of thorium oxide equivalent contained in ore, metal, and various compounds.

PRICES

The price range of Australian monazite (minimum 55% rare-earth oxide including thoria, f.o.b.), as quoted in Australian dollars (A\$)¹, increased from A\$700-A\$780 per ton at yearend 1988, to A\$780-A\$880 per ton at yearend 1989. Changes in the United States-Australia foreign exchange rate in 1989, resulting from the weakness of the Australian economy, caused the corresponding U.S. dollar to be up \$0.06 against the Australian dollar at yearend. The U.S. price range, converted from Australian dollars, increased from US\$598-US\$666² per ton in 1988 to US\$616-US\$695³ per ton in 1989.

Thorium prices quoted by Magnesium Elektron, Flemington, NJ, at yearend 1989 were \$87.29 per pound for thorium hardener (80% Mg-20% Th) in single drum quantities and \$16.26 per pound for thorium-containing HZ-32 magnesium alloy ingot.

WORLD REVIEW

Australia

Rhône-Poulenc SA of France continued its quest to gain approval for a rare-earth separation plant at Pinjarra, Western Australia. Environmental concerns related to the disposal of naturally radioactive thorium halted the project in 1988. Rhône-Poulenc proposed a new plan to dispose of the thorium nitrate by injecting it into deep wells drilled into a confined saline aquifer.⁴

Brazil

Production of thorium-containing monazite concentrates in 1987 was 4,332 tons: 177 tons from the State of Espírito Santo, a decrease from the 197 tons produced in 1986; 3,271 tons from the State of Rio de Janeiro, a decrease from the 1986 production of 3,421 tons; and 884 tons from the State of Bahia, which produced no monazite in 1986.

Measured reserves of monazite were

36,806 tons. Estimated thorium content of these reserves was 2,400 tons of thorium oxide equivalent. Monazite reserves were located in the States of Bahia, Espírito Santo, Minas Gerais, and Rio de Janeiro.⁵

Madagascar

QIT-Fer et Titane Inc. (QIT) announced it would delay development of its joint-venture heavy-mineral sands project at least until 1995. Planned monazite capacity of the project was 6,000 tons per year.

South Africa, Republic of

General Mining Corp. Ltd. continued to produce byproduct monazite from its Naboomspruit fluorspar operations in the Transvaal. Monazite is reportedly removed during processing by wet high-intensity magnetic separators to lower the undesirable phosphate levels in the final fluorspar product.⁶

Taiwan

Pacific Ocean Rare Earth Industry

Co. (POR), continued production of heavy minerals, including monazite, on the west coast of Taiwan from Taichung to Tainan. Reserves of monazite in Yuanlin and Chiai Counties were reported at 50,000 tons. Ore from the area is shipped to Hsinchu for processing and separation of the rare earths from monazite. Monazite capacity of the Hsinchu plant is 1,000 tons per year.

TIN

By James F. Carlin, Jr.

Mr. Carlin is a physical scientist with the Branch of Nonferrous Metals. He has covered tin for 10 years. Domestic survey data were prepared by Regina R. Coleman, Nonferrous Data Section. International data tables were prepared by Harold Willis and Giovanni Jacarepaqua, International Data Section.

For the ninth consecutive year, there was a world excess of tin, largely due to increased production from several major producers. The excess narrowed somewhat, but was believed to be about 30,000 metric tons at yearend. Repercussions from the exhaustion of the International Tin Council (ITC) fund to support the tin price in late 1985

continued throughout 1989. Legal actions continued against the London Metal Exchange (LME) and the ITC. The actions were brought by the tin dealers and banks who had alleged monetary losses due to activities of the LME and ITC in late 1985. The various parties involved in the legal conflicts showed a willingness to compromise, and toward yearend it appeared that an

out-of-court settlement was imminent. The tin contract was reintroduced to trading on the LME after being suspended for 3 years.

The price of tin rose considerably during the first 4 months of 1989, but then declined to levels around those of January for the balance of the year as increased mine production from some leading producers aggravated an oversupply situation. World tin mine and smelter output rose slightly as the higher prices at the start of the year encouraged production. In the United States, there was increased interest in detinning used tin cans because of dwindling dumpsites and new detinning technology. A major detinning facility was started in 1989, while another one neared completion; both were intended to process mostly used tin cans. A meeting was held in Geneva, Switzerland, March 29 through April 7, attended by the world's major tin producers and users. At this meeting, the terms of reference were adopted for a proposed International Tin Study Group (ITSG).

TABLE 1
SALIENT TIN STATISTICS
(Metric tons unless otherwise specified)

	1985	1986	1987	1988	1989

^e Estimated. ^P Preliminary. ^r Revised. NA Not available; the tin contract was suspended from London Metal Exchange trading on Mar. 12, 1986. W Withheld to avoid disclosing company proprietary data; U.S. mine production for 1985-89 was negligible.

¹ Reported figure.

² Exports (excluding reexports).

³ Because of the implementation of the Harmonized Tariff System beginning in Jan. 1989, export/import categories for 1985-88 are not necessarily comparable with those in 1989.

⁴ Prices quoted for 10 months only.

⁵ Beginning in 1985, Kuala Lumpur replaced Penang as the reference market.

LEGISLATION AND GOVERNMENT PROGRAMS

The National Defense Stockpile (NDS) was managed by the Secretary of Defense for the first full year, with day-to-day operations guided by the Defense Logistics Agency.

The Department of Defense sold 2,775 tons of tin in 1989, all of which represented payment for the Department of Defense's Ferroalloy Upgrading Program, which started on April 11, 1984. At yearend, the NDS inventory was 171,233 tons; the stockpile goal was 42,674 tons.

Federal laws provided a depletion allowance of 22% for domestic operations and 14% for U.S. companies producing in other countries.

PRODUCTION

One mine operating in Alaska produced tin concentrates. Total output amounted to only a small fraction of domestic tin requirements.

The only domestic tin smelter, Tex-Tin Corp., in Texas City, TX, recovered tin primarily from imported and domestic concentrates, secondary tin-bearing materials, and its own stockpile of tin residues and slags. The smelter's main source of tin concentrate was Peru. The facility also produced a line of solder. At midyear, the smelter ceased tin production for the balance of the year and converted its equipment to processing copper scrap, from which it produced copper blister.

The United States was believed to be the world's largest producer of secondary tin. Tin metal recovered from new tinplate scrap and from used tin cans was the only type of secondary tin available as free tin; other secondary tin was available in scrap materials as an alloying ingredient. Secondary tin from recycled fabricated parts was used in many categories of consumption and was a major source of material for the solder and the brass and bronze industries. The Steel Can Recycling Association in Pittsburgh, PA, funded and operated by five domestic tinplate producers, sought to advance the collection, preparation, and transportation of can scrap. Also, they began a program of installing representatives in several regions of the United States to work with municipalities, scrap dealers, and detinners to promote the recycling of tin cans.

Until 1989, generally all domestic detinning operations treated only new factory-generated tinplate scrap. This usually came from steel plant tin mills or can plants. Little or no old scrap, such as that from used tin cans, was detinned. This was mostly due to technical difficulty in processing the cans. In recent years, new scrap preparation procedures were developed, especially a new shredding method, that permitted detinning of used tin cans. These developments, combined with increased incentives for municipal recycling of trash due to a lack of landfill space, set the stage in 1989 for large-scale detinning of used tin cans. The domestic detinning industry responded with sev-

eral startups and plant constructions. Late in the year, Proler International Corp. started up the world's largest detinning facility in Houston, TX. The new plant was capable of recycling 163,000 tons of tin-plated cans and clippings per year, the equivalent of 2.5 billion tin cans per year. The operation involved the shredding of feedstock followed by continuous detinning in a series of rotating cylinders. The separated product was sold to various tin refiners for refining. Plans called for the detinned bales of high-quality scrap-steel to be processed by Buffalo Steel Co., a proposed \$260 million minimill joint venture of Proler and two other companies. Buffalo Steel planned to locate the new steel mill near Houston, TX, and intended to purchase the former USX Corp. facilities at Baytown, TX, for its operation, provided all permits could be obtained.

AMG Resources Corp. was completing construction of a plant at St. Paul, MN, to recycle cans. This facility would have an electrolytic detinning system to process up to 40,000 tons of tin cans annually. The extracted tin was to be utilized in the chemical industry, and the scrap steel was to be shipped to steel mills and foundries. AMG also was completing a detinning plant near Princeton, NJ, that was designed to process mostly used tin cans.

In future years, these developments should provide increased tonnages of secondary tin and should augment the supply of domestic scrap steel, which has recently been in short supply.

CONSUMPTION AND USES

Primary tin consumption decreased slightly from that of 1988. The decline tended to affect several usage categories modestly and was most pronounced in brass and bronze, solder, and chemicals. The declines were attributable to increased usage of secondary tin by the brass and bronze and solder makers because of a sharp tin price increase in the first half of the year. Tinplate replaced solder as the largest application for primary tin, followed by chemicals. Although the number of tinplate cans increased absolutely in 1989, tinplate continued to lose market share to aluminum in the metal can category. Tin-plated steel and tin-free steel accounted for 29% of the 120 billion cans shipped domestically and aluminum accounted for 71%; in 1988, when steel accounted for 30% and aluminum for 70%, 114 billion cans were shipped. Aluminum held an overwhelming segment of the beverage can market, while steel predominated in the food can and the general line markets.

PRICES

The price of tin metal, as published in Metals Week, rose steadily during the first 4 months of the year. It peaked in April, then steadily declined the balance of the year, finishing the year at a lower price than in January.

TABLE 2

SECONDARY TIN RECOVERED FROM SCRAP PROCESSED AT DETINNING AND OTHER PLANTS IN THE UNITED STATES

¹ Includes tin metal recovered at detinning and other plants.

² Includes tin recovered from copper, lead, and tin-base scrap.

³ Includes foil,terne metal, and cable lead.

⁴ Based on Metals Week composite price.

After being suspended from LME trading since early 1986 because of problems related to the late 1985 tin market "collapse," tin was reintroduced to daily LME trading on June 1. The new LME contract was quoted in U.S. dollars and was for high-grade tin. Also, a new futures contract for tin metal was available for up to 15 months.

The Kuala Lumpur Commodities Exchange (Malaysia) continued as an active tin trading medium.

FOREIGN TRADE

In 1989, the United States implemented the Harmonized Tariff System (HTS), which resulted in changes in classifications for some materials.

TABLE 4

1988 ^r	149,054	2,375,809	11,582	4.9
1989	153,542	2,263,769	11,764	5.2

^r Revised.

¹ Includes small tonnage of secondary tin and tin acquired in chemicals.

Some data that were aggregated under one category in the Tariff Schedule of the United States (TSUS) classification system were separated under the HTS, and some data that were separated in the TSUS system were aggregated in the HTS. Consequently, trade data that can be identified specifically with one commodity may have changed, and data for 1989 were not comparable with that of 1988 and previous years.

Imports for consumption of tin concentrate declined sharply, reflecting the reduced activity at the TexTin smelter. Imports of tin metal declined substantially, indicating that consumers were drawing down stocks and also utilizing

tin metal from NDS releases. Brazil remained the major source for imported tin metal, followed by Indonesia, Bolivia, and China.

Imports of tin in all forms (ore and concentrate, metal, and waste and scrap) remained free of U.S. duty.

WORLD REVIEW

The Sixth International Tin Agreement, which commenced on July 1, 1982, officially ended on July 1, 1989. In reality, ITC ceased functions a year earlier when it exhausted operating

funds and ceased publications. The United States was not a member of the agreement.

Legal actions continued on behalf of tin dealers and banks that had lost money, allegedly because of activities of the LME and the ITC in late 1985, when the ITC exhausted its credit to support the price. Throughout the year, meetings were held between the various parties involved in the lawsuits to reach an out-of-court settlement. Toward yearend, considerable progress was reported toward such an agreement on a basis that would award the injured parties a financial settlement that was only a fraction of the value originally sought.

The Association of Tin Producing Countries (ATPC), headquartered in Kuala Lumpur, Malaysia, and composed of seven major producer nations—Australia, Bolivia, Indonesia, Malaysia, Nigeria, Thailand, and Zaire—completed its fifth year. Two major tin producing countries, Brazil and China, continued to decline ATPC membership, although each one nominally assented to cooperate with most ATPC goals. ATPC maintained its Supply Rationalization Scheme, basically export controls, for member countries during the year. This was aimed at trying to reduce the long-standing world excess tin supply. Industry sources estimated the world tin surplus at about 30,000 tons at yearend 1989.

During March 29 to April 7, 1989, meetings were held in Geneva, Switzerland, under the auspices of the United Nations Conference on Trade and Development (UNCTAD) to further explore the possibility of establishing the ITSG. These meetings, at which the United States was represented, made considerable progress, and terms of reference for the proposed organization were adopted. To bring the ITSG into being, countries representing at least 70% of world tin trade must ratify the terms of reference.

Australia

The Renison Bell Mine in Tasmania, owned by Renison Consolidated Goldfields Ltd., remained the largest tin mine, accounting for about 90% of mine output. Renison Bell was the world's largest hard-rock underground tin mine and a relatively low-cost producer with substantial high-grade reserves. The entire output of tin concen-

trate from Renison was believed to have been toll-smelted in Malaysia. Renison continued direct sales of refined tin to large U.S. user firms from an affiliate office in Green Cove Springs, FL.

Renison was considering construction of a new tin smelter. Australia's only tin smelter, in Sydney, closed in the late 1980's when tin prices declined sharply.

Greenbushes Ltd. continued to mine

tin and tantalum near Perth. This operation usually produces about 200 to 300 tons of tin concentrate annually, which the firm planned to boost over the next few years as part of its goal of increasing tantalum output.

Bolivia

The tin industry continued to recover from the low production levels of 1986 and 1987, when low tin prices caused a

massive restructuring of the mine and smelter sector.

Historically, the Huanuni tin mine, located in the Department of Oruro, has been the richest underground tin mine. The mine was closed in 1986 but reopened in mid-1988 following modernization. The modernization program included construction of a new 1,000-ton-per-day treatment plant, opening up new crosscuts and drifts, and improvements to the ventilation and pumping systems. During 1989, capacity of the mine was 3,600 tons of tin-in-concentrates annually, with the output being delivered to Corporación Minera de Bolivia's (COMIBOL) metallurgical complex at Vinto. COMIBOL was reportedly seeking a joint-venture partner for Huanuni.

The Bolivar tin-zinc-silver mine, located in the Department of Oruro, operated at a loss in 1989. Recently, this operation was the subject of a favorable feasibility study by Preussag of the Federal Republic of Germany. Development work was proceeding to attempt to increase the reserves. Funding was assisted by a \$12 million loan from the Federal Republic of Germany. In addition, installation of a 750-ton-per-day concentrator was planned at a cost of \$30 million. The new concentrator was expected to be funded by the West German Government, the International Development Bank, and COMIBOL.

The Caracoles tin mine, located in the Department of LaPaz, reportedly operated profitably in 1989, and a rich new vein of tin ore was found that averaged 7% across a 1-meter band.

The Catavi-Siglo tin mine, located in the Department of Potosi, was leased by COMIBOL to four cooperatives employing 4,500 miners. The cooperatives produced about 3,600 tons. COMIBOL was reportedly reevaluating the tin tailings at Catavi and seeking a joint-venture partner to assess the possibility of producing tin concentrates from them; these tailing dumps reportedly contain about 35 million tons grading about 0.3% tin. A Spanish firm, ERAL, was also preparing a pilot project for testing various treatment processes.

The Government-owned Vinto tin smelter, since reopening in 1987, continued to be profitable. With a capacity to treat 20,000 tons of tin ore annually, Vinto officials were reportedly attempting to attract foreign tin ore.

During 1989, there was reportedly an active market in smuggling tin concentrates from Brazil into Bolivia; the concentrates apparently were included in Bolivian production data.

Brazil

Brazil was the world's leading tin producer for the second consecutive year. Tin mine and smelter production was mostly privately owned. Tin was mined from both alluvial and lode deposits. Brazilian mines were generally considered the lowest cost to operate in the world. Brazil was not a member of the ATPC, but generally agreed to co-operate with the spirit of its guidelines and restrict its tin exports.

The Paranapanema Group was the largest private tin producer in the world. The company owned and operated five tin mines. The mines were Capiore, in

the State of Amapa; Massangana (also known as C-75, Ariqueemes, and Serinha), in the State of Rondônia; São Francisco, in the State of Mato Grosso; São Raimundo, in the State of Pará; and Iarape Preto and Pitinga, both in the State of Amazonas.

Pitinga, the country's largest tin mine, used four Elliot bucketwheel dredges and mined to a depth of 6 to 8 meters. The mine site employed nine floating wash plants and seven gravel pump plants. The dredging capacity was about 13 million cubic meters annually. Total investment at Pitinga was about \$115 million. Management was in the process of developing mining of

a soft weathered tin ore, separate from the alluvium, at the Pitinga deposit. Officials also were studying the feasibility of constructing a tin smelter at Pitinga.

Tin mining activity by "garimpeiros" or independent miners increased. Estimated to number 10,000 individuals, "garimpeiros" worked an area about 6 by 12 kilometers in the State of Rondônia, with no specific limits to each person's mining area and with only limited local government control.

Government officials believed that large quantities of tin ore were being smuggled out of the country and indicated that the problem was centered in the Western Amazon State of Rondônia, where tin ore was being trucked to the Madeira and Marmore Rivers, then barged across these rivers to neighboring Bolivia. Thus, some Brazilian tin mine production eventually surfaced as Bolivian production.

Canada

The East Kemptville Tin Corp. Ltd., owned by Rio Algom Ltd., continued tin mining operations at its open pit at East Kemptville, Nova Scotia. The mine contained 41 million tons of high-grade tin ore and 15 million tons of low-grade tin ore. The tin ore at the site is complex and concentration by gravity and magnetic methods was reportedly difficult. In recent years, Rio worked to improve the tin recovery rate by improving the grinding, dewatering, and gravity equipment, and by installing a new flotation circuit. In 1989, Rio sought to improve recovery of copper and zinc and planned to install column flotation cells.

Cominco Ltd. produced a small quantity of tin-lead alloy at its Trail, British Columbia, smelter as a byproduct of the production of indium.

China

Yunnan Tin Corp., Gejiu City, Yunnan Province, was the largest tin producer. It operated 5 underground mines, 7 open pit mines, 10 mineral dressing plants, and 1 smelter, giving it an annual mine production capacity of 7.5 million tons of tin ore, while the smelter capacity was 20,000 tons of refined tin yearly. Both surface alluvial deposits and underground lode deposits were worked. The high-grade alluvial deposits, after 100 years of exploitation, were virtually de-

pleted. In 1989, low-grade alluvial tin ores of fine particle size, tailings, and the underground lode were the main sources.

For smelting and refining, Yunnan used reverberatory smelting of tin concentrate; pyrometallurgical refining of tin metal; electrolytic separation of tin-lead alloy; and tin slag fuming. Yunnan developed a continuous electrothermal crystallizer designed to remove lead and bismuth using the different melting points and specific gravities of tin and lead-tin alloy; direct recovery of tin was increased by 6% over former methods, and manning levels reduced by 50% in 1989. Several other tin smelters around the world utilized Yunnan crystallizer technology.

The DaChang Tin Mining Bureau Mine, located in the southwest region of Guangxi, China, was being expanded and was expected to become the country's largest tin mine in a few years.

India

Hindustan Zinc Co. announced plans to build a 3,000-ton-per-year domestic tin smelter to meet part of the country's demand.

Indonesia

Tin mining occurred predominantly at offshore locales, with large-scale dredging the preferred method. P.T. Tambang Timah (P.T. Timah), the Government-owned mining firm, ranked as one of the world's largest tin-mining organizations, accounted for about 80% of Indonesia's tin output. P.T. Timah's three primary tin production complexes were on the islands of Bangka, Belitung, and Singkep. The facility on Bangka Island accounted for 70% of the firm's tin production.

Timah announced that it intended to direct the extra revenue from sharply higher tin prices in early 1989 toward ensuring long-term growth in tin production, and they increased maintenance, development, and exploration expenditures.

The other leading tin producer was Kobe Tin, owned by Renison Consolidated Goldfields Ltd. (Australia). Kobe also reportedly experienced production gains and invested substantially in tin facilities.

Malaysia

Malaysia Mining Corp. remained the

largest tin-producing organization in the world. A total of 338 tin mines were in operation in 1989, compared with about 800 in 1980. During 1989, 41 gravel pump mines reopened, and 1 dredge restarted due to the impetus of the early 1989 tin price rise. Gravel pump mines accounted for 41% of output, up from 34% in 1988. Dredges accounted for 37% of Malaysia's tin output.

Two large tin smelters on the island of Penang, one owned by Datuk Keramat Sdn. Bhd. and the other owned by Malaysia Smelting Corp. Sdn. Bhd., operated at fairly high levels and made smelter production in Malaysia the largest in the world. Both smelters depended on toll-smelting of imported tin concentrates, especially from Australia, Bolivia, and China.

Mexico

Tin was mined in the three adjoining States of Durango, Zacatecas, and San Luis Potosí in north-central Mexico. The country's major tin mine, the El Perro Mine, was owned by Cía. Minera Pizzuto.

Estano Electro S.A. de C.V. operated a tin smelter at Tlalnepantla, near Mexico City. Fundidora de Estano S.A. operated a tin smelter at San Luis Potosí. Metales Potosí S.A. had a smelter in San Luis Potosí as did Minera de Río S.A. All four smelters processed imported tin concentrates, primarily from Canada and China, as well as domestic concentrates.

Namibia

The Uis Mine, owned by Industrial Minerals Mining Corp. Pty. Ltd., a wholly owned subsidiary of South African Iron and Steel Industrial Corp. Ltd. (Iscor), was the largest producer. Concentrates were shipped directly to the Vanderbijlpark steelworks in the Republic of South Africa, where they provided a large part of Iscor's tin for use in producing electrolytic tinplate.

Nigeria

Five tin-mining companies operated in Nigeria. They were Amalgamated Tin Mines of Nigeria (Holdings) Ltd., Bisichi-Jantar Nigeria Ltd., Kaduna Prospecting Nigeria Ltd., Ex-Lands Nigeria Ltd., and Gold & Base Metal Mines of Nigeria Ltd. All tin concentrates were smelted domestically by

Makeri Smelting Co. Ltd. at Jos, Plateau State.

Peru

The only tin mine in Peru was the San Rafael Mine, near Juliaca, owned by Minsur S.A. The mine was within the northern extension of the Bolivian tin belt. Tin grades averaged 1.8%. Peru remained the major supplier of tin concentrate to the United States.

Portugal

The new Neves Corvo Mine, in its second year as a copper producer, was planning to begin tin production in 1990. This mine was developed by Societed Minera de Neves Corvo (SOMINCOR), owned 51% by the Government-controlled Empresa de Desenvolvimento Mineiro E.P. and 49% by RTZ Corp. PLC. RTZ announced that the tin reserves at this southern Portugal mine were about 2.8 million tons of tin ore with an average grade of 2.6%. The company plans to produce 2,200 tons of tin in 1990 and gradually increase the output to 5,500 tons in 1993. Because tin was a byproduct of copper, tin production costs could be among the lowest in the world.

Beralt Tin & Wolfram Co., headquartered in Lisbon, produced tin, tungsten, and copper concentrates at its underground and processing plants at Minas de Panasqueira in central Portugal. Decades ago, the firm was only a tin producer, but in recent years tin output has declined and tungsten has become its primary product. In 1989, output was about 60 tons of tin concentrate.

Thailand

Tin remained the principal mineral product and export; but, in 1989, tin fell in relative importance as other industries gained. The number of operating tin mines was about 200, located chiefly in the Phang-Nga, Phuket, and Ranong regions. About 60% of the tin was mined with offshore dredges.

Most of the onshore tin mines were idle in 1989. Aokam Tin Co. and Tongkha Harbor Tin Co. continued to operate dredges 10 months per year in the Phuket Bay area, where the dredges were sheltered from monsoons. The largest dredge, Bor Dan, was operated by the Government-owned Offshore Mining Enterprise.

Most domestic tin concentrates were

smelted by the Thaisarco smelter. Because it was not being operated at capacity, it experimented with some foreign concentrates, mostly from China.

United Kingdom

The cost of tin mining in the Cornwall district reportedly was among the highest in the world. Most tin concentrates were shipped to the Billiton smelter in the Netherlands.

The restructuring and downsizing of the Capper Pass tin smelter, owned by RTZ, returned the operation to profitability. Increasingly, the feed came from imported low-grade and complex primary and secondary materials. The plant was also an important producer of byproduct metals such as bismuth and indium.

The attempted purchase by Minorco S.A., based in Luxembourg, of London-based Consolidated Goldfields PLC, was blocked on legal grounds. However, shortly thereafter, Hanson Trust PLC, a British conglomerate, purchased Consolidated for about \$4.8 billion. The purchase was the largest merger in British history. Consolidated operated tin mines in Australia and Indonesia accounting for about 10% of Western World tin output.

Throughout the year, London, as the base for the now defunct ITC and the LME, was the hub of activity related to the numerous lawsuits connected with the 1985 tin market "collapse." Repeated efforts, often clandestine, were made to resolve the conflicts out of court.

CURRENT RESEARCH

Dan Engineering Corp., Denmark, developed a new vacuum distillation furnace for the refining of tin. The furnace reportedly had unique advantages, whether utilized with a primary tin smelter or a secondary recovery facility, for extracting certain impurities or coalloy metals. Dan Engineering indicated the vacuum distillation process was a relatively low-cost procedure effective for high levels of impurities. The furnace was adaptable to handle small quantities in batches or large tonnages continuously. There was no dross from anode or cathode melting; the byproducts were obtained in metal-

lic form and there were no environmental hazards.¹

Work at the International Tin Research Institute (ITRI) resulted in advances for tin compounds used as fire retardants and smoke suppressants in various substrates, especially unsaturated polyesters, rigid polyvinylchloride, natural fibers, and wool.²

Cooperative research by British Steel Corp., Hoogovens IJmuiden (The Netherlands), and Rasselstein A.G., resulted in the development of a nondetachable beverage can end, made from tinplate. Development took place at the Rasselstein Tin Mill in Andernach, Federal Republic of Germany, on a production line capable of producing 200 million can ends annually. This new style end has two buttons etched into it, which are depressed to open the can—one for flow of the beverage, the other for venting. The end remains attached to the can. The new end was commercially available and competed with the traditional aluminum ring-pull end. If commercially successful, this new style end could result in substantial increases in tinplate demand.³

OUTLOOK

Domestic demand for primary tin has been growing slowly during most of the 1980's, and this trend was expected to continue over the next few years. Since 1987, the consumption of tin for tinplate has increased significantly, partly because of higher aluminum prices and partly because of increased recycling of used tin cans using new recovery technologies. This trend also was expected to continue.

There were no known new uses for tin that hold promise for significant future consumption growth.

BACKGROUND

The late 1980's witnessed the disintegration of one of the most enduring and critical components of the tin industry, the ITC, based in London, England. The ITC's demise, the repercussions involving the LME, and subsequent lawsuits, comprised perhaps one of the most significant news events in the entire metals

field since World War II.

The ITC, the latest of several similar tin industry organizations dating back to the turn of the century, was created in 1956. Historically, it had been composed of about 20 to 25 producer and consumer countries, each with voting rights in the council approximating that country's tonnage of either tin produc-

tion or consumption. The goal of the ITC was to stabilize tin supply-demand and tin prices, and to ensure producers a decent profit and users an adequate tin supply at fair prices.

The ITC operated under a complex set of rules. A key feature that allowed it to play a major role in the tin market was the ITC buffer stockpile. The ITC

used this stockpile to influence tin prices by selling tin to protect a predetermined "ceiling" price or by buying tin in another part of the market cycle to protect a predetermined "floor" price. During the 1960's and 1970's, the ITC did a remarkable job in protecting the "floor" prices but was generally unsuccessful in protecting the "ceiling" prices. This was attributed to the relatively small size of the ITC stockpile.

During the 1980's, when the world tin market was generally in an oversupply situation and tin prices weakened, the ITC borrowed funds extensively to support the tin price. Finally, in October 1985, the over-extended ITC exhausted available funds to support the tin price, and lenders would not advance any more credit. This triggered an immediate "collapse" of the world tin market, and by early 1986, trading on the LME was suspended. The crisis soon spread to other metals because many brokers who held tin trading seats on the LME also held positions in metals like aluminum, lead, and zinc. Following this "collapse," the price of tin dropped sharply and remained at historically low levels through 1986, 1987, and 1988.

The collapse was followed by a myriad of lawsuits brought by the creditors, mostly brokers and banks who had loaned or lost money, against the ITC and the LME. The legal actions, mostly centered in London, sought to recover an estimated \$1.5 billion. The ITC, composed of 22 member Governments, denied responsibility for any losses and opposed the legal actions for several years. The U.S. Government was not a party to the matter because it had only been a member of the ITC for one term, the duration of the 5th International Tin Agreement, from 1976-81. The ITC, hampered by lack of operating funds, ceased operations in 1988. Toward the end of 1989, negotiations for an out-of-court settlement of the tangled legal actions were taking place, and a settlement on a reduced value basis was imminent. The LME resumed daily tin trading in early 1989.

One of the most important impacts of the collapse of the tin market was the resultant sharp decline in price for tin metal, which dropped to about one-half of its "precollapse" price by early 1986 and remained low essentially through

1989. These historically low prices caused a market-driven restructuring of the world's tin mining industry. High-cost, low-grade tin mines could not operate profitably and hundreds ceased operation. Although most of the 35 tin producer countries suffered economic hardship during this restructuring, the historically low tin prices offered opportunity to the world's scores of tin consumer countries.

The ATPC, founded in 1983, emerged as a force in the tin world by the mid-1980's as the influence of the ITC was waning. The ATPC started with five charter members: Bolivia, Indonesia, Malaysia, Thailand, and Zaire. Later, Australia and Nigeria joined. Two of the world's largest producers, Brazil and China, did not join, thereby weakening the ATPC's potential influence. The announced goals of the ATPC were to obtain fair returns for tin producers and adequate and stable supplies for tin consumers at reasonable prices, to facilitate cooperation in the marketing of tin, and to enhance the growth of tin usage.

Although the ATPC membership included 7 major producers, effectiveness was weakened by the fact that about 30 countries in the world that mined or smelted tin were not members. Nevertheless, the ATPC tackled rather effectively the estimated oversupply of 100,000 tons of tin that existed during most of the 1980's. The ATPC utilized a series of schemes for the rationalization of supply, in effect imposing export controls on member countries to restrain tin production. By 1989, the world tin oversupply had diminished to an estimated 30,000 tons.

The 1980's also witnessed the rise of Brazil and China as major world tin producers from modest levels just 10 years earlier. This phenomenon was fueled by discoveries of new high-grade, low-cost tin deposits and commitments by the Governments of the two countries to facilitate tin mining and smelting. Although neither country was a member of the ATPC, each generally agreed to cooperate with the spirit of the ATPC's supply rationalization strategies. Tin production levels in both countries became so large that, without their cooperation, the ATPC export controls would not have been effective in reducing the world oversupply of the late 1980's.

Brazil's tin mine production in 1979

^e Estimated. ^P Preliminary. ^r Revised.¹ Data derived in part from the Monthly Statistical Bulletin of the International Tin Council, London and, since 1988, UNCTAD. Wherever possible, total smelter output has been separated into primary (from ores and concentrates) and secondary (tin metal recovered from old scrap). This table reflects metal production at the first measurable stage of metal output. Table includes data available through June 8, 1990.² Reported figure.

was 7,000 tons; in 1989 it was an estimated 50,000 tons. During the decade, considerable exploration occurred and resulted in the discovery of numerous high-grade, mostly alluvial, tin deposits. Most tin discoveries were part of the same geological belt or trend extending up from Bolivia into the far southwestern extremes of Brazil. The Brazilian mines were generally low-cost operations, often the lowest cost in the world, a fact which came to the fore after the late-1985 tin market "collapse." The collapse resulted in a historically low tin price, a price at which the Brazilian mines were among the few in the world that could operate at a profit. Unlike many tin mines in the world, Brazil's tin mines were generally privately owned, sometimes by foreign firms.

It was estimated that tin mine production in China rose sharply from about 15,000 tons in 1979 to an estimated 25,000 tons in 1989. It was believed that most tin mines in China were underground lode operations in the same geological trend extending

from Malaysia, Burma, and Thailand into southwest China. All Chinese tin mines are Government-owned and often named for the province in which they are located. Although China has numerous tin smelters, in recent years considerable tin ore has been shipped to smelters in Malaysia. In recent years, China has emerged as the second leading supplier of tin metal to the United States, after Brazil.

The transactions of the NDS in the United States, administered by the Department of Defense in 1989, have been a major factor in the tin industry. Almost immediately after the creation of the NDS following World War II, tin became the largest dollar volume holding in the entire stockpile of some 80 nonfuel mineral materials. The U.S. Government purchased the tin for the NDS primarily from foreign producers at the then prevailing market prices of well below \$1 per pound. The tin was stored at several warehouses around the country in proximity to industries that could require the tin in wartime. By

1960, the NDS stockpile reached its peak quantity of 358,149 tons and the Nation's consumer and defense-related tin requirements began to decline. Beginning in 1962, stockpile tin that was excess to the goal was offered for sale. Sales, or later swap programs, were elaborately designed to avoid significantly affecting the world tin market.

The immensity of the NDS holdings of tin can be measured by noting that at yearend 1989, after almost 30 years of almost continuous stockpile sales, the stockpile tin inventory of 171,233 tons was still by far the largest dollar volume holding of all the nonfuel mineral materials in the stockpile.

Even though Defense plans call for an eventual tin stockpile of 42,674 tons, it probably will take many decades to sell the excess down to that level, given the legislative processes needed to authorize disposals and the sometimes conflicting aims of avoidance of undue market disturbance and maximization of income from disposals.

Technology

For most of this century, one of the major worldwide uses for tin has been for tinplate, most of which is used for tin cans. Even though tinplate has lost most of the beverage market in the United States to aluminum during the past 25 years, tinplate has continued to dominate the food can market. Until the late 1980's, used tin cans were generally not recycled; when used by the consumer, they were usually taken via trash collection vehicles to municipal landfills. Also, until the late 1980's, technology did not exist for economically removing the tin coating from the base steel (tinplate is 99% steel) on the required volume and speed basis necessary for treating large volumes of cans.

During the late 1980's, new procedures for effectively separating the tin from the base steel were developed so each metal could be reused as scrap. One such technique involved a shredding process that permitted more effective chemical reaction with the tin surfaces. Also during the late 1980's, many of the Nation's landfills were nearing capacity and became a major environmental concern, leading to municipal policies and actions to encourage or mandate household trash recycling programs. This movement started to generate a significant supply of used

tin cans that could be treated by the new detinning technology. In 1989, the impact of both of these developments created a new industry for the collection and detinning of used tin cans, and several new detinning plants were under construction.

TITANIUM

By Langtry E. Lynd and Ruth A. Hough

Dr. Lynd is a physical scientist in the Branch of Nonferrous Metals. With extensive industry experience in titanium mineralogy and extractive metallurgy, he has been the commodity specialist for titanium since 1977. Mrs. Hough is acting chief, Nonferrous Metals Data Section. She has been involved in the collection and preparation of domestic survey data on titanium and other commodities since 1975. Domestic survey and foreign data for this chapter were prepared by Mrs. Hough and Mr. Tony E. Morris, Nonferrous Metals Data Section. International production data were prepared by Ms. Virginia Woodson, International Data Section.

U.S. production of titanium dioxide (TiO₂) pigments increased about 8% to a little over one million metric tons in 1989, reaching a record-high level for the seventh consecutive year. However, domestic consumption of TiO₂ pigments dropped about 4%, reflecting an easing of the very tight supply-demand balance

that had existed for several years. Exports of TiO₂ pigments increased markedly while imports decreased.

U.S. production of titanium sponge metal rose 13% to 25,200 tons, 5% higher than was reached in the previous record-high year of 1981. Demand for titanium mill products also increased, mainly because of the continued boom

in orders for new commercial airliners.

Consumption of titanium concentrates, (ilmenite, high-TiO₂ slag, rutile, and synthetic rutile), also increased, in line with the rising production of titanium metal and TiO₂ pigments. Imports again supplied about three-quarters of U.S. requirements for TiO₂ in concentrates.

LEGISLATION AND GOVERNMENT PROGRAMS

The International Trade Administration (ITA) of the Department of Commerce tentatively decided to revoke an antidumping duty order on titanium sponge manufactured by Osaka Titanium Co. Ltd. of Japan because it had found Osaka's dumping margin for the period November 1, 1985, to October 31, 1986, to be 0.0% rather than the 0.3% found in a preliminary review in July 1988. ITA rejected a request from Toho Titanium Co. Ltd. for revocation of an antidumping duty order after determining that its dumping margin for the same period was 0.83%.

In furtherance of the Department of Defense Appropriations Act of 1990 (PL 101-165, H. R. 3072-13), the Bureau of Mines was preparing to initiate the Soledad Canyon Demonstration Project in Los Angeles County, CA, to develop a reliable supply of titanium ore from ilmenite. The project is concerned with titanium resources in the vicinity of Soledad Canyon and adjacent areas of Angeles National Forest. It will involve a total resource evaluation, bulk sample recovery, evaluation of beneficiation potential, and determination of response to technology to produce synthetic rutile, titanium metal, and TiO_2 pigment. Six million dollars was made available for the project through September 30, 1993.

STRATEGIC CONSIDERATIONS

Security of Supply

Although imports supply a very large proportion of domestic demand for titanium concentrates, these imports come predominantly from Australia and Canada, which have historically been reliable and politically stable suppliers.

Import reliance, defined as imports less exports plus adjustments for inventory changes, may be used as a measure of dependence on foreign sources of supply. Expressed as a percentage of consumption, import reliance for ilmenite, including high- TiO_2 slag made from ilmenite, was 35% in 1980 but increased to about 80% in the 1982-84 period be-

cause of cessation of production at two U.S. ilmenite mines. Ilmenite import reliance through 1989 has been in the 70% to 80% range. Import reliance for rutile declined from about 90% in 1980 to about 60% in 1983 and later years because of increased domestic production of synthetic rutile. However, this decline was at the expense of increased import reliance for ilmenite, because the domestic synthetic rutile was made from Australian ilmenite.

Dependence on foreign rutile sources could be eased or eliminated in an emergency in two ways, using current commercial processing methods: (1) synthetic rutile could be made from domestic ilmenite now being mined in Florida, or ilmenite that could be mined from other deposits, such as the Tennessee ilmenite sand deposits, and (2) titanium tetrachloride (TiCl_4) for metal production could be made directly from ilmenite, as is done by E. I. du Pont de Nemours & Co. Inc. (Du Pont) for TiO_2 pigment manufacture.

Another possible solution to this problem is the development of new processes that utilize domestic ilmenite and perovskite that contain too much calcium and magnesium to be used directly for making TiCl_4 . Availability of such processes would encourage production of domestic ilmenite, which fell from about 450,000 tons of contained TiO_2 in 1975 to about 165,000 tons of TiO_2 in 1982. In 1989, ilmenite mine production capacity was about 200,000 tons per year of contained TiO_2 .

Import reliance for titanium sponge as a percentage of consumption has ranged between 0% and 16% in the period 1980 to 1989. Titanium concentrates currently used to make TiCl_4 for metal production are mostly imported rutile and synthetic rutile, but domestic concentrates could be used for this purpose in an emergency, possibly at higher cost.

Stockpile

Rutile and titanium sponge metal are included in the list of strategic and critical materials for stockpiling purposes. Titanium sponge has been acquired periodically for the National Defense Stockpile (NDS) from domestic producers and from producers in Japan and the United Kingdom. Rutile for the stockpile was acquired mainly in the early sixties from Australia.

The Government's NDS goal for titanium sponge metal remained at 176,901 tons. The NDS inventory in December contained 23,555 tons of specification metal and 9,857 tons of nonspecification material. The Annual Materials Plan for fiscal year 1991 includes a proposal to acquire 2,722 tons of titanium sponge metal for the stockpile. The NDS goal for rutile was unchanged at 96,162 tons. The total rutile stockpile inventory at yearend was 35,549 tons, including 51 tons of nonspecification material.

ISSUES

U.S. Ore Supply

Although the United States has large reserves of titanium in the form of ilmenite, nearly all of U.S. titanium sponge production has been derived from imported rutile and synthetic rutile. This heavy reliance on foreign concentrates has developed because most producers of TiCl_4 , the intermediate compound used to make titanium sponge and a large part of the world's TiO_2 pigment, prefer rutile or synthetic rutile over ilmenite as plant feed material. Possible ways of better utilizing U.S. ilmenite resources and reducing U.S. dependence on foreign sources of titanium concentrates are discussed in the Strategic Considerations section.

Fluctuations in Metal Demand

A major problem affecting the titanium industry is the wide fluctuation in demand caused by changes in requirements for both military and commercial aircraft programs. Titanium sponge producers have repeatedly increased capacity in response to anticipated demand and have then been left with excess capacity when those programs were canceled or cut back. The most recent example of such a fluctuation was the historic peak in demand and price reached in 1980-81 and the subsequent collapse in 1982-84. The sharp rise and fall of demand and prices were believed to have been aggravated by overestimation of aircraft orders that did not materialize or were later canceled as the aircraft market deteriorated. Following the market collapse, some producers and consumers were left with high inventories to be worked off during a period of lower demand.

It has been suggested that the aerospace industry could help stabilize demand and match supply to demand by better long-range planning and forecasting of their requirements, and greater use of multiyear contracts. In the event that additional capacity is needed quickly in a national emergency, incentives such as loan guarantees and a guaranteed floor price for purchases from new capacity could be used, as authorized under the Defense Production Act. Further diversification of titanium into nonaerospace industrial applications would also help stabilize titanium demand.

PRODUCTION

Concentrates

U.S. producers of ilmenite in 1989 were Associated Minerals (USA) Ltd. Inc. (AMU) at Green Cove Springs, FL, and Du Pont at Starke and Highland, FL. P. W. Gillibrand Co., Simi Valley, CA, reported initial commercial shipments of several thousand tons of ilmenite, produced as a coproduct of its rock, sand, and gravel operations.

In December, Nord Resources Corp. announced that production of heavy minerals had begun at the newly completed processing facility of Nord Il-

menite Corp. near Lakewood, NJ. This operation will reclaim zircon, ilmenite, and rutile from tailings at a previously mined mineral sands deposit. The first shipments of zircon were made in early December.

AMU was again the only U.S. producer of natural rutile. Kerr-McGee Chemical Corp. was the sole domestic producer of synthetic rutile, at Mobile, AL.

Du Pont announced plans to begin mining ilmenite at a new location in Florida by 1992. The new mine site is at Maxville, on the northern extension of Trail Ridge, about 15 kilometers (km) north of Du Pont's current operations on Trail Ridge. A Du Pont spokesperson said the new mine site will support the company's plans to expand TiO₂ production capacity by 50% to about 900,000 tons per year by the mid-1990's. Du Pont said it will close portions of one of the two Trail Ridge mine sites now in use when operations at the new site begin.

Renison Goldfields Consolidated Ltd. (RGC), Mineral Sands Div.-USA, was evaluating a mineral sand deposit located in Dinwiddie and Sussex Counties, VA. The deposit was said to contain 7.3 million tons of recoverable heavy minerals, with ilmenite, leucoxene, rutile, and zircon making up nearly 80% of the heavy

mineral concentrate. Heavy mineral content in the deposit reportedly averages about 7%. Mining could begin in about 3 to 5 years.

South East Tisand, a joint venture between Becker Minerals Inc. of England and Consolidated Rutile Ltd. of Australia, was investigating a similar mineral sand deposit in the Greenville County area, VA. Other companies exploring for heavy mineral sand deposits in the southern Virginia-eastern North Carolina area included Du Pont and Piedmont Mining Co. Inc.

Ferrotitanium

Ferrotitanium was produced by Ashland Chemical Co., Columbus, OH; HTP Co., Sharon, PA; Reactive Metals and Alloys Corp., West Pittsburg, PA; and Shieldalloy-GFE Corp., Newfield, NJ. Most of the production consisted of the 70%-titanium grades.

Metal

Oregon Metallurgical Corp. (Oremet) completed construction of an eighth reduction furnace, bringing its sponge production capacity to 5,400 tons per year. Oremet planned further expansion of capacity to 8,000 tons per year by March 1991. In November, RMI Co. completed expansion of sponge production capacity at its Ashtabula, OH,

¹ Based on 7-days-per-week full production. Includes 61,700 tons vacuum arc double/triple melt, of which triple melt generally ranged from 10% to 30%. The remaining 5,000 tons was single-melt electron-beam capacity for remelt electrodes and commercially pure ingot and slab.

² Single melt only.

facilities from 9,500 tons per year to about 11,000 tons per year. In December, Titanium Metals Corp. of America (TMCA) and a Japanese group signed a memorandum of understanding providing for the financing, design, and construction of a 10,000-ton-per-year titanium sponge plant utilizing proven vacuum-distillation technology. The parties expected to, and did, reach a definitive agreement during the first quarter of 1990. The Japanese group, which will provide advanced technology and financing for the project, consists of Toho Titanium Co. Ltd. and its primary shareholders, Nippon Mining Co. Ltd., Mitsui and Co. Ltd., and Mitsui and Co. (U.S.A.) Inc. After production startup, expected by 1993, the Japanese group will have the option to acquire 25% of TMCA's common stock. The new sponge plant will be operated by TMCA in conjunction with its existing titanium sponge, ingot, and research facilities in Henderson, NV.

RMI was making trial runs in its pilot plant for producing titanium metal by the Ginatta electrolytic process. RMI reported that initial results from the extensively automated processing system were promising, yielding products with low levels of oxygen and metallic impurities.

Teledyne Allvac, Monroe, NC, announced in August that it had broken ground for a continuous automated bar mill in Chester County, about 48 km from Monroe. Allvac said the mill is to be on-line in the fourth quarter of 1990 and will be used to roll the superalloys and titanium alloys that the company produces. Allvac believes that when this project is completed, it will have the industry's most cost-effective capability to meet increasingly demanding requirements for the most consistent, highest quality, superalloy and titanium rod and bar products.

Titanium Dioxide Pigments

Supply and demand for TiO₂ pigments remained in close balance, and production facilities were generally operated at full capacity. U.S. producers increased capacity by about 125,000 tons per year, using process optimization as well as major expansions.

Kemira Inc., Savannah, GA, completed a 50% expansion of its TiO₂ capacity to 145,000 tons per year.

¹ Revised. NA Not available.

² Because of the implementation of the Harmonized Tariff System in Jan. 1989, import and export categories for 1989 are not necessarily comparable with those in 1988.

³ Data may not add to totals shown because of independent rounding.

⁴ Excludes sponge imported for the national stockpile.

⁵ Data for sheet and strip, plate, extrusions (other than tubing), pipe and tubing, and other have been combined to avoid disclosing company proprietary data.

Du Pont was on schedule with its addition of 110,000 tons per year of new capacity at De Lisle, MS, to be completed in 1990. Du Pont was also planning a 24,000-ton-per-year expansion of its Altamira, Mexico, TiO₂ plant in 1990, and construction of new 60,000-ton-per-year plants during the next few years in Brazil, the Republic of Korea, and Taiwan.

Kronos Inc. (formerly NL Chemicals Inc.) was proceeding with construction of a new 82,000-ton-per-year chloride-process TiO₂ plant at Lake Charles, LA, scheduled for completion in 1991.

In December, Kerr-McGee announced plans to build a new 54,000-ton-per-year chloride-process TiO₂ plant at a U.S. site to be determined later. Completion is planned for yearend 1992.

SCM Chemicals Inc. announced around midyear plans to expand production at its Ashtabula, OH, plant by about 53,000 tons per year.

CONSUMPTION AND USES

Concentrates

Total U.S. consumption of TiO₂ in concentrates increased about 10%, in line with the increase in production of TiO₂ pigment and titanium metal. Ilmenite consumption decreased slightly, while slag consumption increased 38% and rutile consumption rose 4%. Distribution of total consumption by end

use was pigments, 93%; metal, 4%; and other uses, 3%.

Ferrotitanium

Consumption of titanium in the form of ferrotitanium and scrap for the manufacture of steel and other alloys was about the same as that of 1988. After rising appreciably in 1988, demand for ferrotitanium continued to rise early in 1989, but declined later in the year.

Metal

Net shipments of mill products increased 11% and reached a record-high

level, exceeding the previous record set in 1980 by about 380 tons. Sponge production also reached a new high, surpassing the previous peak reached in 1981. Consumption of scrap for remelting dropped slightly and supplied a calculated 43.5% of ingot feedstock compared with 46.2% in 1988. Castings shipments increased 2.5%.

Mill product shipments by product type were 47% forging and extrusion billet; 39% sheet, strip, plate, extrusions and other; and 14% rod and bar. Estimated U.S. mill product usage by application was commercial aircraft,

42%; military aerospace, 38%; chemical industry, including pulp and paper, 10%; powerplant condensers, 5%; naval and other marine uses, 2%; medical implants, 1%; and other uses, mainly oil drilling, flue-gas desulfurization, and automotive, 2%.

Current use of titanium in large commercial aircraft represents about 6% of aircraft empty weight. Titanium is utilized where high-strength toughness, heat resistance, and high structural efficiency are required. Typical aircraft uses are for structural forgings, such as the landing gear beam in the Boeing 757; wing skins for the F-14 and F-15 fighter aircraft; rotor parts for helicopter systems; B-1B fracture-critical forgings and wing support sections; and rotor discs and compressor blades in various engines. Major nonaerospace industrial uses are mainly those requiring superior resistance to corrosion.

Pigment

Apparent domestic consumption of TiO₂ pigments was about 947,000 tons, 4.5% less than in 1988, despite full-

capacity operation of U.S. TiO₂ pigment plants. The slight easing of domestic demand made a larger part of production available for exports.

STOCKS

A 39% increase in the TiO₂ content of ilmenite stocks was largely offset by a 25% decrease in stocks of titanium slag. Stocks of rutile rose 33%, so that total stocks of TiO₂ in concentrates rose 15%. Stocks of TiO₂ pigment increased 27% to about 63,000 tons, a 24-day supply.

PRICES

Prices of ilmenite rose slightly, and rutile prices increased about 2.5% in 1989, compared with increases in 1988 of 42% and 24%, respectively. Titanium slag prices rose about 10%.

Prices of titanium sponge increased about 12%, while those of titanium mill products rose by an average of about 10%. Titanium scrap prices rose early in the year, but fell considerably in the second half in response to declining demand for ferrotitanium.

Titanium dioxide pigment prices increased 5 cents to 6 cents per pound in the second quarter, and edged a little higher by yearend. There were reports of "gray-market" sales at much higher

prices in response to the continued high demand, but the volume of material sold at these inflated prices was believed to be relatively small. Titanium dioxide pigment prices were reportedly significantly higher in other countries than in the United States.

FOREIGN TRADE

Exports of TiO₂ increased an unprecedented 73%, making the United States a net exporter of TiO₂ for four consecutive quarters. Net exports of TiO₂ were about 46,000 tons, amounting to 4.5% of production. The record-high exports were made possible by recent increases in production capacity and a slight easing of domestic demand, with high prices in other countries providing extra incentive.

WORLD REVIEW

World production of TiO₂ in concentrates rose about 6% in 1989. Several heavy mineral projects were announced, and progress was made on projects already underway. World demand for TiO₂ pigments remained at record-high levels, estimated at about 3.0 million tons, and estimated production capacity increased about 5%.

Titanium metal production in the market economy countries increased 19% to nearly 48,000 tons, reflecting continued growth in demand in the United States, Europe, and Japan.

Industry Structure

The titanium industry is moderately integrated from raw materials to semi-finished products. The world's largest TiO₂ producer, Du Pont, obtains ilmenite, rutile, and leucoxene from its own mines in Florida and from various suppliers in other countries, mainly Australia. NL Industries (formerly National Lead Co.) for many years has supplied ilmenite to its European pigment plants from its mine at Tellnes, Norway. Since 1987, a smelting plant at Tyssedal, Norway, has been processing part of the Tellnes ilmenite to produce titanium slag for the same market. From 1942 through 1983, NL Industries operated an ilmenite mine at Tahawus, NY, that supplied its two U.S. pigment plants, one of which was closed in 1978 and the other in 1982. The Tioxide Group PLC, United Kingdom, owns a 40% share of Westralian Sands Ltd. in Australia. In 1989, Hanson Industries PLC, United Kingdom, owner of SCM Chemicals Inc., acquired a 49% interest in Renison Goldfields Consolidated

Ltd., the major producer of titanium minerals in Australia. Also in 1989, a joint venture between Minproc Holdings and Kerr-McGee was established to develop integrated operations in Western Australia involving the mining and concentrating of ilmenite, processing of the ilmenite to make synthetic rutile, and manufacture of TiO₂ from the synthetic rutile. Nearly all of the remaining TiO₂ pigment manufacturers buy their raw materials from independent producers of titanium concentrates.

None of the sponge metal producers outside the U.S.S.R. or China owns its own titanium mine. Titanium Metals Corp. of America (TIMET) purchases Australian rutile and manufactures TiCl₄, the intermediate compound universally used for commercial production of titanium metal. The other two U.S. titanium metal producers purchase TiCl₄ from a TiO₂ pigment manufacturer. Titanium mineral raw materials are purchased also for use in welding rod coatings, chemicals, and fiberglass.

The United States accounts for about 25% of the world's sponge production capacity. Major U.S. sponge and ingot producers during 1989, their ownership, location, and approximate annual capacities are shown in table 2.

Overseas sponge producers and their shares of the total world capacity of about 116,000 tons in 1989 were the U.S.S.R., 45%; Japan, 23%; the United Kingdom, 4%; and China, 3%.

Titanium dioxide pigment output in 27 countries in 1989 came from about 60 separate facilities ranging in annual capacity from a few thousand tons to 280,000 tons. The United States accounted for 33% of the world's TiO₂ pigment capacity, followed by the Federal Republic of Germany, 10%; Japan, 9%; the United Kingdom, 8%; and France, 7%.

The world's four largest TiO₂ pigment producers are Du Pont, with four plants in the United States and one in Mexico, and an annual capacity of about 650,000 tons; Tioxide, with two plants in the United Kingdom and facilities in Australia, Canada, France, Italy, Spain, and South Africa, and an annual capacity of 510,000 tons; SCM Chemicals, with plants in the United States, the United Kingdom, and Australia, and an annual capacity of 430,000 tons; and Kronos Inc., with plants in Belgium, Canada, the Federal Republic of Germany, and Norway, and an annual capacity of 310,000 tons.

U.S. companies, mainly Du Pont, SCM, Kronos, and Kerr-McGee, own or control nearly half of the world productive capacity for TiO₂ pigments. Tioxide controls about 16%. An estimated 7% is owned by Governments of countries with centrally planned economies. The remaining 30% is principally owned by large chemical firms or groups such as Bayer AG of the Federal Republic of Germany, Ishihara Sangyo Kaisha Ltd. (ISK) of Japan, and Kemira Oy of Finland.

Major U.S. producers of TiO₂ pigments during 1989, their ownership, annual capacities, and plant locations are shown in table 4.

Capacity

The data in table 15 are rated capacities for mines and beneficiation plants, sponge metal facilities, and TiO₂ pigment plants as of December 31, 1989. Rated capacity is defined as the maxi-

² Data may not add to totals shown because of independent rounding.

Source: Bureau of the Census.

imum quantity of product that can be produced in a period of time at a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and temporarily closed facilities that, in the opinion of the author, can be brought into production within a short period of time and with minimum capital expenditure.

Mine and mill capacity for the production of titanium concentrates, metal production plant capacity, and TiO₂ pigment plant capacity are generally based on close to 365-days-per-year operation, three shifts per day. Capacity figures are based on information obtained from the producing companies, from news items, and from Bureau of Mines estimates.

Reserves

U.S. and world reserves and reserve

base data for titanium are shown in tables 16 and 17. U.S. reserves of 7.8 million tons of TiO₂ in ilmenite and 300,000 tons of TiO₂ in rutile occur mainly in ancient beach sand deposits in Florida. Ilmenite concentrates from the U.S. sand deposits contain about 60% to 65% TiO₂, while those from rock deposits contain 45% to 50% TiO₂. The U.S. reserve base of 34.7 million tons of TiO₂ occurs as 23.5 million tons in ilmenite, 9.8 million tons in perovskite (CaTiO₃), and 1.4 million tons in rutile.

Other U.S. resources include additional rock deposits of ilmenite in California, Minnesota, New York, and Wyoming, and sand deposits of ilmenite and/or rutile in Georgia, Idaho, New Jersey, North Carolina, Oregon, and South Carolina, as well as large quantities of accessory rutile in porphyry copper ores and mill tailings.

The Bureau of Mines is compiling a computerized file of worldwide mineral deposit data called the Minerals Availability System (MAS). Most of the

resource data in table 16 and 17 were derived from MAS reports.

Major titanium reserves in the United States are owned by Du Pont and AMU in Florida. Reserves in Australia are held mainly by Associated Minerals Consolidated Ltd. (AMC), a subsidiary of Rension Goldfields Consolidated Ltd., Consolidated Rutile Ltd., Westralian Sands Ltd., and Cable Sands Ltd. Reserves at Allard Lake, Quebec, Canada, are held by QIT-Fer et Titane Inc. (QIT), now a subsidiary of RTZ Corp. PLC. QIT also has a 50% interest in Richards Bay mineral sands deposits in the Republic of South Africa. Major deposits in Brazil, India, and Sri Lanka are held by the respective Governments. NL Industries controls Titania/AS, owner of the large hardrock deposit at Tellnes, Norway.

Adequacy of Reserves

U.S. reported consumption of TiO₂ in concentrates in 1989 was 1,101,000 tons. At this annual consumption rate, U.S. reserves of 8,100,000 tons would

be sufficient for only about 7 years, without imports. However, at the current level of import reliance, 71% of reported consumption, these reserves would provide a 25-year supply of titanium. The U.S. reserve base of 35 million tons TiO_2 content is equivalent to 32 times the 1989 domestic consumption level.

Production and consumption of TiO_2 in concentrates in 1989 in the rest of the world was about 4.1 million tons. World reserves of TiO_2 shown in table 17 total 289 million tons, or 70 times 1989 world consumption.

Australia

RGC announced that its subsidiary, AMC Mineral Sands Ltd., will develop the Enneaba West mineral sands deposit 5 km west of AMC's Enneaba operations in Western Australia. Annual production is expected to be 180,000 tons of ilmenite, 41,000 tons of rutile, and 68,000 tons of zircon, with plant startup planned for early 1991. AMC also planned to expand synthetic rutile production capacity at its Narn-gulu facility from 112,500 tons per year to 260,000 tons per year by 1992.

Partners Kerr-McKee and Minproc

Holdings Ltd. were proceeding with the Cooljarloo Joint Venture in Western Australia. The project will involve operations at three separate locations: mining and wet concentration of the ore at Cooljarloo, 170 km north of Perth, which began in late 1989; a dry-separation plant and a synthetic rutile plant at Muchea, to begin operation in the first half of 1990; and a TiO_2 pigment plant at Kwinana, scheduled for completion in early 1991. Planned annual production capacities were 130,000 tons of synthetic rutile and 54,000 tons of TiO_2 pigment.

Brazil

Compania Vale Do Rio Doce was progressing with plans to construct a plant to produce 300,000 to 500,000 tons per year of 90%-TiO₂ anatase concentrate. A large part of the anatase plant product was reportedly committed to Du Pont, including feed for a proposed 60,000-ton-per-year TiO₂ pigment plant in Brazil to be completed in 1993-94.

Canada

At yearend, QIT announced that it will increase its production capacity of 80%-TiO₂ slag at Sorel, Quebec, to about 1.1 million tons per year by September 1990.

Japan

ISK, the largest TiO₂ producer in Japan, was reportedly expanding its facilities in Yokkaichi by a few percent to about 50,000 tons per year by the chloride process and 96,000 tons by the sulfate process.

Japan has been outstanding in the development of innovative, nonaerospace applications for titanium. In early 1989, Suisman Titanium Corp. published a review and listing of titanium usage in Japanese buildings, which totalled about 180,000 kilograms in 1987 and 113,000 kilograms in 1988.¹

Titanium sponge metal production in Japan rose 17% to about 21,000 tons. At yearend, producers were planning further increases in production rates.

Madagascar

QIT's plans for development of a mineral sands deposit near Fort Dauphin were extended somewhat, with mining expected to begin in 1993-94.

Malaysia

Tioxide was on schedule with plans for construction of a 50,000-ton-per-year TiO₂ pigment plant in Malaysia, to be completed by yearend 1991.

Mexico

Du Pont announced plans for a 24,000-ton-per-year expansion of its chloride-process TiO₂ pigment plant in Altamira. Completion is scheduled for 1990, with plant capacity of 79,000 tons per year.

Mozambique

Kenmore Resources PLC, Dublin, Ireland, was progressing with plans to

develop a mineral sands deposit 15 km north of Angoche. Initial production was expected in the spring of 1992, with annual production of about 420,000 tons of ilmenite, 8,000 tons of rutile, 37,000 tons of zircon, and about 1,000 tons of monazite.

Sierra Leone

In May 1989, International Gold and Minerals NL and MC Mining NL of Australia signed an agreement with the Government of Sierra Leone to develop a rutile-bearing mineral sand deposit about 60 km east of Freetown. A preliminary feasibility study was said to indicate possible production of 56,000 tons per year of rutile, 83,000 tons per year of ilmenite, and 6,000 tons per year of zircon. Reserves of 146 million tons of ore grading 0.6% rutile, 0.8% ilmenite, and 0.06% zircon were delineated in the 1970's by a joint-venture partnership between Bayer AG and Preussag AG, Federal Republic of Germany, when mineral sand markets were depressed.

Singapore

In April, ISK began operation of the first phase of its new chloride-process TiO₂ plant at Tuas, Singapore. Initial production capacity is 36,000 tons per year, and ISK was reportedly considering a second phase of plant construction that would double capacity to 72,000 tons per year.

Spain

Tioxide approved expansion of its TiO₂ plant at Huelva, Spain, operated by Tioxide Espana SA, from 60,000 to 80,000 tons per year, in response to demands from the domestic market.

CURRENT RESEARCH

As part of a Bureau of Mines program to develop a more continuous titanium metal process that utilizes domestic resources, a study was made of the kinetics of hydrofluoric acid (HF) leaching of New York rock ilmenite. The leaching rate was found to be linearly dependent on the HF concentration and inversely proportional to the average starting diameter of the ilmenite particle. Using 19 molar HF at 45° C, 99% of the titanium and 100%

of the iron in the ilmenite were leached in 40 minutes.² The HF leach solution was treated by solvent extraction to remove iron, and calcium carbonate was added to form calcium fluorotitanate (CaTiF₆), which was precipitated by evaporation. Limited reduction tests were carried out on the CaTiF₆ in induction slag casting and melting furnaces. Complete reduction to metallic titanium and calcium fluoride was achieved, with the metallic titanium finely disseminated throughout the slag.³

The Bureau of Mines studied a sulfate-fluoride system to process Colorado perovskite to recover potassium fluorotitanate. This double salt, after washing and drying, was subjected to

^c Estimated. ^P Preliminary. ^r Revised. W Withheld to avoid disclosing company proprietary data; not included in "Total."¹ Table excludes production of unbeneficiated anatase ore in Brazil, in metric tons, as follows: 1985—2,596,122; 1986—2,772,082; 1987—3,344,318; 1988—3,400,000; and 1989—3,500,000(estimated). This material reportedly contains 20% TiO₂. Table includes data available through June 13, 1990.² Ilmenite is also produced in Canada and in the Republic of South Africa, but this output is not included here because an estimated 90% of it is duplicative of output reported under "Titaniferous slag", and the rest is used for purposes other than production of titanium commodities, principally as steel furnace flux and heavy aggregate.³ Data are for fiscal year beginning Apr. 1 of year stated.⁴ Reported figure.⁵ Contains 80% TiO₂.⁶ Contains 85% TiO₂.

metallothermic reductions with either potassium or aluminum to produce titanium metal. Potassium reduction produced titanium metal of fine particle size, with oxygen content of 1%. Aluminum reduction in a molten zinc bath produced titanium metal with only 7% aluminum.⁴

The Bureau of Mines investigated the properties of ceramic particulate composites made from titanium nitride (TiN), alumina (Al₂O₃), and aluminum nitride (AlN) as part of a program to meet the high-performance demands on structural materials for new and emerging technologies. The best test results were obtained on a mixture of 40% TiN, 30% Al₂O₃ and 30% AlN.⁵

Bureau of Mines researchers measured the solubility of TiCl₄ in supercritical, liquid, and gaseous carbon dioxide (CO₂). TiCl₄ proved to be highly soluble in supercritical CO₂, and the two compounds were completely miscible near 1,500 pounds per square inch between 32° and 50° C. The TiCl₄ solubilities measured during this investigation are relevant to processes for recovering or purifying TiCl₄.⁶

The U.S. Geological Survey published results of a study on the geologic evolution of the Trail Ridge heavy-mineral sand deposit in Florida. Trail Ridge apparently represents a coast-parallel transgressive dune complex, analogous to younger dunes elsewhere that have become completely decoupled from parental shorelines.⁷

Research continued on titanium aluminides, especially Ti₃Al (α₂), which was already in limited use in aircraft turbine engines. Addition of stabilizing elements, particularly niobium, was the most successful approach to improving ductility. Properties were also improved by rapid solidification processing. Titanium aluminides have lower density and better resistance to creep and high-temperature oxidation than conventional titanium alloys.⁸ Rapidly solidified titanium aluminide alloys are among the major potential materials needed for the National Aerospace Plane (NASP). NASP materials must combine the use-temperature capability of superalloys with the density of titanium alloys.⁹

Researchers at Sandia National Laboratories, Albuquerque, NM, reported significant progress in the use of solar energy to decompose organic pollut-

ants in water. The promising results were achieved by testing the breakdown of an organic acid with a TiO₂ catalyst. Using concentrated solar power to speed up the reaction makes the process more commercially attractive. A Sandia representative said they believe the process will destroy most organic materials.¹⁰

OUTLOOK

World production and demand for titanium sponge metal in 1989 is estimated at about 96,000 tons. Demand is expected to grow at 3% to 5% per year during the next several years. Titanium demand is being driven mainly by the record-high level of orders for commercial airliners, as well as gradually increasing requirements for other industrial uses. The growth in demand for commercial aircraft is expected to more than offset anticipated cutbacks in military aircraft programs. Recently completed and announced future expansions of U.S. titanium sponge production capacity are believed to be sufficient to take care of increasing titanium demand for the next several years.

World TiO₂ pigment production and demand in 1989 are estimated at about 3.0 million tons. Industry sources project the growth of world TiO₂ demand at about 3% per year. Annual growth in demand by market area is expected to be about 5% in Asian countries bordering the Pacific Ocean, 3% in North America and Europe, and 2% in the rest of the world. If all of the planned TiO₂ pigment projects are completed, it is believed that demand can be supplied with a moderate capacity surplus, at least through 1994. The magnitude of the capacity surplus will depend mainly on economic conditions during that period.

If plans for all of the announced titanium raw material projects are implemented, an additional 1.2 million tons per year or more of TiO₂ in concentrates could be produced by 1995. At 3% annual growth in demand for TiO₂ pigments and 5% for titanium metal, additional annual demand for TiO₂ in concentrates by 1995 would be about 800,000 tons. The supply of TiO₂ in concentrates is, therefore, likely to be adequate through 1995.

BACKGROUND

Definitions, Grades, and Specifications

Ilmenite is the most abundant titanium mineral, with the chemical formula FeTiO₃, and theoretical composition of 52.7% TiO₂ and 47.3% FeO. However, the term "ilmenite" is also used to include material that has been oxidized and leached during weathering, containing up to 70% TiO₂, about 25% to 30% iron oxides, and about 5% of oxides of other elements. When the alteration is extreme, the residual material is essentially amorphous to finely crystalline TiO₂ and is called leucoxene.

Rutile is essentially crystalline TiO₂, and commercial concentrates usually contain about 95% TiO₂. Synthetic rutile or rutile substitutes are derived from ilmenite by processes involving oxidation and reduction treatments followed by leaching of iron. Synthetic rutile concentrates approach rutile in chemical composition but, being residual leached grains, are porous and composed of very fine crystallinities, while natural rutile grains are usually single crystals.

Anatase also is crystalline TiO₂, but has a different crystal structure than rutile. Anatase is not yet available commercially, but large deposits of anatase-bearing ore in Brazil are being developed.

Commercially available titaniferous slags made by electric furnace smelting of ilmenite with carbon contain 70% to 85% TiO₂. Slags being produced at the end of 1989 were 80% TiO₂ slag from Sorel, Quebec; 85% TiO₂ slag from Richards Bay, Republic of South Africa; and 75% TiO₂ slag from Tysnedahl, Norway.

Titanium tetrachloride, the intermediate compound from which titanium metal and chloride process TiO₂ are manufactured, is a colorless to pale yellow liquid at room temperature, with a boiling point of 136° C.

Titanium sponge metal is the primary metal form obtained by vapor phase reduction of titanium tetrachloride with magnesium or sodium metal. It is called sponge because of its appearance and high porosity. Titanium ingot for forging into billet and mill products is obtained by melting sponge in a vacuum-arc furnace, with or without scrap titanium or alloying addi-

tions. Specifications for titanium sponge for the National Defense Stockpile are given in table 19.

Titanium dioxide pigment is characterized by its purity, high refractive index, fine particle size, and surface properties. The particle size is critical and must be closely controlled within the range of about 0.2 to 0.4 micrometer to develop optimum pigment properties. The superiority of TiO₂ as a white pigment is due mainly to its high refractive index and resulting light-scattering ability, which impart excellent hiding power and brightness. Titanium dioxide pigments are produced as two major types: rutile and anatase. Rutile-type pigment, less reactive with paint vehicles in sunlight than is the anatase type, is preferred for use in outdoor paints. Anatase pigment has a bluer tone than the rutile type, is somewhat softer, and is used mainly in indoor paints and as an opacifier in paper.

Specifications for natural rutile for the National Defense Stockpile are

shown in table 20. There are no rigid specifications for raw materials to be used as feed for making TiCl₄ for metals or pigment manufacture or for ilmenite or slag to be used in the sulfate pigment process. However, certain impurities such as chromium, columbium, manganese, phosphorus, and vanadium can seriously impair pigment properties, so these impurities are an important consideration in the selection of concentrates for pigment production. Concentrates to be used for making TiCl₄ should be low in calcium and magnesium, which form high-boiling-point chlorides that cause trouble in fluid-bed chlorinators. Chemical compositions of typical commercial titanium concentrates are shown in table 24.

Technology

Exploration.—Hard-rock ilmenite deposits, because of their inherent magnetic properties, are readily amenable

to the application of aero- and ground-magnetic geophysical surveys. These deposits generally respond to such surveys by reflecting abnormally positive magnetic intensities, although in some cases negative magnetic anomalies may result. Once such anomalies are mapped, further exploration may take place in the form of detailed geological observations and, ultimately, drilling to test the anomalies and delineate the associated ilmenite deposit.

If initial diamond drilling indicates an economic deposit, development drilling proceeds on a set grid pattern of about 200 or 300 feet. Intermediate holes are drilled to fill in major gaps in information on geologic structure or ore continuations. Drill cores are visually logged and split for chemical assay to determine TiO₂ and iron content.

Sand deposits of titanium minerals are mostly located near continental margins where erosion of regional granitic and metamorphic rocks contain-

ing ilmenite and rutile has led to accumulation of these minerals in coastal plain sediments. Working and reworking of these sediments by ocean waves on beaches and in streams resulted in various degrees of sand sorting and concentration by particle size, density, and resistance to abrasion. Well-sorted sands are much more likely hosts for ilmenite, rutile, and other heavy minerals than are unsorted sands.

Titanium minerals are dark in color, and their concentration in predominantly quartz sands is often readily visible. Initial discovery has therefore often been made through surface observation. In exploration, hand panning of samples has been a very useful exploration tool.

Some titanium mineral ore bodies are detectable by ground or airborne magnetometer surveys or, if monazite or zircon is present, by low-level radiometric surveys.

Drilling to determine the extent of sand deposits in the first phase of

development should be done to a depth of at least 50 feet and preferably 100 feet. The type of drill needed will depend on the nature of the ground, including the presence of clay, hardpan, roots, stumps and other organic material, as well as the depth of the water table.

Approximate minimum requirements for an economic sand deposit of titanium minerals include reserves of 300,000 to 1 million tons of TiO_2 content in rutile or ilmenite and heavy mineral content in the ore of 1% to 5%, depending on the mix of ilmenite, rutile, and other valuable minerals.

Mining and Concentration.—For mining sand deposits of titanium minerals, a dredge is usually used. This may be bucket-ladder type, but is more likely to be suction type. The dredge floats in its own pond, digging forward and stacking tailings aft.

Rough concentration, the separation of heavy minerals from the lighter

quartz-feldspar-mica fraction, is usually accomplished by wet-gravity methods. The Humphreys spiral has been standard for this separation since its introduction about 1940, but pinched-slucice separators of various designs have also been used.

In Australia, the Reichert cone concentrator, which operates on the pinched-slucice principle, has been successful for large-tonnage operations. Flotation has also been used to some degree. For separating the minerals from stream-type deposits, jigs are usually chosen because they are the concentrating device least sensitive to extreme grain size variation.

The final wet-mill concentrate is dried, usually in a rotary kiln, prior to further treatment. The subsequent flowsheet depends on the mineral assemblage to be treated. Ilmenite and rutile are usually removed together by electrostatic separation. The ilmenite-rutile conductor fraction of dried wet-mill concentrate is then subjected to high-intensity magnetic separation, yielding a final ilmenite product.

The rutile fraction is further cleaned by screening and additional electrostatic separation. Zircon and monazite products are recovered from the nonconductor fraction of the wet-mill concentrate by a combination of gravity, electrostatic, and high-intensity magnetic separation.

Ilmenite is also mined from two hard-rock deposits, one in Canada, and one in Norway. The ore bodies are massive, and open pit mining is practiced.

At Tellnes, Norway, the ore is crushed, ground, and subjected to wet-magnetic separation to recover magnetite. An ilmenite concentrate containing about 44.5% TiO₂ is recovered by flotation of the nonmagnetic portion, as was formerly done at the MacIntyre Development, Tahawus, NY, where ilmenite-mining ceased in 1982.

At Allard Lake, Quebec, ore at 32% to 36% TiO₂ is shipped from the mine to the beneficiation plant at Sorel, Quebec; some of the ore is shipped to

steel companies as a substitute for fluorspar flux. For upgrading to slag, the ore is crushed and ground, concentrated by gravity methods, roasted to remove sulfur, mixed with a reducing agent, and smelted in an electric arc furnace. A high-purity pig iron is produced. The titanium is concentrated in the slag, known as Sorelslag, which contains 80% TiO₂. Because the iron content of the slag is low, its use reduces the quantity of iron sulfate in the liquid effluent of sulfate process pigment plants. Because of its relatively high content of magnesium and calcium, which cause operating problems during chlorination, Sorelslag is not used to make TiCl₄.

At Richards Bay, Republic of South Africa, both rutile and ilmenite are produced from heavy mineral sand deposits. The ilmenite, containing about 50% TiO₂, is relatively low in magnesium and calcium and is smelted with carbon in an electric furnace to produce an 85% TiO₂ slag. Because of its low content of the above previously mentioned impurities, the Richard Bay (RB) slag is acceptable for manufacturing TiCl₄ and is also a feed material for the sulfate pigment process.

Pigment Production.—Titanium dioxide pigment is produced commercially by two methods that require different raw materials. In the sulfate process, ilmenite or titanium slag is reacted with sulfuric acid; a portion of the iron sulfate formed may be crystallized and removed, and titanium hydroxide is precipitated by hydrolysis, filtered, and calcined. In the

chloride process, rutile is converted to TiCl₄ by chlorination at 850° to 950° C in the presence of petroleum coke. All U.S. commercial chloride-process plants use fluid-bed chlorinators, although static-bed systems can be used for this purpose.

Titanium tetrachloride so prepared may be used either in making pigment or, with additional purification, for reduction to metal. In making pigment, the TiCl₄ is oxidized with air or oxygen at about 1,000° C, and the resulting fine-size TiO₂ is calcined at 500° to 600° C to remove residual chlorine and any hydrochloric acid that may have formed in the reaction. Aluminum chloride is added to the TiCl₄ to ensure that virtually all of the titanium is oxidized in the rutile crystalline form.

Recoveries of TiO₂ in pigment are approximately 90% and 80% to 85% for chloride process and sulfate process plants, respectively.

Metal Production.—Feed materials needed for metal production are the same as those for chloride-process pigment because formation of TiCl₄ is required in both cases. Rutile and rutile substitutes are the only titanium raw material used for metal production in the market economy countries.

Titanium sponge is produced by reducing TiCl₄ with sodium or magnesium under an inert atmosphere at temperatures up to 1,040° C. Residual chlorides are removed by vacuum distillation, inert gas sweep, or after cooling and crushing, by leaching in very dilute acid. The sponge is compacted, usually with some

scrap and alloying additions, and made into ingot by two or more successive vacuum-arc melting operations.

Recycling.—Scrap titanium generally accounts for 40% to 50% of ingot production. Scrap is generated by producers of ingot and mill products and by consumers of mill products in fabricating finished products or components. It is estimated that up to 75% of titanium ingot metal becomes scrap during processing to finished parts. However, the proportion of scrap is gradually being lowered because of increased use of castings and other near-net-shape technologies.

Clean and well-segregated scrap, processed to remove impurities, is blended with sponge metal and alloying constituents and remelted to ingot. Remelting is mainly by vacuum-arc consumable-electrode processing. Electron-beam and plasma-arc cold-hearth melting is also used, especially for chips and turnings. Cold-hearth melting is very effective in ensuring removal of high-density inclusions, such as tungsten carbide tool particles, which settle in the hearth area during melting. A substantial quantity of titanium scrap, particularly unprocessed turnings, is consumed directly or in making ferrotitanium for use in steel and other alloys. In 1988–89, annual use of titanium scrap for remelting to ingot was about 18,000 tons; for use in steel and superalloys, 4,500 tons; and in aluminum alloys, 500 tons.

Economic Factors

Prices.—The price of rutile pigments and titanium sponge in constant dollars decreased 20% and 14%, respectively, from 1969 through 1972, as shown in table 22. Reflecting a sharp increase in pigment demand, the constant dollar price rose 32% in 1974. The rutile price did not surpass that level until 1989, following 6 consecutive years of record-high demand. The titanium sponge price reached a record high in 1980 because of unprecedented demand for commercial aircraft, then dropped sharply in 1982 and 1983 following a severe downturn in the commercial aircraft market. Although sponge consumption was near record-high levels in 1989, the constant dollar price was several percent below the moderate levels of 1975–77. Published prices of

titanium concentrates and products in 1988–89 are listed in table 10.

Costs.—Construction cost of a 110,000-ton-per-year synthetic rutile plant completed in 1977 at Mobile, AL, was reportedly \$53 million, or about \$480 per annual ton of product.

The cost of constructing a new 82,000-ton-per-year chloride-process pigment plant in 1989 was about \$2,500 per ton of annual capacity. Sulfate-process plants, including neutralization facilities, were said to cost considerably more. The operating costs for chloride plants, which may be operated continuously and are more easily automated, reportedly were as much as 30% lower than those for sulfate plants. The cost of finishing titanium pigment for marketing is about the same for both processes and composes a significant portion of the total costs. Mineral raw material costs in the sulfate process are appreciably lower than those in chloride-process plants that use rutile as feed material.

Plant costs for producing titanium sponge are very high. The estimated cost per annual ton of capacity in 1989 was about \$12,000 to \$15,000. Raw material costs for producing titanium sponge are about the same, whether reduction is with sodium or magnesium, and the selection of one reductant over the other depends upon local market economics.

Tariffs.—The duties shown in table 23 reflect results of the Tokyo Round of Multilateral Trade Negotiations completed in 1979 under which tariffs on many items were reduced in several stages over the period January 1, 1980, to January 1, 1987.

Depletion Provisions.—The depletion allowance for ilmenite and rutile is 22% when mined from domestic deposits and 14% from foreign deposits.

Operating Factors

Environmental Requirements.—Heavy mineral sand mining presents few serious environmental hazards. The land is restored by returning the bulk of the sand after removal of the ore minerals and may even be improved in low, flat areas. Dune areas can be left in nearly their original form, and the sand can be stabilized by seeding and replanting.

The major environmental problem in the titanium industry is the disposal of wastes from pigment-producing processes that use ilmenite, generating up to 3.5 tons of waste per ton of product. Solutions to this problem required the development of methods to neutralize and control the effluent now produced by the sulfate pigment process, mainly a solution of waste sulfuric acid and ferrous sulfate heptahydrate. Deep well disposal has been used for waste ferric chloride produced when ilmenite is used to make $TiCl_4$. In processes for making synthetic rutile, the effluent solutions are treated to regenerate the original leaching agent, such as hydrochloric acid, which is recycled, and to form useful byproducts such as sodium sulfate, ammonium sulfate, and iron oxide. In sulfate-process technology, there is a strong trend away from disposal of waste materials in streams or in the ocean. Both U.S. sulfate-process producers now are using waste treatment plants that neutralize acid effluent with limestone and lime and produce gypsum and iron oxide byproducts. Such neutralization processes add about \$100 per ton to the cost of the TiO_2 pigment product. The sale of all byproducts would recover only a small fraction of this cost.

On September 1, 1989, the Environmental Protection Agency (EPA) published a newly revised interpretation of the Bevill exclusion, which exempts mineral processing wastes from regulation under subtitle C of the Resource Conservation and Recovery Act (RCRA). EPA's revised interpretation addressed the definition of mineral processing and established high-volume and low-hazard criteria for waste streams to be retained within the Bevill exclusion.¹¹ Subsequent proposed rulemaking later in 1989, published in January 1990, applied this revised interpretation to 20 waste streams that were conditionally retained in the Bevill exclusion.¹² In the TiO_2 - $TiCl_4$ sector, chloride processing waste solids were retained, passing both the high-volume and low-hazard criteria. However, other waste streams in this sector were not retained: sulfate process waste acids, having failed to pass the low-hazard criterion; and sulfate process waste solids, chloride process waste acids, and titanium leach liquor, which all failed the high-volume criterion. EPA estimated compliance costs for the sulfate process portion of the TiO_2 sector to average

0.8% of the value of shipments for the affected facilities.

Toxicity.—Titanium is a nontoxic material, as demonstrated by the use of TiO_2 in cosmetics and the use of titanium for making pacemakers and other implant devices for humans. However, some titanium compounds can be hazardous; for example, TiCl_4 , which reacts violently with water or moisture in the air, forming TiO_2 and hydrochloric acid.

Energy Requirements.—According to a 1975 study for the Bureau of Mines, energy requirements for alluvial mine production are about 5.1 million British thermal units (Btu) per ton of TiO_2 in concentrate. Production of pigment requires about 75 to 112 million Btu per ton of TiO_2 , depending on the process and feed material used. Titanium sponge production uses from 408 to 466 million Btu per ton of metal, of which about 248 to 270 million Btu is required to regenerate the reductant and chlorine. The conversion of sponge metal to titanium ingot requires an additional 46 million to 57 million Btu per ton of titanium ingot.¹³

TUNGSTEN

By Gerald R. Smith

Mr. Smith, a physical scientist with 26 years of research and commodity experience with the Bureau of Mines, has been the commodity specialist for tungsten since 1986. Domestic survey data were prepared by Cheryl Jackson, mineral data assistant; the world production table was prepared by Virginia Woodson, international data coordinator; and the outlook data were prepared by Barry Klein, Branch of Technical Analysis.

Average prices for tungsten concentrate remained essentially unchanged during 1989 compared with those of 1988, thus preventing any significant resumption of U.S. tungsten mining. Dependence upon China as a predominant source of concentrate continued during the year, increasing from 51% of total U.S. imports of concentrate in 1988 to 69% in 1989. In spite of the decrease in imports of ammonium paratungstate (APT) and tungstic acid (TA) from China as a result of the Orderly Marketing Agreement (OMA) signed in 1987, China's share of all U.S. tungsten imports reached 61% in 1989. The total annual domestic tungsten activity, based upon concentrate consumption, production of APT, and net production of intermediate products remained at about the same level as in 1988.

DOMESTIC DATA COVERAGE

Domestic production data for tungsten are developed by the Bureau of Mines by means of three separate, voluntary surveys. These surveys are "Tungsten Ore and Concentrate," "Tungsten Concentrate and Tungsten Products," and "Tungsten Concentrate." Of the 45 operations to which survey requests were sent, all responded, representing 100% of the total production shown in table 1.

LEGISLATION AND GOVERNMENT PROGRAMS

Physical disposals of tungsten from the National Defense Stockpile totaled 466,000 kilograms during the year. The

tungsten, contained in nonstockpile-grade ores and concentrates, was released as payment material in support of the Defense Logistics Agency's ferroalloy upgrading program, under the National Defense Authorization Act. Disposals of all tungsten remaining for release, under existing authorization within this program, were completed by the end of fiscal year 1989. The Defense Authorization Act for fiscal year 1990, beginning October 1, 1989, in-

cluded no further authority for disposal of tungsten.

In the Report of the Secretary of Defense to the Congress on National Defense Stockpile Requirements, presented in April 1989, a recommendation was made that the stockpile goal for tungsten be raised by about 9,180,000 kilograms. The recommendation, based upon a revised assessment of military requirements, would, if implemented, effectively raise the

goal for all tungsten materials to near the existing inventory level and essentially eliminate the need for future tungsten disposals.

The Environmental Protection Agency (EPA) eliminated tungsten sludges that were produced in ore leaching and waste treatment processes from its original list of mineral processing wastes considered for exclusion from the Resource Conservation and Recovery Act guidelines. This was effectively accomplished in an April 17, 1989 Notice of Proposed Rulemaking (54 FR 15316), in which EPA proposed to remove all but 39 mineral processing streams from consideration. By further applying high-volume, low-toxicity criteria to the remaining process streams, the list was reduced to 26 on September 1, 1989, (54 FR 36592).

The EPA announced final amendments to Clean Water Act regulations affecting nonferrous manufacturing that included the secondary tungsten and cobalt subcategory along with five other subcategories. Notice of these amendments, published October 30, 1989, (54 FR 45299), were in response to settlements with six petitioners regarding regulations in 40 CFR 421 promulgated September 20, 1985, (50 FR 38276). The amendments to the secondary tungsten and cobalt subcategory (40 CFR 421.310-40 CFR 421.317) affect only cobalt effluents but are an obvious integral step in the secondary recovery of cemented carbide components.

STRATEGIC CONSIDERATIONS

Tungsten is an important strategic material necessary for defense purposes. Currently, the heavy metal alloys of tungsten, containing 3% to 10% nickel and small quantities of iron or copper, are used in several of the smaller diameter projectiles for penetrating armor plate. Cemented tungsten carbide parts, which exhibit excellent cutting and wear-resistant properties, are vital to the U.S. metalworking, machining, construction, transportation, mining, and oil- and gas-drilling industries. The Department of Defense (DOD) relies heavily on the maintenance of a broad domestic production base to cover mobilization contingencies. The entire tungsten industry, from

mined ore to manufactured products, thus represents an important component of the U.S. defense policy. The DOD continually assesses the U.S. ability to produce tungsten, in order to ensure that this and other sources of supply are sufficient to meet current and projected levels of demand necessary to preserve the national defense. To that end, the quantity of tungsten in the National Defense Stockpile was

proposed to be maintained at a level exceeding 32,000,000 kilograms.

ISSUES

The world tungsten market became increasingly more dependent on supplies of tungsten materials from China during 1989. Concentrate prices re-

mained low and appeared to be dominated primarily by the production, distribution, and pricing strategies of the Chinese, who possess about 47% of the world's tungsten reserves. As a result, most tungsten mines in the United States and other market economy countries remained closed or were operated at reduced capacity during the year. In addition, little or no economic incentive existed to explore or develop other tungsten resources.

PRODUCTION

Releases of tungsten concentrate from the National Defense Stockpile, in support of the ferroalloy upgrading program, provided about 6% of the supply consumed in domestic processing.

Curtis Tungsten Inc., Upland, CA, completed its sale of the initial offering of common stock on June 28, 1989. Revenues realized from this sale en-

abled production to begin at a relatively low level during the last quarter of the year. A company representative indicated that the annual production capacity of the mine and mill was about 360 metric tons (mt)¹ by yearend. The company continued to modify and adjust its milling operation to ensure the quality of their product. No material was offered for sale on the world market in 1989.

U.S. Tungsten Corp., Bishop, CA, continued as the only other company producing tungsten concentrate. The Pine Creek Mine and mill was operated on an intermittent basis at levels below capacity in order to provide supplemental feedstock to the company's APT conversion facility. Imported concentrate was the primary source of raw material.

Canada Tungsten Mining Corp. Ltd. operated its Fort Madison, IA, APT conversion facility at near capacity levels during 1989, following the plant's reopening in August 1988. The company began selling all of its product on the open market upon completion of the tolling contract with Bomar Resources Inc. in July 1989. The tolling agreement had utilized about 70% of the plant's capacity.

CONSUMPTION AND USES

Total domestic consumption of tungsten in primary end-use categories decreased by about 4% in 1989 compared with that of 1988. Demand for cemented

carbides in the combined cutting tool, mining tool, and wear-resistant component industries was strong during the first 8 months of the year but began to decrease in the final months, showing a small gain for the year. This gain was more than offset, however, by a moderate decline in the demand for other tungsten products, including specialty steels, superalloys, chemicals, and mill products made from metal powder. Demand for tungsten in the oil and gas drilling industry weakened during the first half of the year. The number of active drilling rigs in the United States declined steadily from 940 at the end of 1988 to 737 by the end of May 1989. This trend was reversed during the remainder of the year, reaching 1,061 active rigs by yearend.

PRICES

Average prices for wolframite and scheelite concentrate increased by 7% and 1%, respectively, in 1989, according to quotations published in Metal Bulletin.

Government representatives of tungsten producing and exporting countries met in Sydney, Australia in October 1989 to discuss the world tungsten market. Particular emphasis was placed on the supply-demand balance and prices of tungsten materials. Delegates recognized that price targets for concentrates and intermediate materials set at the September 1988 meeting in Changsha, China had not been met. They agreed that these price objectives, averaging

about \$71.00 and \$78.00 per metric ton unit (mtu)² for wolframite and scheelite, respectively, should remain essentially the same. Consideration was given to certain practical measures that individual countries could take to achieve these objectives in a reasonable period of time. Specifically, the delegates stated that there was a need for the producers and exporters to be responsible and economically rational in their production and marketing policies. They further agreed to carefully examine their sales practices on an individual basis, so as to ensure the consistency of price and supply. Recognizing the importance of the relationship between the price of concentrates and tungsten intermediates, the Chinese delegation stated its intention to coordinate the respective price levels. This would be accomplished by enhancing the administration of its export licensing system for tungsten and tungsten products.

Domestic APT prices decreased about 25% during the year from a range of \$87.63 to \$88.74 per mtu in January 1989 to a range of \$66.41 to \$67.79 by the end of December. Prices for tungsten metal powder and tungsten carbide powder remained virtually unchanged during the year, quoted at \$22.00 and \$21.65 per kilogram, respectively.

FOREIGN TRADE

Total U.S. imports of tungsten materials decreased about 6% in 1989. China continued to be the dominant supplier, providing nearly 61% of all imported tungsten materials. Restrictions in the imports of APT and TA from China, in accordance with the OMA, were offset, as in 1988, by significant imports of concentrates, oxides, and sodium tungstate. Imports of concentrate from China increased by 34% compared with those of 1988. China's share of the total U.S. imports of concentrate increased from 51% in 1988 to 69% in 1989.

U.S. processors of tungsten voiced concern during the year that the OMA limitation of imports of APT and TA from China was being circumvented by the import of tungsten oxides. Although total imports of APT and TA from China in 1989 were about 244 mt less

than the OMA quota of 622 mt, the combined imports of APT, TA, and oxides exceeded the quota by about 80 mt.

WORLD REVIEW

Capacity

The data in table 18 are rated capacity for mines and mills as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced in a period of time on a normally sustainable long-term operating rate, based on the physical equipment of the plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

Mine capacity for tungsten is based on published reports, maximum production statistics, and estimates. The latter is utilized particularly for the centrally planned economy countries where capacity information is either incomplete or unavailable.

United Nations Conference on Trade and Development (UNCTAD)

The UNCTAD Committee on Tungsten convened its 21st session in Geneva, Switzerland, in December 1989. A Secretariat paper and national statements presented to the Sessional Working Group provided a review of current market conditions. The Secretariat noted strong economic growth in tungsten-consuming countries, as well as increased trade, but continued low prices. Tungsten mines in many market economy countries continued to remain closed as a result of these low prices. Such actions as China's licensing system to control tungsten exports, the OMA signed between China and the United States, and efforts by individual producer nations to achieve higher prices, had little or no effect on the market. The statements of delegates from several producing countries were consistent with the Secretariat's analysis. Remarks by the Chinese delegation suggested that the market condition was due to a general economic slowdown, a stronger U.S. dollar, and psychological pressure from the overhang of material in

the U.S. Defense Stockpile.

As part of the Sessional Working Group, a representative from Metal Bulletin presented a detailed description of the derivation of the publication's quoted tungsten concentrate prices. It was noted that several questions were under review regarding the manner in which prices were quoted.

These included the relevance of the present European trading prices as a basis; the need for continuing separate scheelite and wolframite prices, and the importance of initiating individual quotations, namely, one reflecting the trading of Chinese materials, and the other reflecting those of the rest of world.

During the discussions on statistics and market developments, the Secretariat made a strong request for more complete reporting of statistics and for participation by all countries in the reporting of data. The lack of data from the major producing countries with centrally planned economies was of continued concern.

The issue of market stabilization and the need for a commodity agreement to increase prices was again raised by the Chinese delegation. After additional remarks from delegates of producing

and consuming countries, this discussion was ended without evidence of any progress toward an agreement. Suggestions to remove such discussions from the agenda or to modify the words in the agenda for the next meeting received support, but a consensus of the full committee could not be reached.

The Secretariat reported that efforts during the year to survey Research and Development (R&D) activities in tungsten resulted in only limited response. To further this effort, a sample questionnaire was introduced by the Secretariat

for consideration, suggestions, and comments by each of the countries' delegates. On the basis of these replies, it was anticipated that the Secretariat would then be able to accumulate additional R&D information through the country delegations and to report such results at the next UNCTAD meeting.

European Communities (EC)

As a result of its investigation into complaints that China and the Republic of Korea were dumping tungsten materials into the EC, the EC Commission proposed that specific duties be applied. In August 1989, the Commission recommended imposing duties of 40% on ores and concentrates, 30% on APT, and 40% on tungsten oxides and tungstic acid imported from China. The question of the dumping of APT and tungsten carbide powder by the Republic of Korea was dismissed from further consideration by the Commission. After further responses from EC members, the Commission also terminated its investigation into claims that APT and tungsten metal powder were being dumped by China. By yearend, debate was continuing, however, regarding the imposition of duties on imports of Chinese ores and concentrates, tungstic acid, tungsten oxides, and tungsten carbide powder.

International Tungsten Industry Association (ITIA)

The ITIA held its 2nd Annual Meeting in Tokyo, Japan, in October 1989. After election of a new president and vice president, the secretary-general presented a detailed market report, supported by statistics, elaborating on several aspects of the tungsten market. These included trade patterns, supply-demand conditions, actions regarding the U.S. National Defense Stockpile, price trends, and the status of the European Commission's antidumping investigation. On the basis of this information, part of the subsequent discussions focused on attempting to understand the reasons for the low tungsten prices amid a relatively strong demand during the year.

Membership in the ITIA was increased by two; the Association gained four members but lost two of its original members. The new members included one each from the United States and Canada, and two from Japan. The departing members were Eurotungstene

Poudres of France and China National Nonferrous Metals Import and Export Corp. The latter's official reason for its resignation was that the ITIA, which is essentially an industry, consumer-based association, already had one of its subsidiaries, Zhuzhou Cemented Carbide, as a member.

China

The midyear political unrest had little effect on the production and shipment of tungsten materials. Although some brief delays and inconveniences were reported by buyers, there was essentially an uninterrupted flow of material.

Efforts were made by China to gain a share of the market for drill bits used in the mining and oil drilling industries. A private Norwegian company, Bjorn Hansen AS, reportedly was to sell the bits that are to be produced at the Shanghai No. 1 petroleum machinery works. The cost of these bits was said to be considerably less than similar items manufactured in the United States and Europe.

France

Bureau de Recherches Géologiques et Minières (BRGM), through its subsidiary, Cofromines, ceded its 51.15% interest in Eurotungstene Poudres. The latter specializes in the production of tungsten carbide powder, tungsten metal powder and intermediate products of tungsten. The majority of the interest ceded by Cofromines was acquired by Cie Metalurgique et Minière.

Israel

Construction of a tungsten metal powder and tungsten carbide powder production plant began in Ramat Hovav. According to projections, the facility would be in operation in about 2 years at a production capacity of 300 mt per year. After 3 years, the capacity was expected to be doubled. Feedstock will consist of scrap tungsten that is to be processed using a newly developed grinding and purification procedure.

Japan

The Japanese Government added 2.8 days of domestic consumption of tungsten to its ferroalloys stockpile. The private sector was expected to follow the Government's action by increasing its stockpiles of tungsten by 1.2 days. Reportedly, the Government will sus-

pend purchases when the Government and private inventories reach 42 and 18 days of domestic consumption, respectively. As a result of this year's action, the inventories will stand at 28.2 and 12.1 days, respectively.

Korea, Republic of

Korea Tungsten Mining Co. Ltd. began production of tungsten wire at its Daegu facility in November 1989. Output from this new plant was to provide about one-half of the country's estimated annual consumption of wire, predominantly for use as filament in lamp and lighting applications. The additional wire required to meet internal demand is expected to be acquired from traditional suppliers in Japan and the United States.

Spain

Two Spanish banks, the Banco de Credito Industrial and the Banco Español de Credito, acquired a 50% interest in a restructured joint venture formed in efforts to reopen the La Parilla Tungsten Mine and mill near Merida. Officials of the new company, Grupo Minera La Parilla, stated that they expected the project to be viable even at 1989 tungsten concentrate prices. The mine was closed in 1987 after flooding problems and low market prices caused debts to mount.

Sweden

A report by the Swedish Mining Association disclosed that the Yxsjöberg tungsten mine was closed in mid-1989. Officials of AB Statsgruvor, the operator of the mine, stated that negative market forecasts and low profitability were primary factors influencing their decision. Production of concentrate at the facility averaged an estimated 320 mt per year over the last 5 years.

CURRENT RESEARCH

Advancements in roll mill technology increased the utility of cemented carbides in hot rolling applications.³ A cast-in-carbide roll design incorporating a ring of cemented carbide, cast in place in ductile iron, has effectively eliminated problems associated with transmitting torque to the carbide rings. As a result, the established use of

cemented carbides in cantilever-type rolls can be extended to intermediate rod mills, finishing bar mills, and tube mills.

New uses have been discovered for a modified version of a high-illumination argon arc lamp developed by Vortek Industries Ltd., Vancouver, British Columbia.⁴ A 300-kilowatt model, which utilizes tungsten electrodes, and reaches an arc temperature of up to 13,000° C, has been used to anneal silicon wafers for the electronics industry. The process is cleaner and more controlled than traditional heating techniques, resulting in improved wafer quality. The powerful light source also is playing a role in the development of the next generation of aircraft structural materials. It has been employed to test the heat resistance of candidate materials for nose cones and wing leading edges. Another materials area where this lamp is finding increasing application is in the thermal treatment of metals.

A metal-matrix-composite-thermal-spray coating material for wear resistance was developed by Alloy Technology International Inc., Hewitt, NJ.⁵ It is especially effective in resisting attack by combinations of heat, corrosion, and wear. The powder, known as ResiTic, was said to have double the wear resistance of tungsten carbide-based coatings.

Titanium diboride is a substitute for tungsten carbide in some applications. A titanium diboride powder, requiring no pressure during sintering, was developed by Union Carbide Corp., Advanced Ceramics Div., Cleveland, OH.⁶ As a result, greater design flexibility in the manufacture of products made from it, including cutting tools, bearings and bearing liners, was obtained.

OUTLOOK

Tungsten demand in the United States is keyed to several significant end-use sectors including construction and mining machinery and equipment, metalworking machinery, and lamps and lighting. A statistical projection for each of these end uses was correlated with a specific economic indicator to provide a short-term demand forecast through 1995.

Correlation was excellent between

demand data for construction and mining machinery and equipment and the Federal Reserve Board (FRB) index of construction and allied equipment. Usage, predominantly as cemented carbide tools and equipment in wear-resistant applications, was projected to reach approximately 5,500 mt by 1995. This increase, equivalent to an average of about 540 mt per year above that of 1987 demand, will be associated with generally stronger activity in several industries. These include oil and natural gas drilling, coal and nonfuel minerals mining, highway construction, and commercial and residential construction. The projection is contingent upon stable to moderately higher world oil prices. Should oil prices rise significantly during this time, consumption could go considerably higher as the number of oil rigs is increased.

Correlation was good between demand data for metalworking machinery and the FRB index for this end use. Accordingly, demand is expected to reach about 6,800 mt by 1995. This is equivalent to an average increase of about 340 mt per year over the 1987 level. Machine tool requirements in the automotive and aerospace industries should continue to remain strong. In the automotive industry, in particular, there is expected to be further need for turning, milling, boring, drilling, tapping and grinding tools associated with new transmission and engine machining systems. Consumption of cemented carbide tools to meet future industry requirements will be tempered, however, by continuing competition from substitute materials including ceramics, ceramic composites, polycrystalline diamond and cubic boron nitride. Further slowing the rate of demand for these cemented carbide products will be the increased use of ceramic coatings to extend the life of the carbide. In addition, increases in the production of near-net-shape products by techniques such as precision casting, rolling and forging, and powder metallurgy, will lessen machining requirements.

Correlation was poor between lamps and lighting demand data and the FRB index of major electrical equipment and parts. Projected demand for 1995 was about 850 mt. More realistically, the demand for tungsten in lamps and lighting is expected to remain at about 9% to 12% of total U.S. consumption

of tungsten. In 1987, demand in lamps and lighting represented 11% of the total demand of 7,951 mt. In general, the demand for lamps and lighting will increase as the population increases. The average annual growth rate in population between 1987 and 1995 is calculated to be approximately 0.8% per year.

Total annual domestic consumption of tungsten by 1995 is projected to be approximately 17,000 mt. This assumes that tungsten demand in the combined construction and mining machinery and equipment and metalworking machinery industries will represent about 70% of total tungsten consumption.

Supplies of tungsten concentrate and intermediate materials for U.S. con-

sumption have been sufficient in spite of minimal production at domestic mines in recent years. It is uncertain, however, whether this situation will exist through 1995. Questions remain as to the ability of the Chinese, the major supplier of these materials, to continue to meet a large portion of the world's demand. Depletion of Chinese stocks or the resumption of political unrest could seriously diminish China's exports.

BACKGROUND

Definitions

Tungsten, a silvery gray metal, has an atomic number of 74 and an atomic

weight of 183.92. Its most outstanding physical property is its high melting point of 3,410° C, the highest of all metals. Tungsten is one of the heaviest of elements, with a density of 19.3 grams per cubic centimeter at 20° C. It has good corrosion resistance, good thermal and electrical conductivity, and a low coefficient of expansion. At temperatures above 1,650° C, tungsten has the highest tensile strength of all metals.

Tungsten concentrate is sold in units of tungsten trioxide (WO₃). In the United States sales are based on the short ton unit of WO₃. This is equivalent to 1% of a short ton, or 20 pounds of WO₃ and contains 15.86 pounds of tungsten. In most other countries, tungsten is sold in the metric ton unit.

Natural or synthetic scheelite concentrate, in nodular form, is ideal for direct addition to steel melts, since the calcium is removed as slag. Fine material in either synthetic or natural scheelite is not desirable because of high dust losses. Wolframite concentrate is not satisfactory for steelmaking because of the manganese and tin content.

Tungsten ores and concentrates are converted into the following intermediate products: APT, tungstic acid, sodium tungstate, tungsten metal powder, and tungsten carbide powder. Most of the APT is reduced to tungsten metal powder, which then is processed into tungsten carbide powder.

Tungsten alloys and tungsten mill products such as rod, wire, and sheet are produced from hydrogen-reduced tungsten metal powder. The tungsten carbide produced from powder is cemented, usually with cobalt, to form various cutting and wear-resistant tools and parts.

Tungsten chemicals (APT, tungstic acid, and sodium tungstate) are produced as coproducts at some tungsten processing plants and as primary products at others. When not processed further into metal powder, they generally are used in the chemical industry.

Products for Trade and Industry

Tungsten materials can be divided into four major classes, depending upon use: (1) a carbide in cutting and wear-resistant materials, and welding and hard-facing rods; (2) mill products made from essentially pure metal; (3) an alloy constituent

in high-speed and tool and die steels, superalloys, and nonferrous alloys; and (4) various chemicals and compounds for nonmetallurgical applications.

The extreme hardness of tungsten carbide at temperatures exceeding 1,000° C makes it a preferred metalworking material for cutting edges of machine tools subject to intense wear or abrasion, and for metal surfaces in forming and shaping dies. The mining and petroleum industries use tungsten carbide in drill bits, in the cutting edges of earthmoving equipment, and in crushing machinery. Tungsten carbide is used widely in wear parts of transportation and electrical equipment.

In most applications, tungsten carbide generally is cemented with a powdered cobalt metal binder by compaction and sintering. The cobalt content can range from about 3 to 25 weight percent, with the higher content providing greater shock resistance at a sacrifice in hardness. Tantalum and/or titanium carbides are used in conjunction with tungsten carbide in certain cutting and chipping tools. Also, coatings such as titanium carbide, titanium nitride, and aluminum oxide on tungsten carbide are used extensively to increase the life of inserts for machining applications.

Mill products made from pure, or substantially pure, tungsten metal powder are used in significant quantities by the electrical and electronic industries. Tungsten wire is used as the filament in electric lamps and as cathodes for electronic tubes. Disks produced from tungsten rods or sheet are used in automotive distributor points, although this end use is declining as the number of automobiles with electronic ignition systems increases. They are also used as contact points in numerous manufactured products. Tungsten metal is employed as heat and radiation shielding, as electrodes for inert-gas welding, as components of X-ray and cathode ray tubes, and as heating elements in high-temperature resistance furnaces. Tungsten metal is used by the aerospace industry because it retains its strength at elevated temperature in reducing or inert atmospheres. The use of tungsten as a heavy metal for counterweights and balances, especially by the aircraft industry, has been replaced, to a significant extent, by depleted uranium, which approaches the density of tungsten.

Cast tungsten carbide is used princi-

pally as a hard-facing material. In this application, carbide particles are applied by a welding process to provide an abrasion-resisting surface layer on the surface to be coated. The carbide may be initially in the form of rod or loose grains in a tube.

As an alloy constituent, tungsten is used primarily in the production of high-speed steels and tool and die steels. Hardness and oxidation resistance at elevated temperatures are the most important properties possessed by these steels, which are used for machinery and equipment in the metalwork-

ing, construction, and mining industries. Certain grades of stainless and other alloy steels contain tungsten to improve wear and abrasion resistance, shock resistance, corrosion resistance, and/or strength at high temperatures.

Tungsten is an important constituent in a wide variety of superalloys and nonferrous alloys. Tungsten-containing superalloys are being utilized increasingly in high-temperature applications for their high-temperature strength and oxidation resistance. Tungsten alloyed with copper or silver is used for electrical contacts to provide wear resistance

with adequate electrical conductivity.

Nonmetallurgical applications of tungsten include chemicals used in textile dyes, paints, enamels, toners, and coloring glass. Certain tungsten compounds are luminescent and used as phosphors in pigments, X-ray screens, television picture tubes, and fluorescent lighting. Sodium tungstate is employed as a corrosion inhibitor and a fire-proofing agent in textiles. APT is used in making catalysts for the refining of petroleum. Among other chemical applications, tungsten compounds are used in chemical-vapor deposition, as catalysts in other chemical processing, and as laboratory reagents.

The chief nonindustrial use of tungsten is in armor-piercing ordnance, but this has been replaced, in part, by depleted uranium.

¹ Refers to metric tons of tungsten content throughout chapter.

² Equals 1% of a metric ton of WO₃ and contains 7.93 kilograms of tungsten.

VANADIUM

By Henry E. Hilliard

Mr. Hilliard, a physical scientist with more than 20 years Bureau of Mines experience, has been the commodity specialist for vanadium since 1986. Domestic survey data were prepared by Lisa Harley, mineral data assistant, and international data tables were prepared by William L. Zajac, Chief, International Data Section.

The year 1988 proved to be a boom year for vanadium producers as tight supply and strong demand by the steel industry and other consumers pushed up the price of vanadium compounds. The U.S. steel industry, which accounted for about 85% of domestic consumption, recorded its highest shipments since 1980's. By the end of 1989, vanadium's fortunes had turned full circle as the market witnessed prices headed for levels lower than at any time since the early 1980s. Price surges in the fourth quarter of 1988 and the first part of 1989 produced the usual results, a significant increase in production and prices followed by a rise in inventories and a consequent slump in prices. Fourth quarter 1988 vanadium pentoxide (V_2O_5) prices of about \$3.50 per pound held through the second quarter 1989. Then, demand for ferrovanadium (FeV) by the steel industry and aluminum-vanadium (Al-V) master alloys by the aerospace industry increased sharply. At the same time, operating problems developed in some producer units, causing an apparent shortage and forcing some consumers to buy V_2O_5 and downstream vanadium products from alternate sources at higher prices. Producers of tool and other specialty steels were especially hard hit as the price for V_2O_5 soared to more than \$7.00 per pound. As prices continued to rise, consumers began to build inventories in anticipation of even higher prices and tighter supplies expected in the third quarter. Some consumers began to substitute other materials for vanadium. By fourth quarter 1989, it was clear that consumer inventories were excessive and, as producers added new capacity, meeting demand posed no problem. Having built up large stocks, consumers deferred making new purchases while they reduced their inventories. Predictably, prices

for V_2O_5 and downstream vanadium products began to fall. First quarter 1990 producer prices for V_2O_5 were expected to fall to about \$2.50 per pound. Spot market prices were expected to fall even lower to about \$2.30 per pound.

U.S. reported consumption of vanadium was 5,117 tons, a 4% decrease from 1988 consumption.

LEGISLATION AND GOVERNMENT PROGRAMS

On January 1, 1989, the United States and Canada implemented the United States-Canadian Free Trade Agreement (FTA). The objective of the agreement was to eliminate barriers to trade, facilitate conditions of fair competition, liberalize conditions for investment, establish

¹ Recoverable vanadium contained in uranium and vanadium ores and concentrates received at mills, plus vanadium recovered from ferrophosphorus derived from domestic phosphate rock.

² Produced directly from all domestic ores and ferrophosphorus slag; includes metavanadates.

³ Includes vanadium recovered from fly ash, residues, and spent catalysts.

⁴ Excludes U.S. production.

procedures for the resolution of disputes, and lay the foundation for further bilateral and multilateral cooperation. The new agreement contained rules and safeguards designed to ensure that minerals, metals, and material products that originate or are produced in either country have equal access to both markets.

Before enactment of the FTA, about 70% of the goods that crossed the United States-Canadian border were free of duty. The remaining 30% will have their duty removed in one of three ways: (1) duty elimination as of January 1, 1989, (2) duty elimination in five equal steps by January 1, 1993, and (4) duty elimination in ten equal steps by January 1, 1998. Rates of duty, effective with respect to goods originating in the territory of Canada and entered on or after January 1, 1989 through January 1, 1993 are shown in the following table:

HTS Subheading	January 1, 1989	January 1, 1990	January 1, 1991	January 1, 1992	January 1, 1993
7202.92.00	3.3%	2.5%	1.6%	.8%	Free.
2850.00.20	12.8%	9.6%	6.4%	3.2%	Free.
2841.90.10	8.9%	6.7%	4.4%	2.2%	Free.
2825.30.00	12.8%	9.6%	6.4%	3.2%	Free.
8112.40.60	2.4%	1.8%	1.2%	.6%	Free.
2841.90.10	8.9%	6.7%	4.4%	2.2%	Free.

It should be noted that the FTA had no effect on the tariffs of either country with third countries.

On August 23, 1988, Congress enacted the Omnibus Trade and Competitiveness Act (Public Law 100-418). The stated objective of the act was to enhance the competitiveness of the Nation's industries and to improve the management of U.S. trade strategy. The Act also included provisions modifying U.S. customs laws and tariff schedules. Subtitle B of the Act required that all tariff schedules after January 1, 1989, conform to nomenclature of the internationally established Harmonized Tariff System (HTS), an international system for classifying products for tariff purposes that had already been adopted by most U.S. trading partners. The new law restructured the old U.S. import-export classification system. The new schedule B classification was based on the organizational framework of the Tariff Schedule of the United States Annotated (TSUSA). That means that equivalent import and export items

are assigned the same 10-digit classification code.

On July 11, 1989, the U.S. House of Representatives passed House Bill (H.R. 491) calling for a 3-year mining research initiative aimed at reducing the U.S. dependency on the Republic of South Africa and the U.S.S.R. for strategic and critical minerals. During the 3-year period, the Bureau of Mines would be charged with examining new extractive technologies to recover from domestic deposits such strategic minerals as chromium, manganese, platinum group metals, vanadium and several other metals. If the bill were to become law, it would cost the government \$5 million the first year, \$10 million the second, and \$15 million the third year. Most studies would be completed by 1992.

In July 1989 the Senate passed legislation that would establish a Government-

and critical material because of the significant import dependence of the United States for its vanadium supply and because of essential use of vanadium in equipment for defense, energy, and transportation.

The industrialized countries of the Western World are highly dependent on imports of vanadium pentoxide and vanadium-bearing slag from the Republic of South Africa, which was the world's largest producer of vanadium in 1989, accounting for about 60% of the vanadium produced by market economy countries. Between 1983 and 1988, 44% of U.S. vanadium imports came directly from the Republic of South Africa. Additional material was processed in Western Europe and then imported to the United States as FeV or V₂O₅. The European Community (EC) and Japan were more heavily dependent on South African imports than the United States. In 1988, for example, 60% of the pentoxide consumed by Japan came from the Republic of South Africa. Any extended cutback in supplies from the Republic of South Africa would seriously upset the balance between supply and demand in the market economy countries. Sizable, near-term deficits could only be offset by material from China or the U.S.S.R.

Stockpile

The National Defense Stockpile (NDS) had a 1989 goal of 7,700 tons of vanadium contained in V₂O₅ and 1,000 tons in FeV. Actual yearend stockpile inventories were only 721 tons of vanadium as V₂O₅. The 1989 fiscal year Defense Authorization Act required the Department of Defense to outline plans for at least \$20 million in upgrading projects. The Department responded by submitting to Congress an ambitious \$30 million plan to upgrade vanadium pentoxide and other materials in the NDS. To justify the planned upgrading program, Defense stated that, although the need for some traditional stockpile materials remains substantial, current and projected military strategies and high-technology weapons systems would require more of the advanced and upgraded forms of industrial materials and less of the conventional materials and unprocessed mineral ores. In August 1989, the Defense Logistics Agency (DLA) issued its upgrading solicitation of about 1,300 tons of Grade-A

owned U.S. enrichment corporation and provide some relief for the ailing domestic uranium-vanadium mining and milling industry. The new corporation would operate as a private company and presumably be more competitive. The Treasury Department would own all of the stock and collect dividends, if any, generated by the \$1.5-billion-a-year enterprise. A companion bill (H.R. 2480) was introduced in the House on May 24, 1989. Both bills (Senate bill 83 and H.R. 2480) were referred to several committees where their disposition was uncertain. H.R. 491 also faced an uncertain future because the Administration and the Bureau of Mines have stated that its provisions would duplicate efforts already underway.

STRATEGIC CONSIDERATIONS

Vanadium is classified as a strategic

TABLE 2

**STOCKPILE STATUS,

(Short tons of contained vanadium)

Material	Goal	Inventory
Vanadium pentoxide	7,700	721
Ferrovandium	1,000	—

V₂O₅. The solicitation was withdrawn a few weeks later, but was expected to be reissued in the second or third quarter of 1990.

ISSUES

Before 1984-85, more than one-half of the vanadium mined in the United States was recovered as a coproduct with uranium from sandstone mined on the Colorado Plateau. Companies recovering vanadium from uranium ores were hurt by the downturn in nuclear power plant construction in the aftermath of the Three Mile Island nuclear reactor accident and the subsequent reduced demand for enriched uranium. Worldwide recession, high interest rates, and the cancellation of power-plant construction in the United States caused the Nuclear Exchange Corp. (Nuexco) exchange value of uranium oxide (U₃O₈) to plummet from \$40.75 per pound in early 1980 to less than \$10.00 per pound in 1989. The exchange value is Nuexco's judgment of the price at which transactions for significant quantities of uranium concentrates could be concluded on a specified date. Value is based on bids to buy and offers to sell, as well as recently completed and pending transactions.

A direct result of the price decrease was mill closing and decommissioning, personnel cutbacks, and cancelled development and expansion plans. This unstable situation had the potential for creating a much higher degree of dependence by the United States on South African and Chinese imports. However, some of the slack was taken up by increased recovery from petroleum residues. Recovery of vanadium from this source increased during the 1973 Arab oil embargo. Increased demand for petroleum caused refiners to process crude oils with high-sulfur and -metal

content. The trend toward heavier, sour crude and a tightening of sulfur restrictions on fuel products led to the development of the "Flexicoking" process, which concentrated 99% of the metals in the feed in a 2% solid purge from the system. This material has become an important source of vanadium, and in some instances, molybdenum and nickel. At the same time, the combustion of increasingly metalliferous fuel oils at power plants created a second source of feed materials in the form of fly ash and boiler scale. During this period the author performed chemical analyses on some boiler scales that contained as much as 35 weight percent (wt %) V₂O₅. More than 30% of the V₂O₅ produced in the United States is now being recovered from refinery residues, fly ash, boiler scale, and spent catalysts. In 1989, 2,600 tons of vanadium was recovered as oxides from these mostly imported petroliferous materials. This source of vanadium may also dry up as clean air standards lead to a tightening of sulfur restrictions on fuel oil products leading to less production of vanadium containing residues. Gradual depletion of Colorado Plateau vanadiferous uranium ores that have been the principal source of domestic vanadium and the expected reduction of available petroleum residues will require the development of alternative sources to maintain domestic self-sufficiency in this strategic mineral.

PRODUCTION

Vanadium is often considered to be an uncommon element, but actually its abundance in the earth's crust is comparable with or greater than that of nickel, zinc, and copper. Although there is a plentiful supply of vanadium, it is one of the most expensive elements to recover. In most cases, whether vanadium occurs as a primary ore, co-ore, or in petroleum, the vanadium content of the material usually runs 1.5% V₂O₅ or less. V₂O₅ is the principal starting material for the production of all vanadium compounds. Therefore, when one speaks of vanadium production or the supply side of the industry, only those involved in the production of V₂O₅ should be included. U.S. vanadium pentoxide producers are shown in the following table:

Producer	Plant location	Capacity (short tons pentoxide per year)
AMAX Metals Recovery Corp. (a subsidiary of AMAX Inc.)	Braithwaite, LA	2,000
Gulf Chemical & Metallurgical Corp.	Freeport, TX	1,500
Kerr McGee Chemical Corp.	Soda Springs, ID	2,200
UMETCO Minerals Corp.	Blanding, UT	7,500
U.S. Vanadium Corp. (a subsidiary of Stratcor)	Hot Springs, AR	7,500

In January, Atlas Minerals announced the sale of all its Utah and Colorado uranium and vanadium properties and related mining equipment. The sale finalized an earlier decision by Atlas to withdraw completely from the uranium-vanadium business. The company was also reviewing an engineering study with the Nuclear Regulatory Commission (NRC) that would allow Atlas to finalize the decommissioning and reclamation plan for its Moab, UT, uranium-vanadium operations. The Moab mill had the capacity to produce about 2,200 tons per year of V₂O₅.

In February, Strategic Minerals Corp. (Stratcor), based in Danbury, CT, announced plans to renovate and expand its multimillion dollar ferrovandium facility at Niagara Falls, NY. The expansion included new furnace operations that allowed Stratcor to increase its output of Nitrovan by about 50%. Nitrovan, a proprietary compound containing vanadium and nitrogen, can be used by steelmakers for strengthening steel in place of standard FeV. The company also announced plans to double its capacity for the production of vanadium tetrachloride to help meet growing demand for vanadium catalysts.

The Niagara Falls plant depended on Stratcor's Hot Springs, AR, mill for supplies of V₂O₅ that it converted to FeV and other vanadium chemicals. The mill, operated by U.S. Vanadium Corp., a subsidiary of Stratcor, produced V₂O₅ from a variety of raw materials, including vanadium-bearing slag and petroleum refinery residues. Delays in obtaining raw materials and

difficulties with reactivating some mothballed equipment kept V_2O_5 supplies from Hot Springs lower than expected. This caused temporary cut-backs on expected shipments of FeV to customers. The problems at Hot Springs were eventually cleared, ensuring an adequate supply of V_2O_5 for the production of FeV and the expanded Nitrovan facilities.

AMAX Metals Recovery Corp. operated a spent catalyst treatment plant in Braithwaite, LA, that recovered vanadium and other metals from petroleum refinery catalyst. In 1989, the plant produced, in addition to more than 1,000 tons V_2O_5 , 90 tons of molybdenum trisulfide and 10 tons of cobalt concentrate. The company planned to expand its product base to include extracting chromite from waste acid solutions that were used to etch aluminum and vanadium from fly ash. No time-frame was given for completion of the expansion. The company also planned to recover vanadium from waste Stretford process solutions that were used to scrub hydrogen sulfide from gas streams.

Production of V_2O_5 increased sharply at Umetco Minerals Corp.'s Blanding, UT, mill. Production averaged about 330 tons per month. Total production in 1988 was only about 600 tons. A major portion of the 1989 production represented toll work. The mill, which is jointly owned with Energy Fuels Nuclear Corp., produced V_2O_5 at the rate of about 500 tons per month during the first quarter. The mill was then shut down in the second quarter for routine maintenance and improvements to the vanadium extraction process. Production resumed in September. Output of vanadium increased in part because demand increased and prices rose sharply, but also because the Blanding Mill was the only mill still in operating condition capable of recovering vanadium from uranium-vanadium ores.

CONSUMPTION AND USES

Reported consumption of vanadium was a little more than 5,000 tons of contained vanadium or about 4% less than in 1988. Part of this reduction was attributed to reduced demand by the steel industry, in which production was

down by about 2% from that of 1988. Another part could be attributed to substitution of other materials or treatments for vanadium, although an uncertain amount could be assigned to reduced reporting by consumers to Bureau of Mines surveys.

About 85% of all vanadium consumed is accounted for by use in the steel industry as an alloying agent. Another 10% is used in aerospace titanium alloys with the remainder in chemical and catalyst preparations. Vanadium is an essential but not totally indispensable alloying metal. Often the addition of micro amounts can provide considerable improvement in performance without further processing or a significant increase in cost over standard grades. When alloyed with steel, vanadium combines with carbon or nitrogen or both, then precipitates, causing an increase in strength and toughness. In addition, vanadium provides such added benefits as better weldability and heat resistance. Various metals, such as columbium, manganese, molybdenum, titanium, and tungsten, are interchangeable with vanadium, but so far there are no substitutes for vanadium in the all-important aerospace titanium alloys that are used in jet engine mountings and wing structures. High-purity vanadium compounds are used as catalysts in the production of sulfuric acid, maleic anhydride, and in pollution control technology where it is necessary to remove hydrogen sulfide gas from flu gases (Stretford Process). In only a few chemical applications can platinum and nickel replace vanadium catalyst.

STOCKS

Reported consumers' and producers' stocks of vanadium oxides, metal, alloys, and chemicals totaled 1,736 tons contained vanadium at yearend compared with 1,396 at yearend 1988.

FOREIGN TRADE

While overall exports of vanadium products were slightly lower than in 1988, V_2O_5 exports were up sharply in 1989. Canada, Brazil, the Republic of

Korea, and Mexico were the leading importers of U.S. materials. Most countries imported V_2O_5 almost exclusively. Austria, Canada, and the Republic of Korea also imported substantial quantities of FeV. Exports of V_2O_5 totaled 2,310 tons, almost double 1988 exports. The average declared value of the pentoxide was \$7.62 per pound of contained V. Exports of FeV totaled 544 tons gross weight, down from 909 tons in 1988. The average declared value of the FeV was \$18.70 per pound of contained V.

Imports for consumption of vanadium raw materials and down-stream vanadium compounds increased over 1988 imports. FeV imports totaled 716 tons gross weight, up from 147 tons in 1988 and 422 tons in 1987. The imported FeV averaged 81% vanadium with a mean custom value of \$12.34 per pound of contained V. Canada was the largest source of FeV with shipments of 163 tons, followed by the Federal Republic of Germany, 128 tons, and Austria, 109 tons. V_2O_5 imports totaled 102 tons of contained V, down from 241 tons in 1988; the average declared value was \$9.39 per pound of contained V. Imports of vanadium-bearing slag and residues totaled more than 6,000 tons of contained V. About 44% of these imports were from the Republic South Africa in the form of vanadium bearing iron-slag. Another 28% was vanadium-bearing steel slag from Chile. The remaining 28% consisted of an assortment of petroleum residues, spent catalyst, and fly ash.

WORLD REVIEW

Industry Structure

Vanadium was traded on the world market in vanadium-bearing slag, petroleum residues, technical grade V_2O_5 , and FeV. The Republic of South Africa was the largest producer, providing more than 60% of the Western World's market. Most of the Republic of South Africa's exports of vanadium were in vanadium-bearing iron slag. Japan and Western Europe were the chief importers of this material. While the United States imported slag from the Republic of South Africa, it also imported slag, fly ash, petroleum residues, and spent catalyst from many sources. The large importers of vanadium raw materials, for example,

slag, were the chief exporters of V₂O₅, FeV, and other downstream vanadium products. This trade was dominated by a few large West European converters who competed not only within Europe, but also exported to many smaller consumers outside of Europe. Reliable statistics from the U.S.S.R. were not available but it is believed to be second only to the Republic of South Africa in vanadium production. All Soviet trade was thought to be with other Eastern Bloc countries.

Capacity

The data in table 7 reflect rated capacity for mills producing vanadium oxides as of December 31, 1989. Included in this data is the capacity to produce vanadium-bearing iron slag and petroleum coke. Rated capacity is defined as the maximum quantity of product that can be produced on a normally long-term operating rate, based on the physical equipment of the plant and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that can be brought back into production within a short period with minimum capital expenditure.

Australia

Western Australia has large deposits of magnetite ores containing vanadium and titanium. The deposit, consisting of a large magnetite-rich intrusive rock, was analyzed more than 20 years ago and found to contain only about 0.32% V₂O₅. This deposit was ignored for many years because of the low price of vanadium. As the price of vanadium climbed in 1987 and 1988, Precious Metals Australia (PMA) reevaluated

the deposit at its wholly owned Wagoo Hills project in the Murchison District of Western Australia. Surprisingly, the titanium and vanadium mineralization was found to grade up to 0.93% V₂O₅ and 12% titanium dioxide (TiO₂). The deposit lies within a distinct and rea-

sonably well defined geologic structure known as Shepard's Discordant Zone (SDZ) that extends along a 10 mile strike within PMA's property. The latest sampling was carried out across the SDZ in areas of abundant titanomagnetite surface rock with samples

collected at two- and six-yard intervals. Indications were that the region was likely to contain up to 40 million tons of high iron magnetite ore containing an average of 0.75% V₂O₅ and as much as 12% titanium.¹

Preliminary metallurgical work suggested that a magnetite concentrate could be produced from grinding and magnetic separation. An \$86 million mine development and processing plant was planned to produce about 2,100 tons of V₂O₅ per year.

The deposit ranks as a potentially significant iron ore discovery, but given the long distance from the nearest port, it would be more economic to extract the vanadium and titanium and discard the iron as waste.

Canada

Agra Industries Ltd. of Saskatoon, Saskatchewan, teamed with Renzy Mines

Ltd. and Fairfax Financial Holdings Ltd. of Toronto, Ontario, to construct a vanadium pentoxide facility at Fort McMurray, Alberta. The plant, which cost \$14 million, was designed to extract about 2.5 million pounds per year of V₂O₅ from waste fly ash produced by the Suncor Inc. oil sands plant.² The Athabasca oil sands, located in northern Alberta, was well known for its wealth of oil, and a number of projects have been launched to extract it. Less known was the fact that a number of other elements, including vanadium, were also found in the oil sands. In fact, the Athabasca oil sands may prove to be the largest reserves of vanadium in North America.

Vanadium appeared in the oil sands only in trace concentrations, making economic recovery impossible. However, when the material was treated to recover heavy oil, vanadium was concentrated in a stream of waste petroleum coke. Subsequent burning of this coke in the plant's power steamboiler produced a fly ash consisting mainly of carbon and V₂O₅ concentrations ranging from 2% to 5%. The Alberta Suncor and Syncrude refineries produced about 43,000 tons of fly ash per year. To secure access to the vanadium-rich flyash, Carbovan Inc., obtained an exclusive long-term agreement to purchase the waste flyash produced by

Suncor. Carbovan also had access to flyash that had been stockpiled by Suncor over the years. In addition to these supplies of raw materials, Carbovan obtained agreements to purchase vanadium-rich spent catalyst discharged by various petroleum processors in Canada.

Initial concepts of Carbovan's recovery process were developed by Renzy Mines in 1972. Between 1972 and 1985, Renzy spent about \$500,000 to further develop and improve the process. In mid-1985, Renzy and Agra entered into an agreement to conduct further research and development of the Renzy process. Under terms of the agreement, Agra provided financial, management, and engineering support to the research. After expenditures of \$1.5 million and 3 years of research and development, an economical process was developed. The process utilized a hydrometallurgical flotation technique to remove carbon from the fly ash. The carbon free ash fraction was next treated with a high-temperature alkaline leach and pulse column solvent extraction circuits to extract vanadium.

Chile

Compañía Minera del Pacífico (CMP), Chile's sole iron ore and pellet producer, examined the possibility of producing and exporting vanadium from its El Romeral Mine where the iron ore has a grade of 0.5% to 0.7% vanadium.³ A three-stage laboratory, pilot plant, and economic study was completed, and the company began an engineering study to determine the type of equipment required. Based on previous findings, Pacífico decided to use a roast-leach process to produce vanadium as a byproduct from the concentration of 1,500 tons per day of iron ore from El Romeral. The company hoped to earn about \$25 million per year from vanadium exports.

China

China's production of vanadium-bearing iron slag was 93,750 tons in 1989.⁴ Approximately 80% of the output was from the Panzhihua Steel Works in Sichuan Province. Slag from this plant averaged 14% V₂O₅, which placed China's vanadium production at about 7,400 tons of contained vanadium; only the Republic of South Africa and the U.S.S.R. produced more.

Vanadium production was down

¹ Specific import classes only.

about 4% from 1988 production because of a reduction in the operating level at Panzhihua. Exports were also lower than in previous years, mostly because of increased internal demand.

South Africa, Republic of

The Republic of South Africa, the world's largest producer of vanadium, was projected to increase its capacity by 28% over 1988's capacity and produce about 40% more of the alloying element by 1990. In 1988, production of vanadium marked an alltime high of 63 million pounds of V₂O₅, more than 10% above 1987 production. Production figures for 1989 were not available, but were expected to be about the same, or slightly less, than 1988 production. Sales of vanadium totaled 28,900 tons V₂O₅, of which 653 tons was used internally and 28,300 tons was exported.⁵

Most of the planned increase in capacity was from a new facility, which was to obtain its feedstock from reserves of titaniferous magnetite in Bophuthatswana. The project, designed to produce 9,900 tons of V₂O₅ annually, was a co-operative venture between Union Steel Corp. (Usco) and Rhombus Exploration (RhoEx) to exploit a high-grade deposit stretching over a distance of 10.5 miles. Ore reserves were estimated to be sufficient to support production for about 100 years.

The company extracted V₂O₅ by the roast-leach process. While other South African producers used a rotary kiln or a conventional furnace to roast the ore, Usco used a shaft furnace. This furnace reportedly had several advantages: (1) the furnace was fired by South African synthetic oil (Sasol) gas instead of coal,

which tends to introduce impurities, (2) direct energy costs were claimed to be up to 5% lower, (3) the vanadium yield was at least 90% compared with around 80% for a rotary kiln, and (4) chemical costs were reduced by about 50% because a rotary kiln requires 7 wt % soda ash compared with 4 wt % for a shaft furnace. Usco anticipated the cost of production of V₂O₅ flake would be in the range of \$4,500 to \$4,700 per ton. Mechanical commissioning of the beneficiation plant at Rhovan's Mine, which provided the magnetite concentrate, was completed and wet commissioning was scheduled to start in March 1990.⁶ Brandeis Goldschmidt Ltd., headquartered in London, acted as sole agent for V₂O₅ produced by Usco.

Highveld Steel & Vanadium Corp., the world's largest vanadium producer, was forced to cut production at its Vantra Plant by two-thirds because of low spot market prices. Production of vanadium in iron slag at the Highveld steel plant was not affected by the cutback. The decision to cut production at Vantra was an attempt by Highveld to stabilize prices at a comfortable level and maintain a balance between supply and demand.

The newest South African V₂O₅ producer, Vansa Vanadium Corp., began production in October 1988. Its operations were supplied by the Kennedy's Vale high-grade ore deposit. The plant, located in Eastern Transvaal, had a design capacity of 3,000 tons per year of V₂O₅. The company reported that, as a result of postcommissioning problems, the plant had been unable to achieve its full design capacity. For most of the fiscal year ending September 30, 1989, the plant operated at just

over 60% capacity. The company expected that full production would be achieved during 1990.

Other established producers in the Republic of South Africa are Vametco in Bophuthatswana, owned by Strategic Minerals Corp. of the United States, and Transvaal Alloys, which produced V₂O₅ and other vanadium chemicals. The Republic of South Africa's domestic consumption of vanadium was believed to be about 1% of its total production.

OUTLOOK

Outlook For 1990

Vanadium shipments in 1990 are expected to decline approximately 3% to about 5,500 tons. The decline is expected to be the result of a weakness in a key vanadium consuming sector, steel used for nonresidential construction, without equal offsetting growth in other important markets. Demand for the transportation sector is expected to be adversely affected by lower sales of domestically produced motor vehicles. The appliance industry is likely to buy less steel because of a decline in housing starts. On the bright side, some pickup in demand for aluminum-vanadium alloys can be anticipated from aerospace industries, which are benefiting from increased demand for air transports. Also, increased demand is anticipated from large capital goods industries that are benefiting from increased capital investment and increased exports. Individually, aerospace and capital goods industries are much smaller consumers of vanadium than the other important markets. Vanadium exports are expected to rise moderately.

The likely drawdown of inventories by vanadium consumers through the first and second quarters of 1990 should also have an adverse effect on domestic demand. Consumers are expected to draw down their inventories because they are no longer concerned about difficulties in obtaining vanadium in a timely manner and at a reasonable price. Prices of most products are likely to stabilize.

Nearly every segment of the chemical industry using vanadium catalysts is growing. Strong demand for chemicals

and polymers, for fuel from petroleum, for products that reduce pollution, and for biological materials, is increasing. With few exceptions, most sulfuric acid produced in the world is made by burning sulfur to produce the oxide and then oxidizing the dioxide to the trioxide using V_2O_5 catalyst on a diatomaceous earth carrier. Growth in demand for this type of catalyst is forecast to be slow. Resurging markets for vanadium catalyst in other sectors of the chemical industry are providing new incentives for research and development in vanadium catalysts and in processes that require their use.

Long-Term Prospects

Long-term prospects for this highly cyclical industry depend on a number of factors. Producers will certainly be adversely affected by any future economic downturn. Because of restructuring and downsizing that has occurred in the industry since the last recession, the industry will be better able to cope with a recession than it was in the early 1980's. Traditional forces, such as the demand for motor vehicles and machinery, the level of economic activity, and the use of substitute materials, will continue to be of central importance. The strength of the U.S. dollar and its trade effects will also influence the industry's long-term future.

Fundamental changes over the past 10 years in the industry and in the general economy have all but precluded the possibility of a return to the late 1970's and early 1980's level of vanadium mining activity. There will almost certainly be fewer tons of domestic ore shipped and fewer mine workers by 1995 than there were in 1989. Production of V_2O_5 from fly ash, spent catalyst, and petroleum residues will continue to increase. Given favorable economic conditions, plants using these materials as feed will have higher average sales and be more profitable.

BACKGROUND

Vanadium has been used as an alloying element in steel since 1902, when it was first added to tool steels used for high-speed machining operations. It was found that vanadium prevented grain growth in tungsten-bearing steels and enabled the steels to maintain their hardness at the high temperatures generated in tool steels during high-speed machining. Vanadium is also widely used in high temperature steels used in steam power plants. Chromium-vanadium steels are used for steel pipes and headers and molybdenum-vanadium steels are used for rotors because of the high creep resistance produced by vanadium carbides. An increasing amount of vanadium has been used in the production of high-strength low-alloy (HSLA) steels to provide yield points between 36 and 47 kilograms per square millimeter. The addition of small amounts of vanadium, often less than .1 wt %, to an ordinary carbon steel can significantly increase its strength and improve both its toughness and ductility. HSLA steels with high yield points are attractive for structures such as automobiles, bridges, high-rise buildings, and pipelines where advantage can be taken of the savings in weight produced by the high-yield points. Vanadium is also used extensively to provide elevated temperature strength to certain aerospace titanium alloys, the most common of which is an alloy containing 6 wt % aluminum and 4 wt % vanadium. This alloy is widely used for aircraft engine casings and fans and accounts for about 10% of U.S. vanadium use. Oxides and chlorides of vanadium play important roles as catalysts in the production of sulfuric acid, maleic anhydride, synthetic rubber, and other key intermediate organic chemicals.

Vanadium is found in many parts of the world, but usually in association with other minerals. There are few ores

from which vanadium can be economically extracted as a single product. It is therefore often extracted as a byproduct or coproduct in the production of other elements, such as iron, phosphorus, or uranium. Increasing amounts are being recovered from clays, petroleum residues, and spent catalysts. At present projected rates of consumption, world reserves of vanadium should last far beyond the year 2000. The world also has extensive subeconomic resources of vanadium contained in oil sands, carbonaceous shale, and bauxite.

The Republic of South Africa is the world's largest producer of ore and vanadium-bearing slag. Its annual production of more than 17,000 tons is approached only by production in the U.S.S.R. The bulk of U.S.S.R. production is consumed internally or by other Eastern Block countries. Other major producers include the United States, and China. Canada, Japan, and Western Europe are heavily dependent on imports of vanadium slag and pentoxide from the Republic of South Africa. Any disruption of South African supplies could seriously upset the balance between vanadium supply and demand. World demand is forecast to increase by about 2% per year, with total world demand reaching 45,000 tons by the year 2000. World production in 1989, including production from petroliferous materials and spent catalysts, was estimated to be 37,400 tons, of which about 2,600 tons was produced in the United States from petroleum residues and spent catalysts.

Definitions, Grades, and Specifications

The term "ferrovanadium," as used by the Bureau of Mines, includes vanadium-carbon-iron-nitrogen proprietary alloys as well as the conventional forms of ferrovanadium. Some of the more common commercial products are listed in the following table:

Alloy	Composition, weight percent							
	Vanadium	Carbon	Nitrogen	Aluminum	Silicon	Phosphorus	Sulfur	Manganese
50%-60% ferrovanadium	50.0-60.0	0.2 max.	—	2.0 max.	1.0 max.	0.05 max.	0.05 max.	—
70%-80% ferrovanadium	70.0-80.0	—	—	1.0 max.	2.5 max.	.05 max.	.10 max.	—
80% ferrovanadium	77.0-83.0	.5 max.	—	.5 max.	1.25 max.	.05 max.	.05 max.	0.5 max.
Proprietary alloys:								
Carvan (Stratcor)	82.0-86.0	10.5-14.5	—	.1 max.	.10 max.	.05 max.	.10 max.	.05 max.
Ferovan (Shieldalloy)	42.0 min.	.85 max.	—	—	7.0 max.	—	—	4.50 max.
Nitrovan (Stratcor)	78.0-82.0	10.0-12.0	6.0 min.	.1 max.	.1 max.	.05 max.	.01 max.	.05 max.

A standard specification for ferrovanadium has been developed by the American Society for Testing Materials (ASTM).⁷

Aluminum-vanadium master alloys contain fixed ratios of vanadium to aluminum and are used in the manufacture of titanium alloys. Amounts of vanadium up to 1 wt % improve the strength of titanium-base alloys and promote their thermal stability in the presence of moderate amounts of aluminum. When amounts greater than 4 wt % are added, the titanium base-alloy can be significantly strengthened by heat treatment. The three most important commercial titanium alloys containing vanadium are Ti-6Al-4V, Ti-6Al-4V-2Sn, and Ti-8Al-1Mo-1V. Ti-6Al-4V alloy presently accounts for more than one-half of the titanium-base alloy market.

Products for Trade and Industry

Vanadium is usually traded on the international market in the form of technical grade V_2O_5 and ferrovanadium. Most world exports of vanadium raw material is in the form of vanadium-bearing iron slag from the Republic of South Africa and China, while U.S. and west European converters are the major importers of these materials. U.S. and west European converters are the major exporters of vanadium oxides, which supply the many small consuming countries, and compete for the major markets for imported pentoxide in Japan and the Republic of Korea. Trade in ferrovanadium is dominated by the major European exporters. A large part of this trade is within Europe but exports are made to many other consuming countries, particularly by the Federal Republic of Germany.

Industry Structure

The vanadium industry has a five-tiered structure with facilities on all six continents. As expected, mines and oil fields form the base of the structure (figure 1). Since 1979, an estimated 83% of world production has come from vanadiferous magnetite (Fe_3O_4). The principal sources of the magnetite ore were China, the Republic of South Africa, and the U.S.S.R. World vanadium production for 1985-1989, is

shown in table (12). The other 17% of the vanadium was recovered from diverse petroliferous materials.

The second tier is a set of economically unrelated facilities that include (1) pig iron plants with slag recovery units, (2) elemental phosphorus smelters, and (3) generators of petroleum residues, fly ash, and spent catalysts that contain vanadium either as the active material or as a contaminant.

The third tier consists of acid-leaching plants with solvent extraction circuits, and salt-roasting operations. Technical grade V_2O_5 and NH_4VO_3 are the principal products at this level.

To have an easily marketable product, it is customary at this point to either convert the oxides into an alloy or upgrade their purity to greater than 98.5 wt %. The two traditional alloy products have been the 80 wt % ferrovanadium and 35 wt % aluminum-vanadium master alloy. Variations of five different reduction processes are currently in use throughout the world, with aluminum, carbon, or silicon serving as the reductant. These conversion and upgrading plants, which form the fourth tier of the structure, may be located a considerable distance from the mills and slag plants and frequently blend feed materials to improve recovery.

Of the more than 30 privately owned producers, only 1, the Republic of South Africa's Highveld, operates facilities at all 4 lower levels and can be considered totally integrated. Highveld has plants that process vanadiferous-magnetite ores from the Bushveld Igneous Complex. Two other producers, Shieldalloy Metallurgical Corp. and Stratcor, have extensive operations on the second, third, and fourth tiers. Shieldalloy traditionally uses Highveld slag as its starting material for low vanadium grades of ferrovanadium.

The fifth tier is composed of producers of vanadium specialty alloys, high-purity vanadium metal, primary vanadium chemicals, and vanadium catalysts. Reading Alloys Inc., Akzo Chemical, and Teledyne Wah Chang Albany illustrate the diversity of operations at this level.

Geology-Resources

The crustal abundance of vanadium is estimated to be 100 to 150 parts per million (ppm), about twice that of copper, 10 times that of lead, and almost 100 times that of molybdenum.⁸ As a result, trace vanadium mineralization

occurs in a wide range of geologic provinces and environments. At the same time, ore deposits of vanadium are rare because much of the vanadium in igneous rocks occurs dispersed in the relatively insoluble trivalent state and is substituting for ferric iron in ferromagnesian silicates, magnetite, ilmenite, and chromite.

Technology

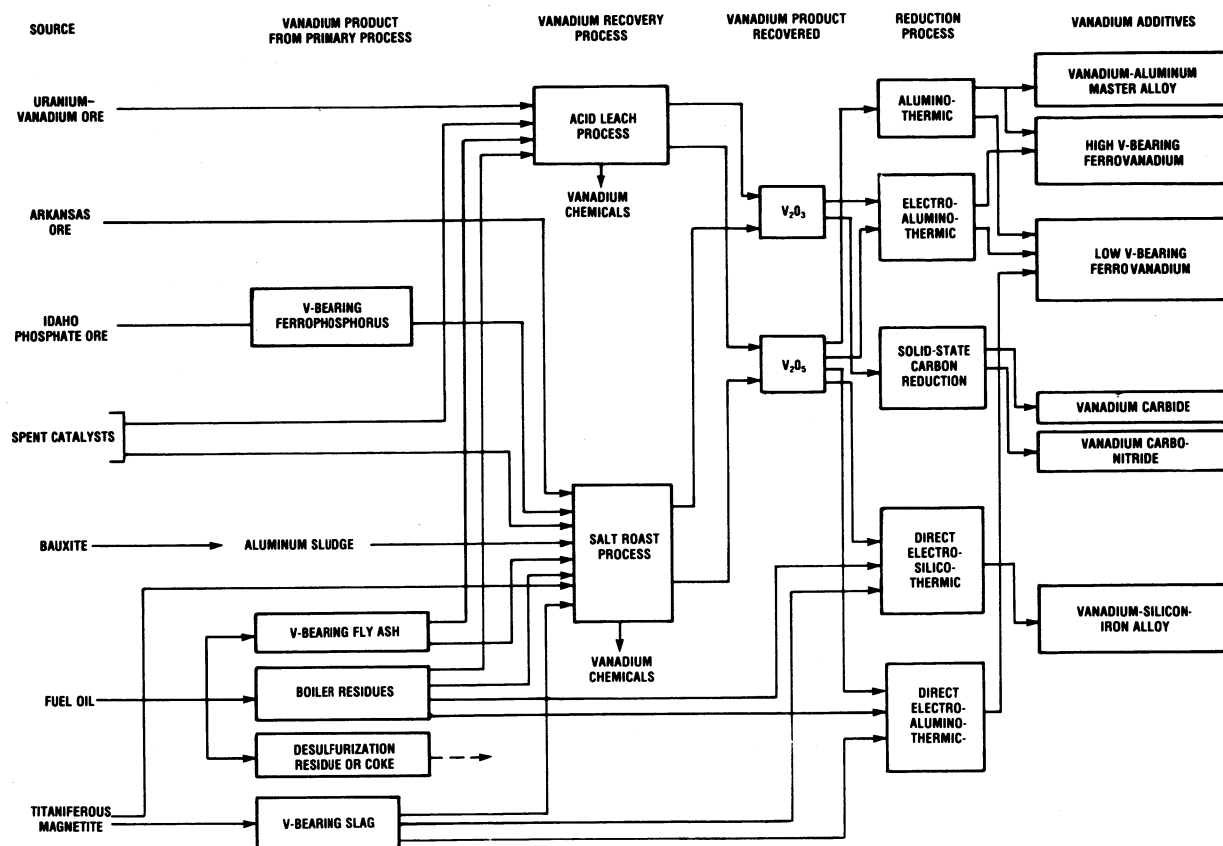

Processing—In the United States, vanadium is recovered as a principal mine product, as a coproduct from carnotite ores, and as a byproduct from ferrophosphorus slag in the production of elemental phosphorus. Increasingly, it is also being recovered from petroleum refinery residues, fly ash, and spent catalysts. In the Republic of South Africa and China, vanadium is recovered as a byproduct of pig iron production from titaniferous magnetite.

The first stage in the processing of vanadium ore is the production of an oxide concentrate. The ore is crushed, ground, screened, and mixed with a sodium salt. This mixture is roasted at about 850 °C to convert the oxides to water-soluble sodium metavanadate. The vanadium is extracted by leaching with water and precipitated at pH 3 as sodium hexavanadate (red cake) by the addition of sulfuric acid. The red cake is fused at 700 °C to yield a dense black product that is sold as technical grade vanadium pentoxide. Technical grade vanadium pentoxide contains a minimum of 86 wt % pentoxide and a maximum 8 wt % sodium oxide. The red cake may be further purified by dissolving it in an aqueous solution of sodium carbonate. Aluminum, iron, and silicate impurities precipitate from solution upon pH adjustment. Ammonium metavanadate is then precipitated by the addition of ammonium chloride. The precipitate is calcined to give a vanadium pentoxide product of greater than 99.8% purity.

Vanadium is extracted as a coproduct with uranium from carnotite by direct leaching of the ore with sulfuric acid. An alternative method is roasting the ore followed by countercurrent leaching with dilute sulfuric acid. In some cases, the first leach may be with a sodium carbonate solution. The uranium and vanadium are then separated from the pregnant liquor by liquid-

FIGURE 1

GENERALIZED FLOWSHEET FOR THE PROCESSING OF VANADIFEROUS RAW MATERIALS

liquid extraction techniques.

In the Republic of South Africa and China, vanadium is concentrated in slag resulting from the production of pig iron from titaniferous magnetite ore. The ore, containing 1.5% to 2.5% vanadium pentoxide, is partially reduced with coal in rotary kilns. The ore is then melted in an enclosed furnace which produces a slag containing most of the titanium and pig iron containing most of the vanadium. After the titanium-bearing slag is removed, the molten pig iron is blown with oxygen to form a slag containing 12 wt % to 24 wt % vanadium pentoxide. The slag is separated from the molten metal and may then be used as a high-grade vanadium raw material in the usual roast-leach process.

Vanadium is added to the steelmaking process as a ferrovanadium alloy, which is produced commercially by the reduction of vanadium pentoxide or vanadium bearing-slag with aluminum, ferrosilicon, or carbon. In the aluminothermic process for preparing ferrovanadium, a mixture of technical grade pentoxide, aluminum, iron scrap, and a flux are charged into an electric furnace and the reaction between aluminum and pentoxide initiated. The reaction is highly exothermic, producing very high temperatures. The temperature can be controlled by adjusting the particle size of the reactants and the feed rate of the charge and by using partially reduced pentoxide or by replacing some of the aluminum by a milder reductant. Ferrovanadium containing up to 80 wt %

vanadium can be produced by this method. A process developed by Foot Mineral Co., Cambridge, OH (now Shieldalloy Metallurgical Corp.), has been used to produce tonnage quantities of ferrovanadium. This process involves the reaction of vanadium-bearing iron slag with silica, flux, and a carbon reductant followed by refinement by vanadium pentoxide. The reaction takes place in a submerged electric arc furnace yielding a ferrovanadium alloy containing about 40 wt % vanadium, 3.5 wt % silicon, 3.8 wt % manganese, 0.1 wt % carbon, and the remainder iron.

Economic Factors

Prices.—Time-price relationships for vanadium contained in fused vanadium pentoxide (metallurgical grade) in terms of actual prices and in constant 1989 dollars are shown in table 3. Beginning in 1974, published quotes of fused vanadium pentoxide reflect a two-tier price listing of upper and lower producer prices. Actual prices reported in table 3 were based on available information from the producer, or they represent averages of the two-tier quotation as reported in the time period indicated.

Tariffs.—U.S. import duties on selected vanadium items as of January 1, 1989, are listed in table 8. The tariff listing includes rates for both most-favored-nation (MFN) and non-most-favored-nation status.

VERMICULITE

By Michael J. Potter

Mr. Potter, a physical scientist with 23 years of industry and Bureau of Mines experience, has been the acting commodity specialist for vermiculite since 1989. Domestic survey data were prepared by Maureen Nash, mineral data assistant; and the international data table was prepared by Audrey Wilkes, international data assistant.

U.S. output of vermiculite concentrate was estimated to be 290,000 short tons, a decrease from that of the previous year. The tonnage of exfoliated vermiculite sold and used was an estimated 215,000 tons, also a decrease from that of 1988. Vermiculite has been facing competition from other cost-effective materials, especially in the building products market. Also, markets have been affected by a decrease in construction activity.

DOMESTIC DATA COVERAGE

Domestic production data for vermiculite are developed by the Bureau of Mines from two separate voluntary surveys, one for domestic mine operations and the other for exfoliation plant operations. Of the six mining operations to which a survey request was sent, two responded. The four nonrespondents' data were estimated using previous years' production levels adjusted by trend of the minerals economy. Of the 35 active exfoliating plants to which a survey request was sent, 8 responded. This represented an estimated 10% of the total exfoliated vermiculite sold and used, see table 1. The 27 nonrespondents' data were estimated using previous years' production levels adjusted by the trend of the minerals economy.

PRODUCTION

The leading domestic producer of vermiculite concentrate continued to be W. R. Grace & Co. with operations near Libby, MT, and Enoree, SC. Other producers during the year were Virginia Vermiculite Ltd., Louisa County, VA;

Strong-Lite Products Corp.'s Carolina Vermiculite mine near Woodruff, SC; Patterson Vermiculite Co., Enoree, SC; and Enoree Minerals Corp., Spartanburg County, SC. South Carolina, with four producers, was the leading producing State for the third consecutive year.

Domestic sales of exfoliated vermiculite by 15 producers came from 35 plants in 27 States. Of these plants, 21 in 17 States were operated by W. R. Grace.

In descending order of output sold and used, the principal exfoliated vermiculite-producing States were estimated to be Ohio, California, South Carolina, Florida, New Jersey, Illinois, Texas, and Arkansas.

PRICES AND FOREIGN TRADE

The average value of vermiculite

concentrate sold and used by U.S. producers was estimated at \$112 per ton, f.o.b. plant, or about the same as in 1988. The average value of exfoliated vermiculite, f.o.b. plant, increased from \$221 per ton to an estimated \$227 per ton.

Imports of vermiculite concentrate from the Republic of South Africa were estimated to be 40,000 tons, compared with 35,000 tons (revised) in 1988. Exports to Canada were estimated to be 20,000 tons, about 7% of total U.S. sales of vermiculite concentrate.

WORLD REVIEW

Table 4 shows rated annual capacity for vermiculite plants as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that can be produced on a normally sustainable long-term operating rate, based on the physical equipment of the plant and given

acceptable routine operating procedures involving labor, energy, materials, and maintenance. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure. Plant capacity for vermiculite is based on engineering capacity provided by the companies or estimated by considering recent peak production during the past 5 years to be equal to rated capacity.

WOLLASTONITE AND ZEOLITES

By Michael J. Potter and Robert L. Virta

Mr. Potter, a physical scientist with 23 years industry and Bureau of Mines experience, has been the commodity specialist for wollastonite since 1976. Domestic survey data were prepared by Pam Shorter, mineral data assistant.

Mr. Virta, a physical scientist with 14 years Bureau of Mines experience, has been the commodity specialist for natural zeolites since 1986. Domestic survey data were prepared by Pam Shorter, mineral data assistant.

WOLLASTONITE

Wollastonite is natural calcium silicate and has a theoretical composition of $\text{CaO} \cdot \text{SiO}_2$.

The tonnage of wollastonite sold or used by U.S. producers in 1989 increased slightly. Specific data were withheld to avoid disclosing company proprietary data. The two producers were NYCO, a division of Processed Minerals Inc., Essex County, NY, and R. T. Vanderbilt Co. Inc., Lewis County, NY.

NYCO reported the discovery of a wollastonite deposit near Lewis, NY. The new Oak Hill deposit, located near the company's current mine, would reportedly double existing reserves.

In October 1989, Engelhard Corp. announced it had agreed in principle to purchase Processed Minerals Inc. of Syracuse, NY, a wholly-owned subsidiary of Canadian Pacific (U.S.) Inc.¹ However, in late 1989, Engelhard announced it was not going to acquire Processed Minerals Inc.

The discovery of a wollastonite deposit in the Gilbert district of southern Nevada was reported by Sikaman Gold Resources Ltd. Grades of material in excess of 50% wollastonite were reported. A detailed mapping and core drilling program was under way. Test work was also being undertaken to determine quality, grade, and market conditions.²

Wollastonite is used as a filler in ceramic tile, paint, and plastics. It serves as an asbestos replacement in some applications such as a reinforcement filler for boards and panels in various heat containment applications including ovens, dryers, thermal ducting, and many other thermal applications. Wollastonite also replaces asbes-

tos in certain cement formulations, in ceiling and floor tile, and in friction applications such as brake linings.

Prices from Industrial Minerals, December 1989, for wollastonite, ex-works, converted to dollars per metric ton, were approximately \$260 for acicular, minus 200 mesh, \$200 for minus 325 mesh, and \$210 for minus 400 mesh. Prices per metric ton for wollastonite, f.o.b. plant, bulk, were \$125 to \$177 for 200 mesh and \$235 for 325 mesh.

In Canada, four samples of wollastonite ore from various locations in the Province of British Columbia in western Canada were evaluated. Wollastonite content varied between 45% and 75%. Processing of the ore samples included wet high-intensity magnetic separation and flotation. For three of the four samples, the Fe_2O_3 content of the wollastonite concentrate was less than 1%; the estimated wollastonite grade was 90%. Wollastonite obtained from the samples is probably suitable for ceramic and filler applications. Final verification of suitability would require detailed product evaluation.³

In China, large reserves of wollastonite occur in Jilin Province. At the Dadingshan Mine, rich ore was separated from lower grade material (tailings) by hand sorting. Test work was carried out on samples of tailings, which contained approximately 45% calcite, 32% wollastonite, 17% quartz, and 2% diopside. Using flotation, calcite was removed, followed by separation of wollastonite and quartz. Preliminary estimates indicated that mineral processing would be economical.⁴

Wollastonite was found to have a reinforcing effect on concrete materials. Test results showed that the compression strength of wollastonite-

reinforced concrete was increased by approximately 30% and the bending strength by 20%, compared with common concrete. The wollastonite concrete has been successfully used in the construction of methane tanks.⁵

The plastics industry has been proving to be an active market for extender and filler minerals. Demand for both filler and surface-treated grades has been increasing, with the trend being driven by the automotive industry. According to a study by Kline & Co. of Fairfield, NJ, calcium carbonate, mica, silicas, talc, and wollastonite will all show demand growth of over 5% a year in this end use area.⁶

ZEOLITES

Zeolites are hydrated aluminosilicates of the alkaline and alkaline-earth metals. Approximately 40 natural zeolites have been identified over the past 200 years, the most common of which are analcime, chabazite, clinoptilolite, erionite, ferrierite, heulandite, laumontite, mordenite, and phillipsite. Zeolites are commercially valuable because of their unique ion-exchange, molecular sieving, and catalytic properties.

Commercial zeolite deposits in the United States are associated with the alteration of volcanic tuffs in saline, alkaline lake deposits; saline, alkaline soils; and open hydrologic systems. The deposits are located in Arizona, California, Idaho, Oregon, Nevada, New Mexico, and Texas. Their composition was determined primarily by the temperature and pressure of formation and the chemistry of the altering fluids. The major components of these deposits are chabazite, clinoptilolite, mor-

denite, and phillipsite. Erionite, orthoclase feldspar, montmorillonite, opal, quartz, and volcanic glass may be present in some deposits as minor components. When the alteration process went to completion, the zeolite content of portions of some deposits approached 100%.

Conventional mining techniques were used in the mining of natural zeolites. The overburden was removed to permit access to the ore, and the ore was stripped for processing using front-end loaders or tractors equipped with ripper blades. The fractured ore was air-dried and then crushed, using either jaw crushers or roller mills. The crushed ore was packaged directly for shipping or was screened to remove fine material when a granular product was required.

Six companies mined natural zeolites in the United States in 1989. Four companies mined clinoptilolite from deposits in California, Nevada, Oregon, and Texas; two companies mined chabazite from deposits in Arizona. Total domestic production and sales were 12,117 metric tons (13,357 short tons) in 1989, an increase of 11% from those of 1988.

Natural zeolites were used for aquaculture, aquarium filters, chemical carriers, desiccants, odor control, pet litter, wastewater cleanup, and water purification. The properties that made natural zeolites commercially valuable included ammonium adsorption (aquaculture, aquarium filters, odor control applica-

tions, pet litter, and water purification), moisture adsorption (desiccants, odor control, and pet litter), and ion-exchange capabilities (wastewater cleanup and water purification). The major application for natural zeolites in 1989 was in pet litter.

The Bureau of Mines continued research on the use of zeolites to remove dissolved metals and other cations from water. The exchange properties of 21 natural zeolite samples from different locations were determined for Pb^{2+} and NH_4^+ ions. The zeolites tested were chabazite, clinoptilolite, erionite, mordenite, and phillipsite. Exchange capacities ranged from 0.6 to 2.1 milliequivalents for Pb^{2+} ions and 0.9 to 2.8 milliequivalents for NH_4^+ ions. In other tests, competing cations such as Na^+ , Ca^{2+} , and NH_4^+ strongly affected heavy metal cation uptake of natural zeolite samples. Wastewater run-off from an abandoned metal mine was passed through columns filled with clinoptilolite to determine the efficiency of heavy metal removal in the presence of competing ions. Twelve percent of the exchange capacity was utilized, and the heavy metal concentration of the treated water exceeded drinking water standards despite several passes through a column. Lime precipitation and aeration of the water reduced heavy metal levels sufficiently to meet drinking water standards.

Research continued on controlling the uptake of cesium by vegetation on Bikini Atoll where levels of surface radioactivity were low enough for habitation but concentrations of cesium in food crops were above acceptable limits. Food crops were grown in cesium-contaminated soils that contained various concentrations of clinoptilolite. The amount of cesium in the food plants were measured after the plants were harvested. The concentration of cesium in plants grown in zeolite-amended soils was significantly lower than in plants grown under control conditions. Further tests were being conducted to determine if the release of exchangeable potassium in the clinoptilolite influenced the results of the tests.⁷

Mordenite, a natural zeolite, was investigated as a combustion catalyst for eliminating residual hydrocarbons and CO in exhaust gases and solvent vapors in factories. Mordenite was chosen be-

cause of its large aperture sizes in the crystal structure and its thermal stability. NH_4 -mordenite, Ca-mordenite, K-mordenite, and Na-mordenite were prepared through cation exchange. The number of acid and basic reaction sites and the catalytic properties were different for each mordenite type. Each mordenite type also had different abilities for oxidizing organic compounds.⁸

There are many potential agricultural applications of natural zeolites in developing countries. Most developing countries lie in the tropical latitudes where soils are depleted of important plant nutrients. Natural zeolites could serve as low-cost carriers for fertilizers for enriching and retaining the nutrients in the soil or to retain moisture in the soil in arid environments. Another potential application is the reduction of local water pollution that is caused by agricultural runoff from animal pens. Animal wastes are frequently washed from animal holding pens, and the contaminated runoff enters local streams. Zeolites mixed with animal wastes would reduce odors by adsorbing ammonia and would improve the handling characteristics of the manure by adsorbing moisture. The mixture has potential for use as a nitrogen-rich soil supplement. Finally, experiments suggest that zeolites are beneficial as an animal feed supplement, reducing disease and improving yield. More extensive exploration for zeolite deposits in developing countries and more thorough field testing is required in order to demonstrate the practicality of these applications.⁹

ZINC

By James H. Jolly

Mr. Jolly is a physical scientist (geologist) with more than 30 years of mining experience, including positions with Hecla Mining Co., Roan Selection Trust, and the U.S. Geological Survey. He has been a mineral commodity specialist for the Bureau of Mines for 17 years and the zinc specialist for the past 8 years. Domestic survey data were prepared by Lura M. Nightlinger and Tony E. Morris, mineral data assistants.

Zinc-producing mines in Alaska, Montana, and New Mexico opened in 1989, resulting in increased domestic output for the third straight year. A world-class zinc mine in Alaska, scheduled to open in late 1989, experienced startup problems, and its official opening was rescheduled for early 1990. Refined zinc metal production was the highest since 1981. Improved production was attributable to near-capacity output at U.S. primary smelters and increased zinc recovery from steelmaking dusts. In 1989, U.S. mines produced 4.0% of world mine output, and U.S. smelters produced 5.0% of world refined metal output.

Domestic metal consumption declined modestly in 1989 but was the second highest in the 1980's decade. The consumption decrease was largely attributable to sharply reduced automobile production in the last quarter of the year. Exports of concentrate, scrap, refined metal, and compounds were the best in years, whereas imports generally declined. Nonetheless, net imports of basic zinc products accounted for \$1 billion of the Nation's trade imbalance.

World mine production was second highest, whereas world smelter output was a record high. World mine and smelter capacity utilization rates were high throughout the year; however, little new capacity was added to either category in 1989.

World zinc metal consumption exceeded 7 million metric tons for the third straight year and was estimated to have been slightly less than the record-high consumption attained in 1988. High consumption resulted in record zinc prices early in the year; however, prices eased in the latter-half of the year owing to a slight fall in demand and increased stock levels.

LEGISLATION AND GOVERNMENT PROGRAMS

Environmental and trade issues continued to be the major thrusts of governmental and legislative actions in 1989. The Environmental Protection Agency (EPA) applied its revised interpretation of the Bevill Amendment (exclusion) to solid waste from the extraction, beneficiation, and processing of ores and minerals. On September 1, EPA identified 5 wastestreams as having Bevill status and conditionally retained 20 other wastestreams for further consideration.¹ All other mineral processing wastes were permanently removed from the Bevill exclusion and were subject to subtitle C regulation of the Resource Conservation and Recovery Act (RCRA) if they exhibit hazardous characteristics. In late September, EPA proposed to retain only 13 of the 20 conditionally retained wastes for further study; this proposal, which was to be finalized in mid-January 1990, retained slag from primary zinc processing, the only zinc related waste remaining in the Bevill exclusion. Final regulatory determination for Bevill processing wastes was expected in January 1991.

Sites that fall under the Comprehensive Environmental Response, Compensation, and Liability Act are called Superfund sites. A number of the Superfund sites associated with zinc mining and processing attracted considerable attention during 1989. The two most prominent sites were the 21-square-mile area surrounding the Bunker Hill lead-zinc smelter complex in Idaho, and the Tristate lead-zinc mining district of Kansas, Missouri, and Oklahoma. The former owner of Bunker Hill, Gulf Resources and Chemical Corp., agreed to keep at least \$150

million in domestic assets to ensure against its potential liability for the cleanup of mainly lead-contaminated soil and residues at the complex and the area around the smelter site. In 1989, cleanup efforts centered on a program to remove and replace up to 2 feet of contaminated soil at private residences, mainly in the nearby mining town of Kellogg.

In the Tristate district, EPA continued its efforts in a few selected areas to reduce heavy-metal contamination of surface and subsurface water caused by lead-zinc mining activity carried out in the area from about 1848 to 1970. Through 1989, about \$6 million had been spent on the cleanup of mining sites in the Tar Creek area of Oklahoma. Other areas in the district have been identified as possible Superfund sites. One of these was the Galena, KS, area where an \$8 million cleanup program was proposed. Cleanup efforts have or were expected to involve recontouring existing land surfaces and redirecting surface streams around mineral areas, burial of residues of mining operations, blocking of mine shafts that provide surface water access to underground workings, and stabilization of mining-related surfaces by revegetation. Mining companies that operated in the Tar Creek, Galena, and other areas in the district have been named by EPA as the "potentially responsible parties" for the pollution problems and might be liable for some or all of the cleanup costs.

The final draft of the Basel Convention for the control of transboundary movements of hazardous wastes and their disposal was completed. The President was expected to approve the Convention in early 1990 with Senate ratification expected by 1993. The Convention is designed to ensure that exported hazardous wastes will be transported,

treated, and/or disposed of by the importing country in a manner that is consistent with the protection of the environment and human health. This could impact future U.S. exports of zinc scrap, wastes, and residues, especially to developing countries where environmental controls are below accepted standards.

On January 1, the U.S. Bureau of the Census replaced the Tariff Schedule of the United States (TSUS) with the Harmonized Tariff Schedule of the United States (HTS) to surmount increasing difficulties arising from the use of different tariff classification systems in other countries and changing international

needs. The new system was international in scope and provided a means for most countries to have a single modern structure for product classification thereby easing duty determination, statistical accounting, and transportation documentation. Many new classification subdivisions were also added to HTS to reflect changes in technology, trade patterns, and user requirements. Because of many, mostly minor, differences between the two U.S. tariff systems, the statistical trade data of 1989 and that of prior years may not be comparable.

Also on January 1, the United States and Canada formed the world's largest free trade area by implementing the

United States-Canada Free-Trade Agreement (FTA) Implementation Act of 1988. The FTA eliminates all tariffs on U.S. and Canadian goods by 1998. U.S. duties on imports of zinc metal, alloys, and dutiable zinc chemicals were to be phased out at 10% per year over 10 years.

In April, the Non-Ferrous Metals Producers Committee (NFMPC) submitted a petition to the U.S. Trade Representatives (USTR) seeking identification of the copper, lead, and zinc industries under section 409(b) of the FTA, which has provisions for addressing unfair trade practices. The NFMPC contended that these domestic industries would face in-

creased competition from subsidized imports from Canada. On July 5, the USTR, in consultation with the Secretary of Commerce, concluded that a reasonable likelihood existed that the copper and lead industries could face increased competition from subsidized production in Canada. Data on the zinc industry, however, were insufficient to identify it under the 409(b) provision, but the USTR would seek zinc information within the scope of any study on the lead industry that might be initiated as a result of the USTR decision on lead.

U.S. zinc-producing companies continued to be granted a depletion allowance of 22% on domestic production of zinc and 14% on foreign production in 1989. The Superfund taxes on production of zinc chloride and zinc sulfate also were unchanged, remaining at \$2.22 and \$1.90 per ton, respectively.

STRATEGIC CONSIDERATIONS

Supply

U.S. zinc mine and smelter production and available capacity are inadequate to supply U.S. zinc requirements. Ore reserves are sufficient at operating mines to permit increased output on a short-term basis and some mines on a care and maintenance basis could be reactivated in 3 to 12 months.

The domestic ore reserve base is large but could not be tapped adequately until after the first year or so of an emergency condition. Domestic smelter capacity is woefully lacking and would be the limiting factor for increased U.S. refined zinc output. Inadequate zinc smelter capacity also severely limits the Nation's ability to produce a number of strategic and critical zinc byproduct materials such as cadmium, germanium, and indium.

Although the Red Dog Mine in northwest Alaska was expected to more than double U.S. zinc mine output by 1991, this new output was not expected to improve U.S. self-sufficiency because all of the zinc concentrates were scheduled for export. Even if Red Dog concentrates were redirected for U.S. consumption only, little or no smelter capacity is available to process the material. In 1989, for example, domestic zinc mine production substantially ex-

ceeded U.S. smelter feed requirements resulting in net exports of about 39,000 tons of zinc in concentrate.

Although imports constitute a large proportion of U.S. zinc supply, about 60% of the zinc metal, concentrate, and compound imports come from Canada and Mexico, and, therefore, the risk of supply disruption is low. Other traditional sources of zinc supply depends on sea transport, and the risk of supply disruption is considerably higher.

Substitutes

Substitution for zinc depends on price and availability of substitutes as well as their technical suitability. In an emergency situation, some substitutions may not be possible because the substituting materials themselves are critical or strategic. Virtually all areas of zinc use have been susceptible to some form of reduced zinc consumption either through substitution or technical innovation. Zinc, aluminum, magnesium, and plastics are competitive materials in diecasting where weight, temperature tolerances, and surface finish are important factors. Aluminum and plastic sheet are substitutes for galvanized steel sheet; the use of molded plastics for automobile body parts in particular, has increased at the expense of galvanized steel sheet uses. Although emphasis on corrosion protection has led to increased zinc consumption in the galvanizing sector, former all-zinc coatings are increasingly being replaced by zinc alloy coatings containing less zinc than before, thinner coatings (reduced coating weights), or alloys such as aluminum-based Galvalume. Aluminum alloys, stainless steel, cast iron, and plastics have replaced significant tonnages of brass in building and marine hardware, plumbing goods, and decorative uses.

The competition in chemical and pigment uses of zinc is also substantial. Aluminum and magnesium replace zinc as reducing agents in chemical reactions, and titanium and zirconium compounds are highly competitive in pigment, ceramic, and enamel applications. Zinc compounds formerly were consumed in large amounts in the paint, photocopy, and synthetic fiber industries, but consumption in these industries has been severely impacted by substitution or technological change. Titanium dioxide largely replaced zinc oxide pigments in

the paint industry. Zinc-sensitized photocopy paper use declined rapidly following the development of the "plain-paper copier." Somewhat similarly, zinc compounds used in the production of rayon fell as rayon was displaced by other synthetic fibers.

Stockpile

A stockpile of zinc for national defense purposes has been maintained by the Government for more than 50 years. Materials in the National Defense Stockpile (NDS), managed by the Department of Defense since July 1988, can be released by the President if deemed necessary for defense or essential civilian purposes.

During World War II, the Government regulated the zinc industry and accumulated zinc stocks to ensure adequate supplies for the war effort. Concerns related to national defense after the war resulted in various stockpiling programs that evolved into the current NDS. The stockpiles contained a record-high inventory of 1.44 million tons of zinc in 1959, but sales of zinc considered excess of goals reduced this inventory to 340,194 tons by the end of 1975. The stockpile goal for zinc, 1.293 million tons, was established in April 1980, but no zinc had been purchased through 1989 to meet this goal. At the end of 1989 the zinc stockpile totaled 343,202 tons, including 2,625 tons of zinc contained in brass. The zinc metal stockpile consisted of 183,175 tons of High Grade (HG), 121,752 tons of Prime Western (PW), and 35,650 tons of other grades. New, sharply lower zinc goals were considered by the Department of Defense in 1989 and were expected to be proposed in 1990.

PRODUCTION

Mine Production

Spurred by continuing strong markets and high zinc prices, U.S. zinc mine production increased for the third straight year. Zinc production began at a new mine in Alaska, a reopened group of mines in Montana, and a copper mine in New Mexico. Startups at three other mines that were scheduled to open in 1989 were delayed by technical and/or permitting problems. The strong market outlook for zinc led

to renewed interest in a number of closed domestic zinc mining properties, several of which were being evaluated for reopening in 1990 or 1991.

The 20 leading U.S. zinc-producing mines accounted for more than 97% of production, with the 5 leading mines accounting for 47%. Tennessee, for the 29th time in the past 32 years, was the principal zinc-producing State, followed by Missouri, New York, Colorado, Alaska, Montana, and Idaho. The leading domestic zinc mine producers were ASARCO Incorporated, Jersey Miniere Zinc Co. (JMZ), and Zinc Corporation of America (ZCA).

In Tennessee, zinc was produced at six underground mines by three companies: Asarco, JMZ, and Union Zinc Inc., the parent company of JMZ. Union Zinc bought USX Corp.'s operating east Tennessee zinc mine in June, in part to secure zinc concentrate supply for JMZ's Clarksville, TN, smelter. The mining operation, renamed the Jefferson City Zinc Div. of Union Zinc, had an annual capacity to produce about 22,000 tons of zinc concentrate plus large amounts of agricultural and construction limestone.

Asarco achieved record output at its four mining operations in east Tennessee. According to the company's annual report, Asarco milled 2.72 million tons of ore producing 63,230 tons of zinc in concentrate in 1989, compared with 2.68 million tons of ore milled yielding 67,850 tons of zinc in 1988. Zinc recovery from ore averaged 93.2% in 1989. At yearend, ore reserves at the four mines were 5.7 million tons averaging about 3.3% zinc, about the same ore tonnage and grade reported at the end of 1988.

Zinc was produced by three companies, Asarco, Doe Run Co., and Cominco American Inc., a subsidiary of Cominco Ltd., as a coproduct of lead at nine underground lead mines along the Viburnum Trend in southeastern Missouri. The State's production was up substantially from that of 1988, mainly because of increased output at most mines, especially at Asarco's two mines. According to the Asarco annual report, zinc output in concentrate at the West Fork Mine was 13,060 tons, up 2,200 tons from 1988, and at the Sweetwater Mine production was 4,260 tons, up 2,800 tons. At yearend, ore reserves at the West Fork Mine were 8.3 million tons averaging 1.5% zinc and

5.8% lead with some copper and silver and at the Sweetwater Mine, 21.9 million tons of ore averaging 4.84% lead and 0.58% zinc.

The Doe Run Co., a joint venture of Fluor Corp. and Homestake Mining Co., produced about 28,000 tons of zinc in 49,700 tons of concentrate at four mills that processed 4.35 million tons of ore from six company mines in 1989. Yearend ore reserves at the six Doe Run mines totaled about 60 million tons averaging 5.1 % lead, 0.9% zinc, and 0.3% copper.

Zinc output at the Magmont Mine, a joint venture of Cominco American and Dresser Industries Inc., fell slightly from that of 1988 owing to a small decrease in ore output. According to the Cominco annual report, the Magmont mill processed about 1 million tons of ore grading 1% zinc yielding 7,720 tons of zinc in 13,400 tons of concentrate in 1989. Ore reserves continued to decline and were expected to be exhausted in about 3 years. At yearend, ore reserves totaled 3.3 million tons, a drop of 0.6 million from 1988. Ore reserves averaged 7.5% lead, 1.2% zinc, and 0.3% copper.

At the end of the year, Cominco Alaska Inc., a subsidiary of Cominco Ltd., had completed nearly all phases of mine and mill construction at its Red Dog zinc-lead-silver mine in northwest Alaska. The first ore was fed into the semiautogenous mills in early November, and the first concentrate was delivered to the port site, 52 miles southwest of the mine, on December 6. Technical problems, however, delayed full commissioning of facilities, and regular production operations were rescheduled to start in the first quarter of 1990. Total annual production, planned in 1991, was expected to be 508,000 tons of zinc concentrate, 109,100 tons of lead concentrate, and 45,000 tons of bulk concentrate.

Capital expenditures on the Red Dog project to the end of 1989 totaled \$317 million for the mine and mill complex and \$170 for the road and port facilities. Ore reserves at Red Dog were 77 million tons grading 17.1% zinc, 5.0% lead, and 2.6 ounces of silver, potentially sufficient for a mine life of 50 years.

The Greens Creek Mining Co., the operating company and a wholly owned subsidiary of RTZ Ltd. through its Kenecott Corp. subsidiary, and minority

partners, Hecla Mining Co., Exalas Resources Corp., and CSX Oil and Gas Corp. brought the Greens Creek silver-gold-zinc-lead mine on Admiralty Island, AK, on-stream in February 1989 at a cost of about \$79 million. Full production was not achieved during the year because of startup problems. According to the Hecla annual report, Greens Creek Mining milled 240,000 tons of ore in 1989 and produced concentrates containing 18,010 tons zinc, 8,700 tons lead, 5.17 million ounces of silver, and 23,500 ounces of gold. At yearend, ore reserves were 2.65 million tons averaging 8.4% zinc, 3.4% lead, 23.6 ounces of silver per ton, and 0.21 ounce of gold per ton.

In Colorado, zinc production was a coproduct of gold-silver operations at the Leadville Unit (managed by Asarco, but jointly owned with the Resurrection Mining Co.) and at the Sunnyside Mine (a joint venture between Alta Bay Venture and Washington Mining Co.). Asarco produced almost 13,000 tons of zinc in concentrates, down about 500 tons from 1988. Both the tonnage of ore milled, 185,000 tons in 1989, fell as did the zinc recovery factor, which fell to 82.2% from 85.1% one year earlier. At yearend, ore reserves were down about 55,000 tons from 1988 and totaled 709,000 tons averaging 7.77% zinc, 3.22% lead, 0.18% copper, 2 ounces of silver per ton, and 0.07 ounce of gold per ton. At the Sunnyside Mine, 198,000 tons of ore was milled in 1989, resulting in yearend ore reserves totaling 546,000 tons estimated to average 5.4% zinc, 3.8% lead, 0.57% copper, 3.5 ounces of silver per ton, and 0.15 ounce of gold per ton.

In Montana, New Butte Mining Co., Inc. began initial production of zinc-silver-lead-gold ore in July at several of its mining properties at Butte. The ore was custom processed at the Contact Mill in Philipsburg, MT. The company was planning to build its own local mill in 1991. Geologic ore reserves at yearend totaled about 1.0 million tons averaging about 5.9% zinc, 1.7% lead, 10 ounces per ton of silver, and 0.06 ounce per ton of gold.

The Montana Tunnels Mining Co., a subsidiary of Pegasus Gold Inc., mined and milled 3.6 million tons of ore at its Montana Tunnels Mine in 1989; concentrates containing 14,900 tons of zinc, 6,800 tons of lead, 1.2 million ounces of silver, and 62,600 ounces of gold were

produced. The discovery of low-grade zones in the ore body and harder than expected ore adversely affected production in the first half of the year and resulted in development of a new mine plan during the year. Ore reserves were also reduced by 1.5 million tons and at yearend totaled 34 million tons averaging 0.62% zinc, 0.23% lead, 0.023 ounce of gold per ton, and 0.4 ounce of silver per ton. At 1989 production rates, a 9-year mine life was expected.

In Idaho, Hecla Mining Co. fully implemented its Lucky Friday Underhand Longwall (LFUL) mining method at the Lucky Friday Mine. The LFUL method, which utilizes rubber-tired vehicles, more mechanized equipment, a ramp system, and cemented sandfill, was developed to enhance safety and improve efficiency. In 1989, ore milled increased about 27,000 tons to 126,000 tons resulting in an output of 2,950 tons of zinc in concentrates, up about 900 tons from 1988. At yearend, ore reserves were 416,000 tons averaging 2.4% zinc, 14.4% lead, and 17.7 ounces of silver per ton.

In April, Cyprus Minerals Co. began zinc production at its Pinos Altos copper-zinc mine in New Mexico. The mine was opened in 1988 but produced only copper. The inactive Groundhog mill at Deming was leased to process the zinc ore. According to the Cyprus annual report, about 900 tons of zinc in concentrate was produced and sold in 1989. Reserves of zinc ore were about 0.9 million tons at yearend.

Both the Ward Mine in Nevada and the Star-Morning Mine in Idaho had been expected to open in 1989, but their openings were delayed owing to permitting and/or technical problems. Both, however, were expected to open in early 1990. Ore produced at the Ward Mine, wholly owned by Alta Gold Co. since November via the merger of Silver King Mines Inc. and Pacific Silver Corp. into Alta, was stockpiled during the year while awaiting the conversion of the nearby leased Taylor mill from a silver processing plant to a 900-ton-per-day base metal concentrator. Plans called for an annual production of about 10,500 tons of zinc, 600 tons of copper, 700 tons of lead, and 300,000 ounces of silver in concentrates. At yearend, ore reserves were 1.45 million tons averaging 6.1% zinc, 1.1% copper, 1.1% lead, and 2.4 ounces of silver per ton. The Ward Mine last operated in 1880.

Star Phoenix Mining Co. leased the closed Star-Morning Mine from Hecla and Bunker Hill Ltd. Partners in July. In late 1989, Star Phoenix began mine rehabilitation, including dewatering and upgrading the 1,000-ton-per-day mill at Burke. Plans called for a mid-1990 ore production target of about 13,000 tons per month, yielding about 1,000 tons of zinc concentrate per month. The zinc concentrates were scheduled to be processed at Cominco's zinc smelter at Trail, British Columbia. An estimated 2 million tons of zinc-lead-silver ore reserves were reportedly available in the upper levels. The Star-Morning Mine last operated in 1985.

Two long-closed zinc mines in Washington were being evaluated and could open in late 1990 or in 1991. Equinox Resources Ltd. was completing a feasibility study on the Van Stone Mine near Coville, WA. The mine last produced in 1970. The infrastructure and a 900-ton-per-day mill were reportedly adequate for rapid commissioning. Ore reserves, identified in the late 1970's, totaled about 7 million tons averaging 3.7% zinc and 0.6% lead. Within the reserve was 1.4 million tons of readily minable higher grade ore averaging 6.5% zinc and 1.5% lead.

Resource Finance Co. (RFC) was evaluating the Pend Oreille lead-zinc mine near Metaline Falls, WA, for possible reopening. The Pend Oreille Mine last operated in 1977. RFC estimated

plants from scrap materials; however, the largest producer of metal from secondary zinc was ZCA at its primary electrothermic smelter at Monaca, PA. A substantial part of the plant's secondary feed was crude zinc calcine recovered from steelmaking electric arc furnace (EAF) dusts by a sister company, Horsehead Resource Development Co. (HRD), at Palmerton, PA, and Calumet, IL. The largest producers of zinc metal at secondary plants were Huron Valley Steel Corp., Interamerican Zinc Co., and Gulf Metals Corp.

ZCA installed two new furnaces as part of an expansion program at its 103,000-ton-per-year Monaca plant in 1989. Other furnace units and a new sinter plant were expected to be constructed in 1990 and 1991, gradually leading to 45,000 tons of new capacity. Most of this new capacity was expected to be dedicated to the processing of EAF zinc calcine.

Florida Steel Corp. and Nucor-Yamato Steel Co. began production of commercial-

grade zinc metal directly from EAF dusts in 1989 at their respective steel plants at Jackson, TN, and Blytheville, AR. Both plants utilized plasma furnace technology developed by Tetronic Research and

Development Co. and Bethlehem Steel Corp. Plans called for annual zinc metal production of 1,400 tons and 1,800 tons, respectively.

ZCA temporarily reopened its DePue,

W Withheld to avoid disclosing company proprietary data.

IL, zinc dust plant at midyear to produce special grades of zinc dust products not produced at other ZCA facilities. The plant had been scheduled for permanent closure when shut down in January 1988.

Two other companies, Zia Technology of Dallas and Laclede Steel Co., planned to build EAF dust processing facilities at Caldwell, TX, and St. Louis, MO, respectively. Zia was sched-

uled to have a plant capable of treating 54,000 tons per year of EAF dusts in operation by mid-1990. It planned to use an inclined rotary reduction system to extract a crude zinc product that will then be fed into a top-feed vertical retort for metal reduction, vaporization, and capture in a conventional splash condenser.

Laclede Steel planned an on-site facility to treat about 36,000 tons of EAF

dusts per year. The company planned to use an electric-slag-resistance reduction furnace developed by Elkem Technology/AS to produce a crude zinc oxide product suitable for metal recovery.

U.S. Zinc Co., a subsidiary of Gulf Metals, and Meteor Investments formed Plasmet Inc. to produce 7,200 tons of PW zinc metal annually from zinc drosses, wastes, and residues from

³ Includes Brushy Creek Mill.

galvanizing and die-cast operations. The plant was under construction in Houston, TX, and was expected to be operational by the second quarter of 1990. Plasma-furnace technology, licensed from Tetronic, was to be used.

Zinc Oxide

Domestic American- and French-process zinc oxide was produced entirely from zinc metal and scrap by eight companies in 1989. All but one company, Eagle Zinc Co. of Hillsboro, IL, produced French-process zinc oxide. Some impure oxide produced at secondary plants was sold directly for animal feed and agricultural purposes. The principal zinc oxide producers in 1989 were Asarco, Pasco Zinc Corp., and ZCA.

In 1989, Asarco produced 15,650 tons of zinc oxide at its 27,500-ton-per-year Hillsboro, IL, plant. Modifications and the addition of a new furnace were underway to increase the efficiency and plant capacity in 1990.

North American Oxide, Inc., an affiliate of the Rogers Group Inc., planned to build an 18,000-ton-per-year French-process zinc oxide plant at Clarksville, TN. Startup was expected in mid-1990.

Byproduct Sulfur

Production of sulfur in byproduct sulfuric acid at primary zinc plants was 134,000 tons, down slightly from the 136,000 tons produced in 1988. Acid production at zinc plants in 1989 was valued at \$17.4 million.

CONSUMPTION AND USES

Zinc is found in all sectors of the economy, but its role is less obvious to the public because zinc tends to lose its identity in the end products. Zinc-containing products were extensively used by the military, industry, and general public for construction, transportation, electrical, machinery, and chemical purposes. Zinc-coated steel sheet, structural shapes, fencing, storage tanks, fasteners, nails, and wire rope were widely used in all types of construction, including transmission and radar towers, industrial plants, culverts, roads, bridges, and airfields. Zinc sacrificial anodes were used to protect ship hulls, offshore drilling rigs, and submerged and buried steel

works, tanks, and pipes. Brass was used as shell casings in ammunition and tubes, valves, radiators, and fittings in vehicles, motors, refrigeration equipment, heat exchangers, communication units, and electronic devices. Zinc die-cast parts, such as handles, grilles, bezels, brackets, locks, hinges, gauges, pumps, mounts, and housings, were used extensively in vehicles, machinery, business machines, appliances, scientific equipment, and electronic equipment. Zinc dust was used in primers and paints; in alkaline dry cell batteries; in the sherardizing process to protectively coat nuts, bolts, and small parts; for the precipita-

tion of noble metals from solution; and in the zinc industry for the removal of impurities, such as copper, cadmium, and lead, before electrolysis. Zinc oxide was a necessary ingredient in the vulcanization of rubber and as pigment in paints. The metal casings of zinc-carbon dry cell batteries were zinc. In 1989, about 30,700 tons of Special High Grade (SHG) in rolled zinc was used by the U.S. Mint to produce 12.8 billion pennies.

Zinc compounds were used in corrosion-inhibiting paint primers, chemical catalysts, welding and soldering fluxes, fungicides and pharmaceuticals, phosphors for cathode tubes and radar

scopes, chemical smoke, and additives to lubricating oils and greases. Zinc ferrites were used in electrical devices in transformers, coils, amplifiers, motors, and tuners, and in electronic devices in radio, television, and computers.

In 1989, domestic consumption of slab zinc for galvanizing and light metal alloying purposes and oxide manufacture increased, whereas other use categories were lower than in 1988. Galvanizing and electrogalvanizing, mainly for sheet and strip, continued to be the principal use of zinc metal consuming an estimated 52%, followed by zinc-based die-cast alloys, 21%; brass alloys, 12%; and other uses,

15%. SHG accounted for about 52% of the reported slab zinc consumed, followed by PW, 24%; HG, 14%, and other grades, 10%.

Overall, the construction sector of the economy was the largest consumer of zinc, accounting for an estimated 46%, followed by transportation, 20%; machinery, 11%; electrical, 11%; and other, 12%. Zinc metal accounted for about three-fourths of consumption and zinc chemicals about one-fourth in 1989.

According to the American Iron and Steel Institute, shipments of galvanized sheet and strip totaled 9.7 million tons, up 0.4 million tons from 1988. Of the total shipments, electrogalvanized sheet accounted for 20% compared with 21% in 1988. In the first half of the year, the galvanized sheet and strip market was strong, being characterized by near-capacity production, extended delivery schedules, and premium prices. In the second half, domestic prices, delivery times, and production declined in response to falling automobile production and an easing in construction activity. Concurrent with the slowdown in demand were falling zinc prices, especially in the last quarter of the year.

According to the Bureau of the Census, zinc-base alloy die and foundry casting shipments totaled about 200,000 tons, down from 223,000 tons reported in 1988. The decline was attributable to reduced demand by die-cast manufacturers in the second half of the year and partly to the high price of zinc relative to substitute materials. Zinc die-cast shipments by weight were estimated to have been equally distributed between automotive, hardware, and other uses.

Zinc consumption in the production of copper-base alloys by brass mills, ingot makers, and foundries was down slightly from 1988 according to the Copper Development Association Inc. (CDA). The brass and bronze industries were estimated to have consumed about 280,000 tons of zinc, the source of which was about equally divided between refined zinc metal and brass and bronze scrap metal. According to CDA data, brass mills accounted for 85% of the total zinc consumed as metal and scrap.

The zinc content in typical U.S.-manufactured automobiles was estimated to average about 40 pounds in 1989, about the same as in 1988.

TABLE 13

^r Revised.

¹ Excludes secondary slab and remelt zinc.

Diecastings accounted for about 21 pounds; corrosion protection via galvanizing and coatings, 16 pounds; and other, including rubber, brass, and zinc solder, 3 pounds.

The apparent domestic consumption of zinc oxide was about 176,000 tons, down from 190,000 tons in 1988. Domestic production was up substantially, but so were exports. Imports fell for the first time since 1981. Because the Bureau of Mines information on zinc oxide consumption by industry sector reflects only shipments as reported by the domestic producers, the consumption data listed in table 20 only accounts for about two-thirds of the apparent market. Of the reported amounts, the rubber industry continued to be the principal consumer followed by chemicals and paint.

STOCKS

Metal stocks held at yearend by domestic producers, consumers, and merchants rose for the first time after 7 straight years of decreases, but were the second lowest in the 1980's. Domestic stock levels tended to rise through mid-year, before declining in line with declining demand. Merchant stocks tended to rise at the end of the year, accounting for the modest rise in domestic stock levels. At any given time in 1989, slightly less than 1 month domestic consumption was available as stocks. Metal stock levels in the market economy countries (MEC), according to the International Lead and Zinc Study Group (ILZSG), were relatively stable in the first half of the year, averaging about 515,000 tons but rose

to about 592,000 tons at yearend. The stock rise in the second half of 1989 was mainly attributable to increased world metal production, in part because of fewer strikes rather than any substantial fall off in demand.

The London Metal Exchange (LME) planned to terminate its HG contract in March 1990 in favor of the SHG contract that was introduced in September 1988. As a result, LME zinc metal

TABLE 18

stocks of HG fell from 14,400 tons to 5,800 tons during the year, whereas SHG stocks rose from 26,100 tons to 74,800 tons in the same period.

Inventories of zinc in concentrate at domestic primary smelters totaled 35,500 tons at yearend compared with 49,400 tons at the end of 1988, according to the American Bureau of Metal Statistics Inc. Concentrate stocks were at their lowest level at yearend.

PRICES

Zinc metal prices rose sharply to record-high levels in the first 3 months of the year, continuing a 17-month price uptrend that began in November 1987. The North American producers' quote for HG was raised to a record-high 95 cents per pound at the end of February. By late March, the tightness in world zinc supply began to ease and prices on the LME trended downward, in turn lowering domestic prices to the

^r Revised.

80-cent-per-pound level by June. Overall, world demand remained strong in the summer months, and U.S. zinc prices stabilized at about the 80 cents level. In September, LME zinc stocks increased, resulting in downward pressure on prices. In the last quarter of the year, domestic zinc prices fell in response to

lower LME prices, stock increases, and reduced demand in the domestic economy, in part, owing to sharp cutbacks in automobile production.

Zinc oxide prices, as quoted in the American Metal Market, followed the price trends of zinc metal. Prices ranged from a high of about 95 cents per pound

in March to a low of about 72 cents in December, averaging about 90 cents for the year. Imported zinc oxide averaged 75.4 cents per pound compared with 49.4 cents in 1988.

The price quoted in Chemical Marketing Reporter (CMR) for zinc sulfate, monohydrate industrial grade, 36% zinc in bags in carload lots, was \$30 per 100 pounds through February and \$41 thereafter. Agricultural zinc sulfate in bulk was listed by CMR at \$460 per short ton. Technical-grade zinc chloride, 50% solution in tanks, was quoted at \$22 per 100 pounds in January and \$24 thereafter.

The LME was the principal basis for world zinc pricing in 1989. Not only were most of the world's concentrate sales based on LME prices but also most metal sales. Producers' quotes, including those in North America, tended to become more responsive to LME price changes in 1989. Because of this increased price volatility, some zinc companies were considering dropping producer quotations altogether in favor of basing sales on the LME SHG price.

Most custom zinc smelter companies and producers of zinc concentrates agreed to use the LME SHG cash settlement price as the basis for determining treatment charges in 1989 and in the future. This agreement, plus the fact that LME zinc contracts were U.S.-dollar-based, provided a convenient reference price for both metal and concentrate and made zinc contracts hedgeable at the LME.

Changes in annual U.S. zinc metal prices from 1850 through 1988, and a

brief analysis of the factors that influenced those changes were included in a Bureau of Mines report on nonferrous metal prices.² The average annual zinc price over the 1909-88 period, based on 1987 constant dollars, was 57.2 cents per pound.

FOREIGN TRADE

Exports of basic zinc materials in 1989 were the best in years. Waste and scrap exports rose for the eighth consecutive year and set record highs in both content and value. Exports of slab zinc and zinc oxide increased many-fold over 1988 levels and, respectively, were the highest since 1974 and 1947. Exports of zinc in concentrates were the highest since 1985; most were shipped to Canada from western U.S. zinc producers. Interestingly, U.S. exports of zinc in concentrate in 1989 exceeded imports for the first time since the early 1930's.

General imports of zinc in concentrates totaled 388,566 tons, whereas imports for consumption totaled only 40,947 tons. The disparity was due to shipments of concentrates through Skagway, AK, to world markets from Canada's Faro zinc-lead mine in the Yukon Territory. Imports of slab zinc and zinc oxide both fell substantially from those of 1988; however, they were, respectively, the second and third highest levels ever recorded. According to CDA, 397,000 tons of brass mill products were imported and 133,400 tons exported in 1989, compared with 433,600 imported and 115,000 exported in 1988.

WORLD REVIEW

World zinc metal consumption continued its record-setting pace, exceeding 7 million tons for the third straight year. Smelter output was a record high and mine output was the second highest ever recorded.

Zinc metal consumption was about 7.2 million tons, slightly less than that of 1988. The MEC, according to IL-ZSG, consumed 5.23 million tons, down about 40,000 tons from that of 1988. The MEC accounted for about three-fourths of consumption and the

centrally planned economies (CPE) about one-fourth or about 1.9 million tons. The world's leading consuming nations, in order of estimated consumption, were the United States, the U.S.S.R., Japan, the Federal Republic of Germany, China, and France. The United States, Japan, and Western Europe accounted for slightly more than one-half of world consumption and about 70% of the MEC consumption. According to ILZSG, the principal uses of zinc metal in 1988 in the major Western countries were: galvanizing, 45.1%; brass and bronze, 20.4%; zinc-based alloys, 15.0%; chemicals, 8.1%; zinc semimanufacturers, 7.0%; and others, 4.4%.³ In 1989, galvanizing was estimated to have increased to 46%, whereas other uses were about the same as in 1988 except brass and bronze, which declined to slightly less than 20%.

World zinc mine production was 7.06 million tons, marginally higher than in 1988, but about 160,000 tons less than the record high of 1987. In tonnage terms, Australia, Peru, and the United States recorded significantly higher production in 1989, whereas, Canada, Japan, and Sweden produced significantly less than in 1988.

On a geographic basis, North and

South America accounted for about 38% of world mine output; Europe, including, Greenland and the U.S.S.R., 30%; and Australia, 11%. Canada was the leading world zinc mine producer despite a second consecutive sharp decrease in output. Canada, together with the U.S.S.R., Australia, and Peru, accounted for 48% of world zinc production.

World exports of zinc in concentrates totaled about 2 million tons, of which more than 90% were from the MEC. Australia, Canada, and Peru accounted for about 75% of the total exported. Japan was by far the leading importer of zinc concentrates, followed by the Federal Republic of Germany, France, Belgium, and the Netherlands. According to ILZSG, the MEC imported 106,000 tons from CPE countries and exported 111,000 tons to CPE countries in 1989.

World refined metal production was up about 70,000 tons to 7.2 million tons in 1989. According to ILZSG, MEC production was 5.23 million tons, virtually the same as in 1988. Most countries produced at last year's level; however, China, the Republic of Korea, and the United States recorded notable increases, whereas Belgium and Canada produced less. Canada, China, Japan, and the U.S.S.R., the four largest

zinc metal producers, accounted for about 38% of world refined zinc metal production.

The world supply-demand position was extremely tight in the first few months of 1989, continuing the tight supply-demand situation that persisted throughout 1988. Prices rose to alltime high levels in the first quarter before easing in the second quarter. After August, stock levels rose, easing prices further. According to ILZSG, net exports of metal from the MEC to the CPE countries were 11,000 tons in 1989. The U.S.S.R. was the largest importer of the CPE countries, importing 47,000 tons of the 117,000 imported by that group.

Further corporate concentration of the world's zinc industry took place in 1989 continuing the trend of the past few years. The Société Générale de Belgique, located in Belgium, merged its majority-owned zinc companies into an 87.5%-owned subsidiary, called Acer-Union Minière SA. The new company was estimated to control about 10% of world zinc smelter output. Acer-Union Minière's zinc subsidiaries included Metallurgie Hoboken-Overpelt S.A.; Soc. des Mines & Fonderies de Zinc de Ra Vielle Montagne S.A., the world's largest custom zinc producer; and Union Zinc and JMZ in the United States.

Curragh Resources Inc., operator of the Faro zinc-lead mine in Canada, bought a 20% interest in Europe's largest zinc producer, Asturiana de Zinc S.A. Curragh, one of the world's largest exporters of zinc concentrate, expected to gain further diversification of its concentrate markets, and Asturiana expected to gain zinc supply to feed its ongoing 80,000-ton smelter expansion in Spain as well as help replace future zinc concentrate deficiencies owing to the possible closure of its partially-owned Rubiales Mine in 1991.

In September, Noranda Ltd. and Trelleborg AB jointly completed their acquisition of Falconbridge Ltd. that included the Kidd Creek zinc-copper operations in Ontario. Through this acquisition, Noranda's direct share of world zinc mine and smelter capacity rose to about 3.5% and 4.7%, respectively. In 1989, Trelleborg, through its Boliden subsidiary, also acquired zinc mining interests in Portugal and in Maine, where the company planned to develop the Bald Mountain copper-zinc-silver-gold deposit.

Capacity

World mine capacity was about 8 million tons, up about 200,000 net tons from 1988. Seven new zinc-producing

mines opened, four closed, and six mines expanded capacity in 1989. The Red Dog Mine in Alaska, which was expected to add 325,000 tons to world zinc capacity, was not included in the 1989 total owing to startup problems that delayed full commissioning into 1990. The Hellyer Mine in Australia, rated at 92,000 tons capacity and San Vicente Mine in Peru, 33,000 tons new capacity, respectively, were the largest zinc producers to open and to expand in 1989. The Prieska Mine in the Republic of South Africa, 24,000 tons capacity, was the largest zinc producer to close.

World smelter capacity gained about 0.1 million tons to 8.0 million tons in 1989, mainly as a result of minor capacity additions in a number of countries. Greenfield smelters under construction in India and Iran and expansions underway in Belgium, Brazil, the Federal Republic of Germany, Mexico, Spain, and the United States were expected to add about 400,000 tons of new smelter capacity in the next few years.

The data in table 36 are rated annual production capacity for zinc mines and primary zinc refineries as of December 31, 1989. Rated capacity is defined as the maximum quantity of product that

can be produced in a period of time on a normally sustainable, long-term operating rate, based on the physical equipment of the mine or plant, and given acceptable routine operating procedures involving labor, energy, materials, and maintenance. Refinery capacity is based on engineering capacity provided by the companies or as estimated by the Bureau of Mines. Capacity includes both operating plants and plants temporarily closed that, in the judgment of the author, can be brought into production within a short period of time with minimum capital expenditure.

CURRENT RESEARCH

The Bureau of Mines continued to conduct zinc-related research in many diverse areas. The lead, silver, tin, and zinc resources of the Sheep Creek prospect in north-central Alaska were evaluated by field investigations and mineralogical, characterization, and concentration tests.⁴ The effect of common sulfide minerals, including sphalerite, on the corrosion rates of various types of ferrous alloy grinding media was studied.⁵ The extraction of gallium and germanium from hydrometallurgical zinc process residues were studied.⁶ Extraction rates of more than 90% were attained. Soil-extraction methods on agricultural lands contaminated by acid mining waste were studied to provide a means for predicting potential phytotoxicity of zinc, copper, and arsenic.⁷ One of the extraction procedures provided good correlations with metal levels in plant tissues and was anticipated to be a useful measure of toxicity for plants. A hydrothermal sulfidation and chloride leaching procedure was investigated to detoxify and recover lead and silver from plumbojarosite, a hazardous residue product generated during pressure-oxidative leaching of zinc concentrates in commercial operations.⁸ The procedure tested was a potentially effective method for detoxification of such residues and, in addition, resulted in high-lead and high-silver recovery.

A comprehensive coverage of zinc-related investigations and an extensive review of current world literature on zinc extraction, alloys, uses, products, and research was available in quarterly issues of Zincscan, published by the

OUTLOOK

U.S. demand for zinc was forecast to rise slowly, increasing from about 1.06 million tons in 1989 to about 1.2 million tons by the year 2000. No major shifts in domestic zinc use were foreseen, although some present uses may yield further to substitution.

Despite having an adequate zinc resource base, imports were expected to continue to account for more than one-half of U.S. zinc demand in the next

decade. Mine output was anticipated to reach record-high levels in the 1990's, but smelter capacity was expected to rise only modestly. No new primary zinc smelters will likely be built in the United States during the 1990's owing to permitting delays and economic indecision caused by the uncertainty of environmental regulations and the long-term liability threats posed by Superfund. Ironically, the United States is poised to become a major world exporter of zinc concentrates, and, at the same time, to remain the world's largest importer of refined zinc metal.

Secondary zinc recovery from waste and scrap was anticipated to be a strong growth sector for the zinc industry.

Domestic secondary zinc production could increase by more than 50% of present levels in the next decade and constitute 40% of total U.S. zinc metal and compound consumption by the year 2000. Increased secondary recovery was expected to be driven by public policies related to waste recycle, environment, and public health.

World zinc metal consumption was expected to continue upward, rising to about 8.5 million tons by the year 2000 from the 7.2 million tons consumed in 1989. No new major-consuming uses of zinc were on the horizon. Traditional zinc uses in meeting the needs of a rapidly growing and more affluent world population were expected to be the driving force for increased zinc usage in the next decade. No long-term problems with supply were foreseen, although environmental concerns could affect zinc mine and refinery production, especially in developed countries. World zinc resources and reserves were adequate to supply the higher demand through the year 2000, and the industry, historically, has always responded to shortages with increased production.

BACKGROUND

Zinc is the fourth most widely used metal after iron, aluminum, and copper, yet through most of its history, zinc was not known as a distinct metal. Zinc

has been found in bronze artifacts made 5,000 years ago and has been used as a component of brass in Europe and Asia for more than 2,500 years. Although a few artifacts composed mainly of zinc metal have been dated back to 500 B.C., the extreme scarcity of such items before A.D. 500 suggest the metal was made by accident or the technology was short lived and forgotten. In the 6th century, A.D., the Chinese are known to have produced articles of zinc metal and are generally credited with being the first to develop the technology to make zinc metal. Recent archeological studies, however, suggest that smelter technology in India may have preceded that in China.⁹ Zinc was smelted in the Zawar area of India as early as A.D. 1000 and was produced there on a large scale beginning in the 13th century. Europeans were apparently unfamiliar with zinc metal until the 16th century, even though they had used earthy forms of zinc compounds for many years to make brass.

The derivation of the name zinc is obscure but "zinken" and "zinck" were used by alchemists in central Europe in the early 1500's in reference to a "semi-metal," the source of which is unknown, but was likely zinc metal formed by accident in smelting zinc-rich lead and copper ores. Paracelus, a German-Swiss professor of medicine who died in 1541, is credited with being the first European to list zinc as a distinct metal and to describe some of its properties. During the 17th and 18th centuries, zinc metal was imported from Asia by Portuguese and Dutch traders and was sold under various names, but eventually became known as spelter, the commercial form of slab zinc. Spelter, as a term for slab zinc, is still used, but in many countries, including the United States, the term is used little today.

The technology of smelting zinc is thought to have been brought to Europe from China around 1730, and in the early 1740's the first European zinc smelter was erected in England. By the end of the 18th century, large-scale commercial smelting had begun in Europe, mainly as a result of improved distillation methods utilizing horizontal muffles of large capacity known as the Silesian method. Zinc distillation by the Belgian method or by numerous

small horizontal retorts in a single furnace followed within a few years. The Belgian method gained widespread acceptance and became the preferred production method for the next 100 years.

In the United States, the first zinc metal was produced in 1835 at the Arsenal in Washington, D.C. The Government brought in workers from Belgium to build and operate a small spelter furnace to produce zinc from zincite ore from New Jersey. The primary purpose for the zinc produced was to provide alloying metal to make brass for the manufacture of U.S. standard units of weight and measure.

The U.S. zinc mining industry began about 1850 with production of oxides and compounds from zinc ores in New Jersey and Pennsylvania. The first commercial zinc metal production began in 1860 when smelters were built in Illinois and Pennsylvania to treat nearby ores. By the turn of the century, U.S. zinc mining and smelting activity had grown rapidly, mainly developing in Illinois, Kansas, and Missouri because of closeness to Tristate and Wisconsin zinc ores and adequate coal for smelting fuel. The discovery of low-cost natural gas in Kansas in the mid-1890's led to increased smelting in that State and made Kansas the leading zinc-producing State by 1899. The development of mineral flotation processes early in the 20th century made it possible to recover zinc from complex ores and produce high-grade concentrates. This led to zinc production in many areas of the United States.

World zinc metal production was centered in Europe in the 18th and 19th centuries; however, toward the end of the latter century, U.S. zinc production had risen substantially, resulting in a

second major world production center. By 1901 the United States had become the leading world zinc producer, a position held for most of the next 70 years. After World War I, a number of countries, including Australia, Canada, Japan, and the U.S.S.R., developed significant zinc smelting industries. Despite increased zinc production elsewhere, Europe, except during the two World War periods, and the United States continued to be the main zinc smelting centers, in part because they also were the high zinc consumption areas. From the late 1960's, U.S. zinc production declined because numerous smelters closed for environmental and technical reasons, resulting in the reduction of U.S. zinc smelter capacity to one-third its former level. Occurring concurrent with the decline of the domestic zinc industry and in the prior decade, many countries began or expanded their zinc mine and smelter production. Whereas only 9 countries were known to be producers of zinc metal in 1900, 37 produced metal in 1989. Zinc mining was similarly limited to a few countries in 1900, but 54 countries produced zinc in 1989.

Uses before zinc metalmaking by the Chinese in the sixth century involved the naturally occurring zinc minerals and oxidic zinc materials resulting from smelting lead and copper ores. Zinc's presence in bronze was most likely accidental and dependent on the ores used, whereas, zinc compounds were recognized and were deliberately mixed with copper to produce brass by the cementation process. Some cosmetics of ancient Egypt contain appreciable amounts of zinc carbonate and/or zinc oxide.

Zinc was a little used and obscure metal in most of the world until production began on a small scale in England in 1740. Since then, world consumption of zinc has increased from less than 100 tons per year to more than 7 million. Zinc metal consumption grew slowly, initially being used mainly to make brass, pigments, and rolled products, and later to produce galvanized steel and die-cast products. From 1740, 173 years (1913) lapsed before world zinc metal consumption reached 1 million tons and 203 years (1943) before it reached 2 million tons. After World War II, annual world consumption increased rapidly, reaching 7 million tons in the mid-1980's.

Definition, Grades, and Specifications

Zinc is a bluish-white metal with a melting point of 419.6 °C and boiling point of 907 °C. The melting point permits low-temperature casting, and the boiling point is an important factor in purifying the metal by distillation methods and in producing metal dust and zinc oxide in very fine particles, a feature desirable for many uses. The properties of being chemically active and alloying readily with other metals are utilized industrially in preparing a large number of zinc containing compounds and alloys. The relatively high position of zinc in the electromotive series largely accounts for the extensive use of the metal to protect iron and steel products against corrosion.

Zinc produced from ores is termed "primary" zinc. When zinc is produced from scrap or residues, it is termed "secondary," "redistilled," or "remelt" zinc, depending on the recovery process. Primary zinc metal is categorized as electrolytic or distilled zinc according to the reduction process used. Commercial zinc metal cast in various shapes and sizes is termed slab zinc in the United States; the older term spelter is now rarely used in this country.

The American Society for Testing and Materials (ASTM) has approved specification in the past for as many as six commercial grades of slab zinc at one time, but currently lists only three—PW, HG, and SHG. The compositions of these grades are as follows:

Grade ¹	Analysis (percent)			
	Lead, maximum	Iron, maximum	Cadmium, maximum	Zinc minimum (by difference)
Special High Grade ²	0.003	0.003	0.003	99.990
High Grade	.03	.02	.02	99.90
Prime Western ³	1.4	.05	.20	98.0

¹ When specified for use in the manufacture of rolled zinc or brass, aluminum shall not exceed 0.005%.

² Tin in Special High Grade shall not exceed 0.001%.

³ Aluminum in Prime Western shall not exceed 0.05%.

Historically, PW zinc was the first specification and was established for hot-dip galvanizing. HG, and later SHG, were established when metal of high purity was required for diecasting purposes.

Two other grades of nonspecified slab zinc, Continuous Galvanizing Grade (CGG) and Controlled Lead Grade (CLG), have gained acceptance for galvanizing purposes. CGG and CLG are

prepared to customer specifications. CGG contains up to 0.35% lead and some aluminum, whereas, CLG contains less than 0.18% lead and no aluminum. Former specified grades, known as Immediate, Brass Special, and Selected, were largely used in alloying with copper to form brass.

Galvanizing is the process of coating iron with zinc to form a protective coating. This is generally accomplished by immersion of clean steel or iron in a bath of molten zinc (hot-dip galvanizing) or by electrodeposition of zinc from solution onto steel or iron (electrolytic galvanizing). Other forms of galvanizing are accomplished by tumbling a heated mixture of zinc dust and small steel parts, such as nails or bolts (sherardizing), by spraying atomized molten zinc metal through a gun onto clean steel (metallizing), and by painting with zinc dust paint.

The zinc used in hot-dip galvanizing, historically, was PW, HG, or specially prepared alloys composed of more than 98% zinc, and for electrolytic galvanizing, the zinc metal quality was SHG or HG. In recent years, a number of alloy coatings have been developed that have superior characteristics over those mentioned above. The two principal new hot-dip coatings are Galfan and Galvalume. Galfan, 95% zinc and 5% aluminum-mischmetal alloy, has gained widespread acceptance as a coating for sheet, tube, and wire; whereas, Galvalume, a 55% aluminum and 45% zinc

plus some silicon alloy, is highly competitive with typical galvanizing and Galfan mainly in steel sheet uses. In electrolytic galvanizing, alloy coatings such as iron-zinc, manganese-zinc, and nickel-zinc are gaining an increased share in the automotive sheet market compared with pure zinc coatings.

In recent years, the usage of 1-sided, 1½-sided, and 2-sided galvanized and

electrogalvanized sheet and strip, especially in the automobile industry, has increased to provide corrosion protection. One sided has a normal zinc surface on one side; the other side is uncoated or stripped of its coating to provide a smooth paintable surface. The 1½ sided has a galvanized surface on one side and a thinner paintable iron-zinc alloy coating on the other side. Galvanized steels have also made inroads in automobile manufacturing and are used for both exposed and unexposed parts. Galvanized steel differs from regular hot-dipped products in that an additional annealing treatment is employed to more fully alloy the zinc with iron in the substrate, thereby improving the weldability, formability, and paintability of the product.

The typical hot-dip galvanizing strip is coated on both sides with anywhere from 0.1 to 2.0 ounces of zinc per square foot. Designations such as G-90 and G-60 for galvanized strip indicate coating weight; G-90, for example, indicates a coating weight of 0.9 ounce of zinc per square foot.

For electrogalvanizing, coating weights range from 20 to 120 grams per square meter. A designation such as 70/50 electrogalvanized sheet indicates both sides are coated but with different coating weights, 70 grams per square meter on one side and 50 grams per square meter on the other.

Zinc diecasting alloys, commonly known commercially as Zamak alloys or as die-cast alloys No. 2, 3, 5, or 7 are any of several zinc-base alloys in which aluminum and copper are the principal alloying elements. The most widely used of these alloys, No. 3, contains from 3.5% to 4.3% aluminum, up to 1.25% copper, and from 0.03% to 0.08% magnesium. The aluminum imparts wear resistance, high strength, and corrosion resistance properties to the alloy; copper improves tensile strength, hardness, and other physical properties; and the magnesium counteracts subsurface corrosion caused by certain impurities.

Three zinc-based aluminum alloys, generically identified by their approximate aluminum contents, 8%, 12%, and 27%, are used for general-purpose industrial foundry castings. These alloys are specifically intended for gravity-casting methods, where they provide substantial energy savings in casting over conventional foundry alloys, such as alu-

minum, bronze, and iron.

Brasses are copper-base alloys in which the zinc content ranges from 5% to 40%. Some bronzes, whose principal alloying materials are copper and tin, contain up to 4.5% zinc.

Zinc dust is made by zinc distillation from slab zinc or secondary zinc metals; the particle size is controlled by the rate of distillation and condensation. The principal standard grades of zinc dust have metallic contents of 95% to 97% with the remainder in oxide form. Materials of lower metallic contents are not suitable for pigment use but are suitable for some chemical uses. Dust with an average particle size of 7 to 9 micrometers can be classified as a standard grade, while an average particle size of 4.5 to 7 micrometers would be classified superfine dust, and dust of 2.5 to 4.5 micrometers would be ultrafine. The term "blue powder" generally refers to the zinc dust distillation product of pyrometallurgical retort smelting processes. Blue powder was the earliest form of zinc dust and owes its name to its bluish-gray appearance caused by surface oxidation on dust particles.

Zinc powder is generally produced by atomizing a stream of molten zinc metal by a high-pressure blast of air or other gases. The resultant particles, which are considerably coarser than distilled zinc dust, are sized before use. Leafed or flaked zinc powder is composed of flattened particles generally made by milling spherical zinc powder with stearic acid added to prevent agglomeration.

Zinc vapor burns in air to form the white powder, zinc oxide. Zinc oxide is produced commercially by both the indirect or French-process from zinc metal or metallic residues and by the direct or American-process from zinc ores or oxidic secondary materials. The following table present zinc oxide specifications:

	American process	French process
Zinc oxide, minimum	99.0	99.0
Sulfur, maximum	.2	.1
Moisture and other volatiles, maximum	.5	.5
Total impurities, maximum	2.0	1.0
Material retained on 325-mesh (44-micrometer) sieve, maximum	1.0	1.0

Source: ASTM Standards, pt. 28, pp. 28-29 (Specification 079-44), reapproved 1974.

Lithopone is a white pigment composed of a mixture of barium sulfate and zinc sulfide. Formerly an important paint pigment, its use has declined in recent decades.

Products for Trade and Industry

Commercial zinc is traded or sold to industry mainly in the grades produced at primary smelters or as zinc-based alloys specified by diecasters and galvanizers. The size and shapes of metals sold are varied, but generally are in the form of slabs, blocks, or waffle ingots. Slabs typically weigh 25 kilograms, whereas blocks range up to 2 tons. Each slab or block is identified as to grade and producer by a registered brand cast into the metal. Zinc metal is also commercially available in the form of plate, rolled sheet and strip, wire, dust, powder, and flake.

Brass is generally marketed as ingot that is used in foundries for castings and in brass mills for production of rolled, extruded, and forged products. Zinc oxide is the most widely marketed zinc chemical. It is purchased according to ASTM specification, particle size and shape, and customer requirements. For example, acicular and plate-type forms of zinc oxide are favored as paint pigments, whereas, nodular forms are preferred in rubber compounding. Special treatment may be required for photoconductive and pharmaceutical uses.

Other zinc chemicals, such as zinc sulfate and zinc chloride, are marketed in high-purity and technical grades in solid and liquid form. Solids are sold in bags, drums, and carload lots, whereas, liquids are sold in drums and tanker car volumes.

Industry Structure

The U.S. zinc mining and smelter sector underwent profound changes in the past two decades. Most changes involved closures and industry contraction and restructuring. A number of old-line companies, long identified with the domestic zinc industry, disappeared from the zinc scene. Among them were Anaconda, American Zinc, AMAX, New Jersey Zinc, St. Joe, and Eagle Pitcher. Many mines and most smelters, including all those using horizontal-retort technology, closed during this period. Mine capacity declined by one-half and smelter capacity by two-thirds. Of 14 primary smelters

operating in 1969, 11 were permanently closed and 3 were extensively modified after extended shutdowns. Only one new "greenfields" zinc smelter has been brought on-stream in the intervening period. In 1989 only four U.S. primary zinc smelters with a capacity of 325,000 tons were in operation compared with 14 smelters with a capacity of about 1 million tons in 1969. Also during this period, all domestic slag-fuming zinc plants at lead smelters and the remaining ore-based American-process zinc oxide plants were closed permanently. In the 1980's decade, both mine and smelter output were the lowest since the 1900–09 decade. In the latter half of the 1980's, the domestic zinc industry began to improve, mainly in the area of mine output, but structurally it was much different than it had been in the 1970's.

In two decades, the United States fell from a position of world leader and near self-sufficiency in zinc metal production to a Nation two-thirds dependent on imports. Concurrent with the smelter production decline, U.S. mine output fell from second highest in the world to sixth place. Foreign ownership of the surviving industry also had increased to major proportions. In the 1970's, virtually all domestic zinc mining and smelting were controlled by U.S.-owned companies, but by the end of 1980's about 60% of the domestic mine production capacity, including Red Dog, and 30% of the primary smelting capacity was controlled by

U.S. subsidiaries of foreign companies.

Since the early 1900's, world zinc mine and smelter production has risen from 1 million tons to more than 7 million tons. Many countries mine and refine zinc; however, a relatively small number of private and state-owned companies control the bulk of world zinc production. State-owned zinc operations mainly in the CPE countries but also in countries such as Greece, India, Iran, Italy, Peru, Zaire, and Zambia accounted for an estimated 40% of world mine and smelter capacity. Much of the world's privately held mine and/or smelter capacity is related to 16 companies either through direct ownership, subsidiaries, holding companies, or equity sharing. These companies often own interest in each other either directly or via subsidiaries. As a consequence, ownership links and production control in the zinc industry are less than clear. The major privately held companies in the world zinc industry include MIM Holding Co. and Pasminco Ltd. (Australia); Acer-Union Miniere (Belgium); Cominco and Noranda Ltd. (Canada); Outokumpu Oy (Finland); Metaleurope S.A. (France); Metallgesellschaft AG (Federal Republic of Germany); Mitsui Mining and Smelting (Japan); Grupo Industrial Minera Mexico, S.A. de C.V. (Mexico); Asturiana (Spain); Anglo American Corp. (Republic of South Africa); Trelborg (Sweden); RTZ Corp. (United Kingdom); and Asarco and ZCA (United States).

Geology-Resources

Zinc is the twenty-third most abundant element in the Earth's crust and is a trace constituent in most rocks. Many minerals contain zinc as a major component; however, only a few are economically important. Sphalerite (ZnS) is, by far, the most important ore mineral and is the source for most of the world's zinc production. Zinc sulfide oxidizes readily to the common oxide zinc minerals smithsonite (ZnCO₃) and hemimorphite (H₂Zn₂SiO₅). Ores containing these oxide minerals were mined extensively before the development of froth-flotation processes, but currently only a few deposits are exploited. At the world famous Franklin Furnace and Sterling Hill deposits in New Jersey, a unique assemblage of zinc minerals—willemite, ZnSiO₄; franklinite, (Zn, Fe, Mn)(FeMn)₂O₄; and zincite, ZnO—were mined for more than 120 years before ore depletion in 1986.

Sphalerite is commonly associated with cadmium, copper, lead, and silver minerals and to a lesser degree with tin minerals and gold. Sphalerite nearly always contains iron and commonly small amounts of elements such as cadmium, gallium, germanium, indium, mercury, and thallium, which substitute for zinc atoms in the mineral crystal structure.

Exploitable zinc deposits, together with associated elements, are found in many diverse geological environments. These can be divided into seven broad categories based on differences in their geological occurrences: (1) volcanic-hosted submarine exhalative massive sulfide deposits, (2) sediment-hosted submarine exhalative deposits, (3) strata-bound carbonate-hosted deposits, (4) strata-bound sandstone-hosted deposits, (5) vein deposits, (6) diatremes, and (7) metamorphic deposits. Oxidized zinc deposits are sometimes formed at the surface or near surface by supergene enrichment or laterization processes acting on primary zinc deposits.

Most major zinc deposits occur as massive, often strata-bound, sulfide ore bodies or as fillings in breccia or replacement strata-bound deposits in carbonate rocks, commonly known as "Mississippi Valley Type." Examples of massive ore deposits are the Broken Hill and Mount Isa Mines in Australia, the Sullivan and Kidd Creek Mines in Canada, lead-zinc mines in the Bath-

urst district in Canada, the Ducktown district in Tennessee, and the Red Dog Mine in Alaska. Mississippi Valley Type deposits are common worldwide; the major deposits of this type in the United States are in the East and Central Tennessee districts in Tennessee, the Viburnum Trend in Missouri, and the Tri-state district in Kansas, Missouri, and Oklahoma.

Technology

Exploration and Development.—Most of the important zinc-producing mines of the United States except those in Tennessee, St. Lawrence County, NY, Sussex County, NJ, and the Picher portion of the Tri-state district, began as lead or lead-silver mines discovered as outcrops. In recent years, outcrops with base metal mineralization or surface indications of base metal mineralization have led to the discovery of a number of large zinc deposits. Such discoveries include the Polaris Mine in Canada, the Rubiales Mine in Spain, the Black Angel Mine in Greenland, and the Red Dog Mine in Alaska.

Prospecting techniques using geophysics and geochemistry have been used increasingly in mineral exploration. Airborne magnetic surveys were instrumental in the discovery of large reserves of base metals, including zinc in Canada and Missouri. The massive sulfide deposit at Crandon, WI, was discovered by drilling in an anomalous area identified by geophysical methods. Geochemistry has been widely used in Tennessee, Virginia, and elsewhere to determine favorable areas of drilling on the basis of anomalous quantities of zinc in the soil or vegetation. In middle Tennessee, much of the exploration was by surface mapping, by study of stratigraphy from oil-well drilling, and from random widespread diamond drilling. After initial discovery, exploration is continued by further drilling, shaft sinking, crosscutting, and drifting.

Mining.—The principal methods employed in zinc mining are room and pillar, shrinkage stoping, and cut and fill. Several different methods may be used within one mine. Except for a few open pit mines in Australia, Brazil, and Canada, and more recently at the Montana Tunnels and Red Dog Mines in the United States, open pit methods

^e Estimated. ^p Preliminary. ^r Revised.¹ Wherever possible, detailed information on raw material source of output (primary—directly from ores, and secondary—from scrap) has been provided. In cases where raw material source is unreported and insufficient data are available to estimate the distribution of the total, that total has been left undifferentiated (primary and secondary). To the extent possible, this table reflects metal production at the first measurable stage of metal output. Table includes data available through June 29, 1990.² Excludes zinc dust.³ Reported figure.⁴ Detail may not add to totals shown because of independent rounding.

have not been used extensively in zinc mining.

Room and pillar mining involves the extraction of ore from a flat or gently dipped ore body by excavation of rooms supported by unmined pillars of ore or waste rock. Zinc and lead-zinc stratiform bodies are the types of deposits most often mined by some variation of this method. Examples are to be found in the zinc mines of Tennessee, the Missouri lead belt, and the Balmat-Edwards zinc district in New York.

In shrinkage stoping, ore is mined in successive flat or inclined cuts or slices progressing upward from a haulage level. After each slice, enough broken ore is drawn off through chutes or drawpoints to provide working space between the top of the pile and the new back or roof of the stope. The remaining broken ore serves as the floor on which the miners prepare to cut a new slice. Shrinkage stoping is generally employed in mining vein deposits, but is sometimes used in conjunction with

room-and-pillar mining at zinc mines in east Tennessee.

Cut-and-fill mining is best suited to steeply dipping veins such as found in the silver-lead-zinc mines in the western United States. In the cut-and-fill method, the ore is broken and removed from the stope; waste in the form of rock, sand, and tailings is backfilled into the stope to within working distance of the back; and the mining cycle is repeated. A modification of this method is used at the Lucky Friday Mine in Idaho where the process is reversed. In this case, the mined area is completely sandfilled, followed by mining immediately under the backfilled stope. The method was developed to improve safety by reducing rock bursting problems.

The cycle of operations in mining consists of drilling, blasting, and removing broken rock. Drilling usually is done with compressed-air percussion drills mounted on self-propelled jumbos with either crawler-treads or rubber tires. Following blasting, broken ore is loaded

with a variety of diesel or electric, high-capacity, specialized shovels or loaders, and haulage is done with trucks or load-haul-dump units. Track haulage is by electric, diesel, or compressed-air locomotives, but the trend is toward trackless haulage using rubber-tired, high-speed, maneuverable machines that service stopes at great distances from the entry and convey the broken ore rapidly to the hoisting skip with a minimum of handling.

Beneficiation.—Most zinc ores are treated in a mill to separate the desirable mineral constituents in the ore from unwanted impurities or gangue. This process involves the crushing and grinding of the ore to release the individual mineral constituents from each other, followed by flotation procedures to selectively concentrate the valuable minerals in fractions separate from the gangue components. For noncomplex, carbonate-hosted ores such as those in Tennessee, heavy media separation pretreatment before zinc flotation has been designed into some mills to reduce the amount of nonmineralized, low specific gravity gangue going to the grinding and flotation circuit.

A general scheme for the flotation of a mixed sulfide ore is (1) flotation of the lead-copper minerals and depression of the zinc and iron minerals, (2) separation also by flotation of the lead-copper concentrate into separate lead and copper concentrates, (3) activation and flotation of the sphalerite from the iron and gangue minerals, and (4) flotation of the pyrite if a recovery is desired.

Column cells, large cylinders typically 35 feet or more in height, are increasingly being installed at lead-zinc operations for flotation purposes. Substantial cost reductions, increased recovery, and higher grade concentrates are generally attained using column cells compared with standard flotation equipment.

Many zinc and zinc-lead mills are highly automated and require few operating personnel. Many have instrumentation, sensors, and on-stream X-ray analyzers to provide central control of most mill functions ranging from head feed rates and flotation reagent control to tailings disposal.

High-grade concentrates, 60% zinc or better, are produced from straight-zinc ores. Zinc concentrates from zinc-lead ores contain about 50% to 59%

zinc, and concentrates from more complex mixed ores range from 35% to 55% zinc. The concentrate is shipped to smelters for refining to zinc or zinc oxide, recovery of byproduct metals, and production of sulfuric acid.

The zinc content in lead concentrates or in mixed bulk lead-zinc concentrates is sometimes recovered as a zinc oxide fume from processing lead slags, produced at lead smelters using sinter-blast furnaces. The zinc fume, after deleading and densifying, is sent to a zinc plant for refining. Zinc fume has been an important smelter feed source in the United States but because of high costs, all domestic slag fuming plants have closed; the last operating plant closed in 1985. Two recently commercialized lead smelting methods, known as the QSL (Ouenau-Schuhmann-Lurgi) and Kivcet CS processes, similarly yield a zinc oxide or metal product from zinc-rich lead feed owing to zinc fuming in the reduction section of the furnaces.

Smelting.—Reduction of the concentrates to zinc is accomplished by electrolytic deposition from a sulfate solution or by distillation in retorts or furnaces. For either method, the zinc concentrate is roasted to eliminate most of the sulfur and produce impure zinc oxide known as roasted concentrate or calcine. At a few refineries, pressure leaching of the concentrates is employed instead of roasting. The zinc pressure leach process, developed by Sherritt Gordon Ltd., produces leachable zinc sulfate directly, as well as elemental sulfur, thereby supplanting the roast and acid plant processes. In Thailand, an electrolytic zinc refinery produces zinc from run-of-mine zinc silicate-carbonate ore that averages about 26% zinc. Zinc is leached directly from the ore by hot sulfuric acid followed by electro-winning. The typical roasting step is again not required.

At electrolytic zinc plants, which comprise about four-fifths of world primary metal capacity, the calcine is leached with dilute sulfuric acid to form a zinc sulfate solution. The solution is then purified and piped to electrolytic cells, where the zinc is electrodeposited on aluminum cathodes. The cathodes are lifted from the tanks at intervals and stripped of the zinc, which is remelted and cast into slabs. The quality of this zinc is either SHG or HG. The electrolysis of the

solution regenerates sulfuric acid, which is used in succeeding cycles of leaching. During the roasting of concentrates, iron reacts with zinc to form insoluble zinc ferrite, which on leaching remains in the leach residue and results in decreased zinc recovery. Several processes, known by the iron residue product produced—jarosite, goethite, and hematite—are used in smelters to treat leach residues to extract this zinc and increase recovery. Lead and silver, which are commonly found in zinc concentrates, are also insoluble in the roast-leach process and are concentrated in the leach residue. Residues with sufficiently high lead and silver contents are usually shipped to a lead smelter, where the lead and silver are recovered in lead bullion.

There are three basic types of distillation retort plants: (1) batch horizontal retorts, (2) continuous vertical retorts externally heated by fuel, and (3) continuous vertical retorts heated electrothermally. Only a few horizontal and vertical retort plants remain in the world. One of the four primary smelters in the United States is an electrothermic plant, a type of vertical retort. Calcine or sinter together with coal or coke as a reducing agent yield zinc vapor and carbon monoxide which pass into a condensation zone or splash-type condenser where the zinc is collected as liquid metal ready for casting into slab form. Zinc produced by distillation is normally the lower commercial grade, but it may be upgraded by redistilling to reduce impurities. In refining, the impurities such as lead and cadmium are separated by distillation in vertical fractionating columns. The zinc product can be 99.995% pure.

A blast furnace process for producing both lead and zinc, known as the Imperial Smelting Process (ISP), follows the normal blast furnace practice of burning coke in intimate association with calcine sinter, and as in the retort process, the zinc is released as a vapor and condensed. Twelve plants of this type have come on-stream in the past two decades and account for about 12% of world zinc capacity. An important advantage of the process is the ability to treat a wide range of zinc-lead materials and recover both metals, as well as any gold or silver present, with no extra coke consumption and little extra labor. The zinc metal produced by ISP smelting is typically PW grade.

Recycling.—Recovery of zinc from old scrap, mainly in the form of diecastings, steelmaking electric arc furnace (EAF) dusts, and brass and bronze, currently represents about 7% of the total U.S. demand. New scrap, which typically is two to three times the quantity of old scrap, is mainly zinc-base and copper-base alloys from manufacturing operations and drosses and skimmings from galvanizing operations. The large use of zinc in galvanizing, paints, and rubber has limited recovery of zinc from old scrap, but in the past few years, increasing amounts have been recovered from these sources, especially from galvanized steel scrap where zinc is recovered in steelmaking EAF dust. The zinc in calcine recovered from the intermediate processing of EAF dust is typically produced as metal at pyrometallurgical plants such as ZCA's Monaca plant or an ISP plant. Plasma-furnace technology is also increasingly being used to recover zinc by the direct processing of EAF dusts. Electrolytic recovery is generally not cost effective because of the high expense of solution purification required by the process. At several plants, crude zinc oxides are recovered from processing used automobile tires.

Recovery of zinc diecastings from scrapped automobiles is highly efficient and is a major source of old scrap. However, this source is not expected to grow significantly because the weight of zinc diecastings in automobiles has declined from the mid-1970's as a result of downsizing and weight-reduction programs. Zinc in zinc-base alloys is generally recovered by distillation as zinc oxide, dust, or slab zinc, whereas the zinc in copper-base alloys is generally recovered by remelting and recasting directly back into brass or bronze ingot. Scrap is the source material for most of the domestic output of zinc dust and chemicals and about one-half of the zinc oxide production.

ZIRCONIUM AND HAFNIUM

By James B. Hedrick and David A. Templeton

Messrs. Hedrick and Templeton are physical scientists with the Branch of Nonferrous Metals. They have shared coverage of zirconium and hafnium for about 2 years. Domestic survey data were prepared by Ms. Imogene P. Bynum, Nonferrous Metals Data Section.

Zirconium and hafnium occur together in nature at a ratio of about 50 parts zirconium to 1 part hafnium. Hafnium must be separated from zirconium that is to be used for certain nuclear applications but the two elements are used in combined form for most other applications.

Domestic production of zircon and zirconium oxide (zirconia) increased over that of the previous year. Two companies produced zircon as a coproduct of processing titanium minerals from three mines in Florida. Two companies in New Jersey recovered zircon from tailings previously accumulated as a byproduct during processing for ilmenite. The world production of zircon increased to a record-high level in 1989, but the supply continued to remain slightly below the level of demand. Zircon's strong demand in 1989 continued to result in historically high price levels.

Major uses for zirconium were in foundry sands, refractories, ceramics, abrasives, chemicals, and metallurgical applications. Hafnium was used in metallurgical applications, refractories, and ceramic cutting tools.

Advanced technology applications of zirconium included stabilized and partially stabilized zirconia used in extrusion dies, industrial cutting blades, ceramic engine parts, thermal barrier coatings for jet engines and other high-temperature environments, and radar transparent covers for radar equipment (radomes). Zirconium fluoride and hafnium fluoride glasses were used in fiber optics.

LEGISLATION AND GOVERNMENT PROGRAMS

Teledyne Wah Chang Albany (TWCA) requested Federal and State permission to dispose of low-level ra-

dioactive sludge generated by the pre-1980 refining of zirconium from zircon sand. The plans submitted for approval were prepared for TWCA by CH₂M-Hill, based in Corvallis, OR. The estimated 85,000 to 100,000 cubic yards of material, currently held in evaporation ponds, contains traces of uranium and thorium, and the decay products radium and radon. Previous findings concluded that the concentrations of these elements were insufficient to classify the waste as radioactive or hazardous. However, a Nuclear Regulatory Commission law disallowing the waste from being stored on a flood plain (Willamette River, 500-year) and public pressure prompted the company to seek disposal elsewhere. The plans included transport, via truck or rail, to a solid waste landfill, consolidation with Portland cement to prevent leaching, and disposal of the aggregate in a sealed structure. The Environmental Protection Agency (EPA) Record of Decision for Operable Unit #1 (Sludge Ponds) was signed at yearend, affirming the company plans. The EPA expected the estimated \$10 million cleanup to commence in mid-1990.¹

STRATEGIC CONSIDERATIONS

The National Defense Stockpile stocks of zirconium ore, totaling 14,507 metric tons, were classified as excess to goal. Zircon was produced in the United States, and there were no stockpile objectives for zirconium and hafnium materials.

Zircon was used in important defense related applications. Investment casting molds of zircon and zirconia were used to cast superalloy components of jet engines. Zirconia was used to form the crucibles in which superalloys were

melted and in several other strategic applications, such as thermal barrier coatings on jet engine combustors and turbine vanes, as a white pigment for camouflage coatings in snow environments, and in sonar equipment for submarines.²

Zirconium was a minor constituent of many superalloys, and hafnium was a major component of an engine alloy used in the F-15 and F-16 military fighter planes. Both metals were required for use in U.S. Navy submarine nuclear reactors because of their dependability and performance in this application. At yearend 1989, the U.S. Department of Energy inventories were approximately 15 tons of zirconium sponge, 899 tons of zirconium ingot and shapes, 24 tons of zirconium scrap, 1 ton of zirconium crystal bar, 5 tons of hafnium oxide, 28 tons of hafnium ingot and shapes, and 3 tons of hafnium crystal bar.

PRODUCTION

Zircon was produced primarily as a coproduct or byproduct of processing heavy mineral sands for titanium minerals. Associated Minerals (USA) Inc., a subsidiary of the Australian firm Renison Goldfields Consolidated Ltd., produced zircon from heavy minerals mined and processed at Green Cove Springs, FL. E.I. du Pont de Nemours & Co. Inc. operated two mines near Starke and Lawtey in northeastern Florida that produced zircon and other heavy minerals. Heritage Minerals Inc. and Nord Ilmenite Corp. produced zircon from tailings that were previously generated during processing for ilmenite at Lakehurst and Jackson, NJ, respectively.

Molycorp Inc., a wholly-owned subsidiary of Unocal Corp., and the Mes-calero Apache Tribe announced a joint

venture agreement to develop a deposit on the tribe's reservation in New Mexico. The deposit, identified by Molycorp in 1985, contains the mineral eudialyte, a zirconium- and yttrium-bearing silicate mineral. Reported reserves were 2.4 million metric tons grading 1.2% zirconium oxide and 0.18% yttrium oxide. Initial metallurgical tests by Molycorp indicated that the ore could be processed with conventional heap-leach technology, a low-cost process presently used by many gold and copper operations. Although Molycorp was engaged in the production and processing of yttrium and other rare earths for the past 20 years, zirconium would be a new addition to its product line. A schedule for development was not set.³

Piedmont Mining Company, Inc. was reportedly investigating occurrences of titanium minerals and zircon in North Carolina.

TAM Ceramics Inc., a subsidiary of the United Kingdom-based Cookson Group, began construction of a new facility at Niagara, NY, to produce zirconia using a recently developed chemical precipitation process. The new process, developed by Cookson Research, reportedly yields ultra-high purity zirconia using selective precipitation on an industrial scale. Completion of the new plant was scheduled for late 1990.⁴

CONSUMPTION AND USES

Apparent consumption of zircon in 1988 and 1989 was calculated by adjusting domestic production for net trade and changes in stocks. Prior to 1988, production data were withheld to avoid revealing proprietary data and consumption was estimated, based on a survey of the industry. The zircon consumption pattern, shown in the following table, was estimated based on survey data and were adjusted to equal total apparent consumption as rounded for 1988 and 1989. These data were not consistent with end use data published by the Bureau of Mines in prior years.

End use	1988 ^r	1989
Zircon refractories ¹	29,000	23,000
AZS refractories ²	15,000	12,000
Zirconia and AZ abrasives ³	W	W
Alloys ⁴	W	W
Foundry applications	50,000	41,000
Other ⁵	60,000	50,000
Total	177,000	145,000

^r Revised. W Withheld to avoid disclosing company proprietary data, included in "Total."

¹ Dense and pressed zircon brick and shapes.

² Fused cast and bonded alumina-zirconia-silica-based refractories.

³ Alumina-zirconia-based abrasives.

⁴ Excludes alloys above 90% zirconium.

⁵ Includes chemicals, zirconium metal, welding rods, sandblasting, and other miscellaneous uses.

WORLD REVIEW

World capacity to produce zirconium minerals, shown in table 7, lagged demand by approximately 5%. Because of the strong and persistent demand for zirconium in both natural and processed forms, several deposits were in either the exploration, pilot plant, or development stage. The additional supplies provided by anticipated new and expanded operations should substantially ease the worldwide shortage of zircon.

Australia

The Nissho Iwai Corp. of Japan purchased RZ Mines (Newcastle) Ltd. and Cable Sands Pty. Ltd. for A\$240 million from Pioneer International Ltd. Nissho had been importing rutile and zircon produced by RZ Mines for 20 years prior to the purchase. The company anticipated growth in demand for zircon resulting from Japan's increase in steel production and from the expanding European markets for fine ceramics. Combined, the two mining companies produced 50,000 to 60,000 tons of zircon per year, about 5% of world production.⁵

Cable Sands continued development of the Jangardup deposit in the southwest of Western Australia. The heavy

⁵ American Metal Market. V. 96, No. 253, Dec. 30, 1988, p. 6; and v. 97, No. 252, Dec. 30, 1989, p. 6.

mineral mine was expected to begin operation in 1990 or 1991, with an estimated capacity of 10,000 tons per year of zircon concentrate.

Production from Australmin Holdings Ltd. mine at Newrybar, New South Wales, was postponed because of an appeal by environmentalists to the Land and Environment Court. The appeal was not upheld and the company expected production to begin early in 1990. Processing of the 30,000 tons of concentrate expected to be produced annually will reportedly yield 10,000 tons of zircon and 12,000 tons of rutile.⁶

Associated Minerals Consolidated (AMC) Mineral Sands Ltd. began development of the Eneabba West deposit. The deposit, due to come on-stream in 1990 or 1991, reportedly contains 230 million tons of sand with a heavy mineral grade of 3.1%. Projected annual production of zircon from Eneabba West was expected to reach 70,000 tons.

Two companies investigated heavy mineral deposits in the Scott River area of Western Australia. BHP-Utah Minerals International indicated that the Beenup deposit would be capable of dredging upwards of 500,000 tons of heavy mineral-bearing sand per year. The environmental impact on agricultural activity nearby was studied. A joint venture comprised of Golden Plateau NL, Kingsgate Consolidated Ltd., and Wynarde Pty. Ltd. found encouraging concentrations of ilmenite (39% to 64%), rutile (3% to 8%), and zircon (0.5% to 2%) on leases held in the vicinity. The overburden on the concentrated zones and slimes generated during the treatment phases were expected to present difficulties.⁷

North Broken Hill Peko Ltd. was evaluating the feasibility of the King Island, Naracoopa, mineral sand project. Total reserves were estimated to contain 25 million tons grading 5.2% heavy minerals. King Island is situated midway between Victoria and Tasmania near the Bass Strait.⁸

The Cooljarloo mineral sand deposit near Catabay, Western Australia, was expected to begin production near the end of the year. With reserves containing over 18 million tons of heavy minerals grading 12% zircon, the estimated 80% recovery rate should bring about one and three-quarter million tons of

zircon to market during the life of the mine. Zircon production expected in 1990 and 1991 was 31,000 and 67,000 tons, respectively. The Oklahoma City-based Kerr-McGee Chemical Corp. had a 50% interest in the venture through its Australian subsidiary KMCC Western Australia Pty. Ltd. The Australian firm Minproc Holdings Ltd. had equal equity in the project through its subsidiary Minproc Chemicals Pty. Ltd.

Mineral Deposits Ltd. planned to have a new mine near Bundaberg, Queensland, in operation by 1991. Initial output of zircon from this heavy mineral deposit, on the coast north of Rocky Point at Agnes Water, was projected to be 30,000 tons per year.⁹

The offshore portion of the Eastern Australian Rutile Province, encompassing the nearshore from Sydney north to the Queensland border, was found to contain over 2 million tons of zircon and rutile in noneconomic deposits as surveyed in the mid-1960's. New exploration for heavy minerals in the Province began in June on the nearshore of the continental shelf off the coast of New South Wales. The new marine geophysical survey includes sidescan sonar mapping and seismic reflection and magnetometer profiling; all data were to be digitized for high-resolution processing.¹⁰

Bangladesh

The Government was reported to have begun a mineral sands project which was previously discontinued. A survey of 240 square kilometers (km²) of beach sands indicated heavy mineral resources totaling 420,000 tons. Minerals identified included titanium minerals, monazite, and zircon.¹¹

Denmark

Morstrøl Minerals conducted exploratory drilling on an extensive (100 km²) beach sand deposit exhibiting anomalous concentrations of zircon and other heavy minerals. The sands are located on the Thy Coast of the Jutland Peninsula in the vicinity of the Hanstholm Harbor.¹²

Guyana

An estimated 450 river-based diamond and gold dredges were reportedly processing heavy mineral-containing resources. Zircon and titanium miner-

als comprised the largest portion of the heavy minerals.¹³

Madagascar

QIT-Fer et Titane Inc. (QIT) indicated that problems mounting against the development of a mineral sand deposit, on the southeast coast in the Mandena region near Toalagnaro (formerly Fort Dauphin), would delay production until 1995. The ilmenite project, with reserves of 145 million tons, was a joint venture between QIT-Madagascar Mineral (49%) and the National Military Office for Strategic Industries (OMNIS), 51%. OMNIS reportedly initiated pilot plant construction, further exploration, and related industrial activity at the outset of the year. Annual zircon production of 24,000 tons was expected when fully operational.¹⁴

Mozambique

Kenmare Resources PLC of Ireland began the preconstruction and finance sourcing stage of its Congolone project after receiving approval from the Ministry of Mineral Resources to mine the deposit. Proven reserves of 167 million tons grading 3.25% heavy minerals were estimated to contain 373,000 tons of premium zircon. Beginning in early 1992, 37,000 tons per year of zircon were expected to be produced. Kenmare held a 71.25% equity in project, the Mozambican Government held 25%, and the geologic survey of Yugoslavia, Geoloski Zavod, which first explored the deposit, held 3.75%.¹⁵

New Zealand

In December, Fletcher Titanium Products Ltd. brought on stream a pilot mine located on the west coast of South Island. Combined production of 400 tons per year of monazite, rutile, and zircon was expected.¹⁶ The possibility of more zircon production from South Island was to be decided upon the completion of a A\$4 million feasibility study funded by Nissho Iwai Corp. of Japan, to be completed by May 1990. The study concerned a proposed titanium slag and pig iron plant at a 17-million-ton ilmenite deposit at Westport. Zircon, monazite, and gold would be byproducts of the operation.¹⁷

Republic of South Africa

Rhombus Mining (Pty.) Ltd. planned

to develop a deposit to produce 27,000 tons of zircon per year. Drilling and seismic data on the heavy mineral sand deposit in the Transkei at Wavecrest, near the southeast coast, indicated reserves of 200 million tons grading 5% heavy minerals. Approval of the mining lease by the Department of Commerce, Industry, and Tourism was uncertain at yearend.¹⁸

The Anglo American Corp. of South Africa Ltd. studied the feasibility of developing heavy mineral sand deposits in Namaqualand. The deposits were on lands owned by De Beers Consolidated Mines near the west Cape coast, 30 miles north of the Olifants River. A wet concentration pilot plant was operated during the year. If a decision is made to proceed with the project, production was planned to commence in 1992, with expected annual zircon output of 100,000 tons per year. Rutile and monazite production were expected to be 25,000 and 1,000 tons per year, respectively.¹⁹

Severin Mining and Development Co. (Pty.) Ltd. conducted pilot plant tests in Australia on samples taken from a deposit it was exploring, 30 miles south of Richards Bay at Mitunzini. The deposit was reported to have a 10% heavy mineral grade resembling the Richards Bay Minerals deposit and a tentative mine life of 20 years. A decision was expected in early 1990, following completion and analysis of pilot plant tests.²⁰

Richards Bay Minerals delayed exploration and development work on its project at Lake St. Lucia in the Natal Province because of environmental concerns. Although the company had reclamation practices which, according to the parent company QIT, "meet the highest standards for such operations anywhere in the world," environmentalists asked the International Union for Conservation of Nature to officially protect the area.²¹

Richards Bay Minerals received approval for the construction of a second dry mill which would double its zircon production to 300,000 tons per year by 1991-1992. The increase in raw feed material for the plant arises from the addition of two dredges in the past few years for a total of four. The company also planned to upgrade more of the standard grade zircon produced to an improved prime grade having a lower iron content than the prime grade previously produced.²²

Sierra Leone

Australian mining companies, Intercontinental Gold & Minerals NL and MC Mining NL, expected to begin production of a heavy mineral deposit at Rotifunk in late 1990. Exploration of the deposit in the mid-1970's delineated reserves measuring 146 million tons grading 0.06% zircon (87,000 tons). The joint venture estimated production of 6,000 tons of zircon per year for 13 years. Rutile and ilmenite were to be the primary coproducts.²³

Sierra Rutile Ltd. expected to begin zircon production of 15,000 tons per year in late 1990. Production is expected from stockpiled, zircon-rich tailings, and from a rutile deposit at Pejebu. Parent company Nord Resources Corp. recovered zircon from heavy mineral-rich tailings in New Jersey, in the United States. Following completion of the New Jersey project, operated by subsidiary Nord Ilmenite Corp., the company tentatively planned to dismantle and ship the separation plants to Sierra Leone to support these operations.²⁴

United Kingdom

Butte Mining PLC, a precious and base metals producer, purchased Gramcol Zircon Ltd. for \$6.6 million (£4 million).²⁵ Gramcol produced milled zircon for use as opacifiers in the ceramic industry. The company was reported to have a mill capacity of 1,500 tons per year.²⁶

In a move to increase zirconium chemical production by one-third, Magnesium Elektron Inc. allocated \$49 million (£30 million) for new plant construction and expansion of existing facilities at its manufacturing complex in Manchester. The company provided a full line of zirconium chemicals processed from raw zircon sand. Expansions were also planned for the company's facility in Flemington, NJ, in the United States.²⁷

British Petroleum exited the mining business upon its sale of subsidiary BP Minerals Development Ltd. to the Rio Tinto Zinc Corp. PLC for \$3.9 billion (£2.4 billion).²⁸ Rio Tinto Minerals Development Ltd. acquired total ownership of QIT-Fer et Titane Inc., which held 50% interest in a zircon producer, Richards Bay Minerals, in the Republic of South Africa. QIT tentatively planned to develop an ilmenite deposit in Madagascar.

CURRENT RESEARCH

The increased use of zinc-coated and electrogalvanized steels by the automobile industry created a need for more durable electrodes such as resistance spot welding (RSW) electrodes on assembly line welding robots. When spot welding zinc-coated steel, the coating melts and brass tends to form on the copper-based electrode surface, thus affecting integrity and service life. Similar affects occur when spot welding galvanized steels because of the higher current and longer welding times required to weld these metals. Tests conducted on various compositions of RSW electrodes by an Outokumpu Copper subsidiary, the Nippert Company, and the Edison Welding Institute found that copper-zirconium electrodes showed "superior performance" in the conventional electrode life test.²⁹

The National Aeronautics and Space Administration contracted Basic Industry Research Laboratory of Northwestern University, Evansville, IL, to evaluate wear characteristics on coating materials for eventual use on the main-engine bearings of the space shuttle. Among the many materials to be tested

are zirconium- and hafnium-nitride hard film coatings and nitride alloys of titanium and zirconium. The coatings were to be developed via a high-rate reactive sputtering process and deposited in vacuo within a reactor vessel.³⁰

A new mill developed by Metprotech, based in the Republic of South Africa, for increasing the recovery of gold from refractory ores was reported to reduce the milling time required to mill zircon. The mill, which has a throughput range of 2 to 4.5 tons per hour, incorporates a horizontal central arm which stirs both feed material and grinding balls within a cylindrical drum.³¹

The Bureau of Mines sponsored research which identified a zirconium-nickel compound that may possibly substitute for the platinum-group metals catalysts currently used in automobile emission control systems.³²

A new zirconia-alumina ceramic was developed by Diamonite Products of W. R. Grace & Co. The flexural strength was reported to be twice that of 87% alumina, accompanied by a five-fold increase in wear resistance. These qualities combined with its resistance to chemical attack made it an ideal candidate for industrial applications including mineral handling and processing. The ceramic was said to be capable of fabrication by many different processes.³³

Sumitomo Metal Industries, Ltd. of Japan produced zirconium-manganese alloys for hydrogen storage. The high-frequency melted, coarse alloy powders absorb and desorb hydrogen between 200° C and 300° C and perform effectively after many cycles. The new alloy was reported to work faster and cost less than lanthanum-nickel alloys.³⁴

A new zirconia-based thermal barrier coating was developed by Woking, United Kingdom-based Metco Ltd. which reportedly outperformed standard yttria-stabilized zirconia thermal coatings. Incorporating 24% to 26% cerium, 2% to 3% yttria, and the balance zirconia, the coating was claimed to have more resistance to cyclic thermal fatigue, less susceptibility to hot corrosion and erosion, lower thermal conductivity, and more predictable performance. Standard stabilized zirconia coatings (i.e., calcia-, magnesia-, and yttria-stabilized) have proven to be efficient thermal barriers in clean fuel environments; however, fuel contaminated with chlorine, sodium, sulphur, and/or vanadium adversely affect the performance of the coating. The company used its own plasma spray process to apply hollow, spherical particles to form the coating. This development was related to work initiated by U.S. parent company Perkin-Elmer Corp.³⁵

OUTLOOK

Exploration and development of heavy mineral deposits in recent years was expected to lead to development of several new zircon mines by the early 1990's. The increase in production from planned, new, and expanded operations was expected to ease the supply shortages experienced in the late 1980's. An increase in world production of about 100,000 tons, or 10% of current world production, was expected by 1991. The near-term affect on zircon prices will likely be downward; however, it also was possible that increased availability of processed materials could create new demand pressures and prices could remain high.

New uses for zirconia grew dramatically in recent years. Substantial increases in consumption of this material in end products, ranging from scissor and knife blades to wear-resistant bearings and oxygen sensors, are expected in the next few years. Growth of wear-resistant ceramics and composites for the coming decade have been estimated at 18% to 23%.³⁶ Certain niches of the tungsten cutting tool market have already been penetrated by ceramics and ceramic-metal composites, some of which contain zirconia. Stabilized zir-

conia thermal barrier coatings are becoming the mainstay of commercial and military turbine engine components. The added costs of manufacture are negligible considering the added performance and extended service life.

A multimillion dollar expansion being implemented by one of the largest zirconium chemical producers foreshadowed growth in this area.

The supply side outlook for zircon is rather encouraging. The demand for other heavy minerals, such as ilmenite and rutile to make titanium dioxide (white pigment) and metal, is very strong and expected to remain so. Also, there is no slack in demand foreseen regarding the rare earths and hence the source mineral monazite. As these minerals are the marketable products of most heavy mineral mining operations, there appears to be adequate incentive for mining companies to fully exploit existing deposits and to continue with exploration and development efforts.

The world reserve base for zircon was conservatively estimated to be about 75 million metric tons. At the current rate of production this is ample supply for nearly 75 years.

BACKGROUND

Definition, Grades, and Specifications

Zirconium and hafnium are chemically similar elements with atomic numbers 40 and 72, respectively. Both elements are classified in the periodic table as members of Group 4b, and have only one oxidation state, +4, and have similar ionic radii. Owing to these similar properties, zirconium and hafnium are usually found together in nature.

Zircon purity is commonly measured by the combined zirconium dioxide (zirconia) and hafnium dioxide (hafnia) content. Hafnium occurs in zircon in a typical ratio of 1 part hafnium to 50 parts zirconium. Commercially available zircon typically grades 64.5% to 66% combined zirconia-hafnia. Zircon grades are similar on a worldwide basis, but no standard requirement exists. Standard grade zircon has a typical analysis of 65% minimum zirconium dioxide-hafnium dioxide, 0.25% maximum titanium dioxide, and 0.12% maximum iron oxide. Intermediate

grade zircon has a typical analysis of 65.5% zirconium dioxide-hafnium dioxide, 0.03% maximum titanium dioxide, and 0.1% maximum iron oxide. Premium grade zircon has a typical analysis of 66% minimum zirconium dioxide-hafnium dioxide, 0.1% maximum titanium dioxide, and 0.05% maximum iron oxide.

Zirconium metal for the chemical process industry is available in three American Society for Testing and Materials (ASTM)-approved grades: R60702 for unalloyed zirconium, R60704 for the titanium alloy, and R60705 for the niobium alloy. Zirconium alloys for the nuclear industry, the compositions of which are specified, are designated as Zircaloy-2, Zircaloy-4, or Zr-2.5 Cb.

Hafnium metal as produced by the Kroll process is called hafnium sponge or "Kroll-process" sponge or metal. After refining by the iodide process, the metal is called crystal bar.

Industry Structure

Zirconium ore minerals are sold by mine producers directly to processors, consumers, and commodity brokers. Primary ore concentrate of zircon and baddeleyite may be used in certain industrial uses with little or no processing, but most applications require additional processing. Processors grind the concentrates to specification for certain applications or convert zircon and baddeleyite to refined products such as zirconium metal, hafnium metal, alloys, high-purity zirconia, and other compounds. Extensive processing is required to produce ultra-purity powders and nuclear-grade metals. Processors producing oxide and metal are often partially integrated, and market fabricated and semi-fabricated products directly to manufacturers. The worldwide distribution of the mining industry is illustrated in figure 1.

Geology-Resources

Zircon is a common accessory mineral in igneous rocks. It is frequently found associated with silicic rocks, including granite, granodiorite, syenite, monzonite, and nepheline syenite. Zircon is also found in pegmatites, crystalline limestone, and the metamorphic rocks gneiss and schist. One occurrence of zircon is reported from a meteorite. From an economic viewpoint, sedimentary placer deposits are the most significant.

Placer deposits begin forming when chemical and mechanical weathering liberates minerals from the source rock. This is followed by transport of the minerals to the sea by water, wind, and gravity. Upon reaching the sea, deposits of economic value form primarily by hydraulic sorting. Heavy minerals, including zircon, are concentrated by marine currents and wave action. Mechanical sorting by the sea and wind further sorts the grains to produce well-sorted beach deposits.

With distance from the source, zircon undergoes varying degrees of rounding, but because of its hardness typically retains an elongate shape with rounded edges and high relief. If sufficient source material exists, an economic heavy mineral deposit forms. Zircon and other heavy minerals are primarily recovered as sand ranging in size from very fine to coarse.

Technology

Economic concentrations of zircon are found in association with other heavy minerals such as ilmenite, rutile, and monazite. Heavy mineral sand deposits are usually mined by floating cutterhead- or bucketwheel-dredges that handle up to 2,800 metric tons of sand per hour. Sand recovered by these techniques is sent to a wet mill and treated by wet-gravity methods, using spirals, cones, sluices, or jigs, to produce a mixed heavy mineral concentrate containing zircon. The mixed concentrate typically contains other economic minerals such as the titanium minerals (ilmenite, rutile, and leucoxene) and oftentimes smaller amounts of the rare-earth mineral monazite. In southeast Asia, heavy mineral sand deposits containing zircon are mined primarily for the tin minerals cassiterite and stannite.

The mixed heavy mineral concentrate is scrubbed, dried, and screened, and the individual heavy minerals are separated by electrostatic, electromagnetic, magnetic, and gravity processes. Zircon, in contrast to ilmenite, rutile, and many other heavy minerals, is nonconductive and can be separated along with monazite, by electrostatic methods. Monazite, which is slightly magnetic and may be slightly higher in specific gravity, can be separated from zircon by electromagnets or by additional gravity methods.

To obtain premium grade zircon, the zircon concentrate from the electrostatic-

electromagnetic circuit is again subjected to gravity concentration to reduce the content of aluminum- and titanium-bearing minerals. Certain zircon products are leached in an acidic solution to remove iron oxide and other grain coatings.

Zircon used in foundry and certain refractory applications is graded, sized, and, in many cases, ground or milled to produce zircon flour. Foundry applications generally use zircon sand and flour mixtures, which may be treated with resin coatings and binders.

Zirconia is produced directly from zircon by either plasma fusion or electric arc techniques. The plasma method for zirconia production employs heating a finely divided zircon above its dissociation temperature to form small zirconia crystallites and glassy amorphous silica. The hot zirconia and silica particles are rapidly quenched, and the silica removed by leaching with sodium hydroxide, leaving insoluble zirconia crystallites.

In electric arc production, zircon is heated to temperatures of approximately 2,500° C producing dissociation. The silicon component is vaporized and recovered as fumed silica leaving a residual zirconia melt that is rapidly air quenched to form spherules. A more complex electric arc method melts a mixture of limestone and zircon to form calcium zirconate and tricalcium silicate clinker. Cooling of the mixture disintegrates the mixture into a very fine powder composed of tricalcium silicate and lime and a coarser fraction of calcium zirconate crystals. The calcium zirconate is separated from the other constituents by either air classification or flotation. The acid-soluble calcium zirconate crystals are treated with acids or other reagents forming zirconia or zirconium salts.

Other compounds of zirconium, such as the hydrous or carbonated oxide, acetate, sulfate, fluoride, chloride, and organic complexes are usually prepared from zirconia or its salts by chemical reactions.

The deBoer-van Arkel iodide process, first described in 1925, is essentially a refining process and was commercially adopted in 1945 as the first practical method for producing ductile zirconium metal. Zirconium metal is reacted with iodine vapor at 200° C to form zirconium tetraiodide, leaving

most impurities except hafnium in a solid state. The gaseous halide diffuses to a heated filament where, at 1,300° C, the reaction is reversed, depositing very high-purity elemental zirconium on the filament and regenerating iodine vapor for reuse. The process yields high-purity metal but is expensive to operate.

Industrial scale plants for producing zirconium metal are based on the Kroll process in which zirconium tetrachloride is reduced with molten magnesium in an inert atmosphere. The resulting mixture of zirconium metal sponge and magnesium chloride is vacuum-distilled to remove the magnesium chloride. The zirconium is crushed, sized, and compacted to form a consumable electrode. The electrode is arc-melted in an inert atmosphere to give a first-melt ingot. The first-melt ingot is then used as a consumable electrode to produce a metallurgically homogeneous second-melt ingot, which is machined to give a clean surface and readied for fabrication.

Zirconium tetrachloride is produced by chlorinating zircon sand in a fluidized bed containing carbon at a temperature of about 1,150° C.

BYPRODUCTS AND COPRODUCTS

Zircon is mined from deposits with a heavy mineral grade between 2% and 20%. The associated economic heavy minerals are ilmenite, leucoxene, rutile, monazite, and the tin minerals cassiterite and stannite. Its classification as a byproduct or a coproduct depends on the fraction of zircon in relation to the other minerals. If zircon and the titanium minerals are expected to account for the majority of the revenue, it is considered a coproduct. If minerals other than zircon provide the carrying costs of the operation, then zircon is considered a byproduct. Small quantities of baddeleyite are recovered as a byproduct of copper, phosphate, and vermiculite mining in the Republic of South Africa.
